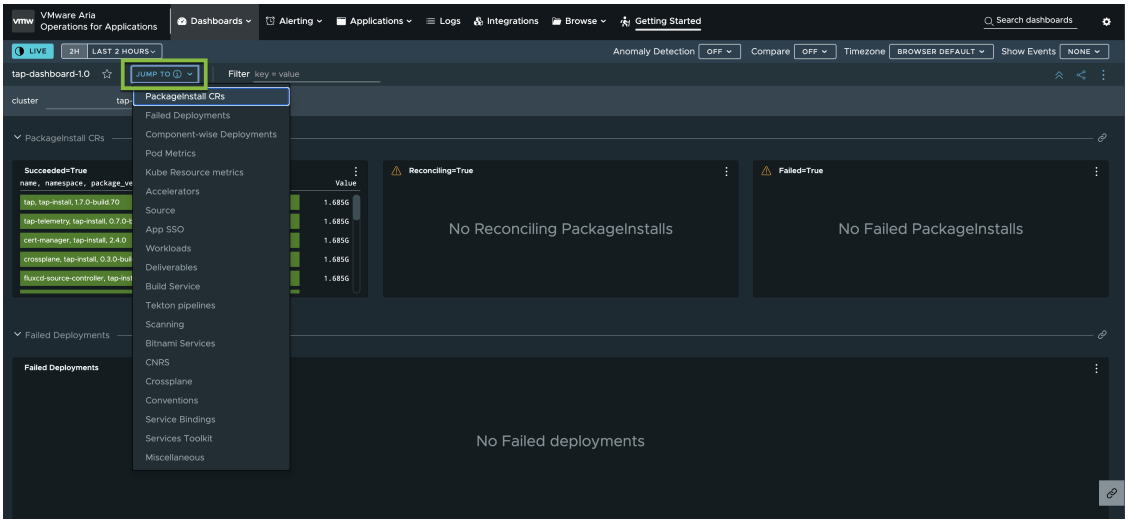
This topic tells you about using the Aria Operations for Applications (AOA) dashboard for use with Tanzu Application Platform (commonly known as TAP).

Use this dashboard to monitor:

- Statuses of the various Tanzu Application Platform-related `PackageInstall` resources that are associated with each Tanzu Application Platform component
- Failed deployments and the statuses of deployments related to Tanzu Application Platform components
- Pod metrics, which include metrics such as memory and CPU use
- The health of individual Tanzu Application Platform components

Use the **JUMP TO** drop-down menu to quickly go to a view.



Overview of AWS Services

AWS Services provides an integration with Amazon Web Services (AWS) for Tanzu Application Platform (commonly known as TAP).

Through integration with Crossplane and Services Toolkit, you can offer these AWS services for apps teams to consume with only minimal setup and configuration required from ops teams. This makes it quick and easy to get started working with AWS services on Tanzu Application Platform.

Getting started

If this is your first time working with AWS Services on Tanzu Application Platform, you can start by reading About the AWS Services package to help you to understand the goals of the package and some of its limitations.

After you understand the concepts, if you are a service operator, you can Install AWS Services. If you are an app developer, see Working with AWS Services.

You can also see the How-to guides and Reference material.

Overview of AWS Services

AWS Services provides an integration with Amazon Web Services (AWS) for Tanzu Application Platform (commonly known as TAP).

Through integration with Crossplane and Services Toolkit, you can offer these AWS services for apps teams to consume with only minimal setup and configuration required from ops teams. This

makes it quick and easy to get started working with AWS services on Tanzu Application Platform.

Getting started

If this is your first time working with AWS Services on Tanzu Application Platform, you can start by reading About the AWS Services package to help you to understand the goals of the package and some of its limitations.

After you understand the concepts, if you are a service operator, you can Install AWS Services. If you are an app developer, see Working with AWS Services.

You can also see the How-to guides and Reference material.

Install AWS Services

This topic tells you how to install the AWS Services package from the Tanzu Application Platform (commonly known as TAP) package repository.

Note

The AWS Services package is not in any of the Tanzu Application Platform profiles. To use this package, you must follow the instructions in this topic.

Prerequisites

Before you install the AWS Services package:

- Install Tanzu Application Platform
- VMware recommends that you read About the AWS Services package. The topic provides context about the features and goals of the package, and some of the considerations and compromises that were made as part of its development.

Step 1: Plan and configure your infrastructure

There are a wide range of infrastructure and networking setups available when integrating services on AWS into Tanzu Application Platform. Therefore, the first step is to decide which of these setups you want and to configure the AWS Services package for this topology.

Note

This section provides setup guidance for the most simple setup, which is a Tanzu Application Platform cluster running on AWS EKS in a virtual private cloud (VPC) connecting to RDS PostgreSQL service instances running in the same VPC.

To plan and configure your infrastructure:

1. Decide which topology you want to use. For more information about the topologies supported by the AWS Services package, see Supported Topologies.
2. Create a DBSubnetGroup and SecurityGroups:
    1. To learn how to create a DBSubnetGroup, see the AWS documentation.
    2. To learn how to create SecurityGroups, see the AWS documentation.

> **Note**
>
> The current version of the AWS Services package does not create these resources for you. You must create them manually using the AWS console. This is a one-time manual setup step that you must complete before installing the package.

3. If you are configuring RabbitMQ, choose an existing subnet or create one. For how to create a subnet, see the AWS documentation.
4. Record the name of the DBSubnetGroup, which includes IDs of the SecurityGroups and Subnets. These are required when installing the package.
5. Complete any remaining configuration tasks listed in Supported Topologies.

Step 2: Install the AWS Services package

The AWS Services package is not installed as part of any profile so you must explicitly install it. To install the AWS Services package:

1. Confirm that you have the AWS Services package available by running:

```
tanzu package available get aws.services.tanzu.vmware.com -n tap-install
```

2. Prepare an `aws-services-values.yaml` file to configure the installation:

```
# aws-services-values.yaml
---
# Optional, add any custom CA certificate data required by your Tanzu Applicati
on Platform installation
ca_cert_data: |
    -----BEGIN CERTIFICATE-----
    MIIFXzCCA0egAwIBAgIJAJYm37SFocjlMA0GCSqGSIb3DQEBDQUAMEY...
    -----END CERTIFICATE-----

# Optional, the ARN for the role to be associated with the service account runn
ing the providers.
role_arn: "ROLE-ARN"

# Configuration specific to the RDS PostgreSQL service
postgresql:
  # Enable the RDS PostgreSQL service. The default is set to false.
  enabled: true
  region: "REGION"
  provider_config_ref:
    name: "PROVIDER-CONFIG-NAME"
  # Infrastructure configuration for the RDS PostgreSQL service
  infrastructure:
    subnet_group:
      name: "SUBNET-GROUP-NAME"
    security_groups:
      - id: "SECURITY-GROUP-ID"
  # Instance-level configuration for the RDS PostgreSQL service applied to all
service instances
  # All instance_configuration is optional. See below for default values.
  instance_configuration:
    instance_class: "INSTANCE-CLASS"
    engine_version: "ENGINE-VERSION"
    skip_final_snapshot: SKIP-FINAL-SNAPSHOT
    publicly_accessible: PUBLICLY-ACCESSIBLE
    maintenance_window: "MAINTENANCE-WINDOW"
```

```
# Configuration specific to the RDS MySQL service
mysql:
  # Enable the RDS MySQL service. The default is set to false.
  enabled: true
  region: "REGION"
  provider_config_ref:
    name: "PROVIDER-CONFIG-NAME"
  # Infrastructure configuration for the RDS MySQL service
  infrastructure:
    subnet_group:
      name: "SUBNET-GROUP-NAME"
    security_groups:
      - id: "SECURITY-GROUP-ID"
  # Instance-level configuration for the RDS MySQL service applied to all servi
ce instances
  # All instance_configuration is optional. See below for default values.
  instance_configuration:
    instance_class: "INSTANCE-CLASS"
    engine_version: "ENGINE-VERSION"
    skip_final_snapshot: SKIP-FINAL-SNAPSHOT
    publicly_accessible: PUBLICLY-ACCESSIBLE
    maintenance_window: "MAINTENANCE-WINDOW"

# Configuration specific to the Amazon MQ (RabbitMQ) service
rabbitmq:
  # Enable the Amazon MQ (RabbitMQ) service. The default is set to false.
  enabled: true
  region: "REGION"
  provider_config_ref:
    name: "PROVIDER-CONFIG-NAME"
  # Infrastructure configuration for the Amazon MQ (RabbitMQ) service
  infrastructure:
    subnet_id: "SUBNET-ID"
    security_groups:
      - id: "SECURITY-GROUP-ID"
  # Instance-level configuration for the Amazon MQ (RabbitMQ) service applied t
o all service instances
  # All instance_configuration is optional. See below for default values.
  instance_configuration:
    publicly_accessible: PUBLICLY-ACCESSIBLE
    engine_version: "ENGINE-VERSION"
    instance_class: "INSTANCE-CLASS"
    maintenance_window_start_time:
      day_of_week: "DAY-OF-WEEK"
      time_of_day: "TIME-OF-DAY"
      time_zone: "TIMEZONE"
```

Where:

- (Optional) `ROLE_ARN` is the ARN for the role to be associated with the service account running the providers.
- `REGION` is the AWS region you want, for example, `us-east-1`.
- `PROVIDER-CONFIG-NAME` is the name of the ProviderConfig for this service. Choose a name, or enter `default`. Choosing a name allows you to use a different ProviderConfig per service type offered by the AWS Services package.
- `SUBNET-GROUP-NAME` is the name of the DBSubnetGroup you created in Plan and configure your infrastructure earlier.
- `SECURITY-GROUP-ID` are the IDs of any security groups you created in Plan and configure your infrastructure earlier.
- `SUBNET-ID` is the ID of the subnet used for the resource that you chose or created in Plan and configure your infrastructure earlier.

- `INSTANCE-CLASS` is the instance type of the RDS instance. The default is `db.t3.micro`.
- `ENGINE-VERSION` is the engine version. For PostgreSQL the default is `13.7`. For MySQL the default is `8.0`. You can find the list of available versions in the AWS documentation.
- `SKIP-FINAL-SNAPSHOT` is whether a final snapshot is created before the instance is deleted. If you specify `true`, no snapshot is created. If you specify `false`, a snapshot called `final-snapshot-INSTANCE-NAME` is created before the instance is deleted. The default is `false`.
- `PUBLICLY-ACCESSIBLE` is whether or not PostgreSQL service instances are publicly accessible over the Internet. The value can be `true` or `false` depending on the topology you chose. See Supported Topologies. The default is `false`.
- `MAINTENANCE-WINDOW` is the window to perform maintenance in. The syntax is `ddd:hh24:mi-ddd:hh24:mi`. The default is `Mon:00:00-Mon:03:00`.
- `DAY-OF-WEEK` is the day of the week to perform maintenance in. The syntax is `MONDAY`. The default is `MONDAY`.
- `TIME-OF-DAY` is time of day to perform maintenance in. The syntax is `00:00` (24 hour). The default is `00:00`.
- `TIMEZONE` is the timezone for the maintenance window. The syntax is `UTC`. The default is `UTC`.

For the full list of values you can configure, see Package values for AWS Services.

3. Review which versions of AWS Services are available to install by running:

```
tanzu package available list -n tap-install aws.services.tanzu.vmware.com
```

For example:

```
$ tanzu package available list -n tap-install aws.services.tanzu.vmware.com
  NAME                               VERSION           RELEASED-AT
  aws.services.tanzu.vmware.com  0.1.0             2023-11-07 14:35:15 +0000 UT
C
```

4. Install the AWS Services package by running:

```
tanzu package install aws-services \
  --package aws.services.tanzu.vmware.com \
  --version VERSION-NUMBER \
  --namespace tap-install \
  --values-file aws-services-values.yaml
```

Where `VERSION-NUMBER` is the AWS Services version you want to install. For example, `0.1.0`.

5. Verify that the package installed by running:

```
tanzu package installed get aws-services -n tap-install
```

In the output, confirm that the `STATUS` value is `Reconcile succeeded`.

For example:

```
$ tanzu package installed get aws-services -n tap-install
NAMESPACE:          tap-install
NAME:               aws-services
PACKAGE-NAME:       aws.services.tanzu.vmware.com
PACKAGE-VERSION:    0.1.0
```

```
STATUS:             Reconcile succeeded
CONDITIONS:         - type: ReconcileSucceeded
  status: "True"
  reason: ""
  message: ""
```

Step 3: Configure credentials for access to your AWS account

You configure credentials and access information for your AWS account through the `ProviderConfig` resource.

This section shows you how to create a `ProviderConfig` using the `Secret` source in which your AWS account credentials are stored in a `Secret` on the cluster. However, there are alternative methods, for example, an option to assume an IAM Role. To learn about the full range of configuration options available, see the Upbound documentation.

To create a `ProviderConfig` using the `Secret` source:

1. Create the `Secret` to hold the AWS credentials by running:

   ```
   export AWS_ACCESS_KEY_ID="foo"
   export AWS_SECRET_ACCESS_KEY="bar"

   echo -e "[default]\naws_access_key_id = $AWS_ACCESS_KEY_ID\naws_secret_access_k
   ey = $AWS_SECRET_ACCESS_KEY" > creds.conf

   # (optional) if you are required to use a session token to access your AWS acco
   unt, you must also set AWS_SESSION_TOKEN
   # export AWS_SESSION_TOKEN=""
   # echo -e "aws_session_token = $AWS_SESSION_TOKEN" >> creds.conf

   kubectl create secret generic aws-creds -n crossplane-system --from-file=creds
   =./creds.conf
   rm -f creds.conf
   ```

2. Create a `ProviderConfig` and configure it with the `Secret` source by running:

   ```
   kubectl apply -f -<<EOF
   ---
   apiVersion: aws.upbound.io/v1beta1
   kind: ProviderConfig
   metadata:
     name: PROVIDER-CONFIG-NAME
   spec:
     credentials:
       source: Secret
       secretRef:
         namespace: crossplane-system
         name: aws-creds
         key: creds
   EOF
   ```

   Where `PROVIDER-CONFIG-NAME` is the `postgresql.provider_config_ref.name` value you configured in your `aws-services-values.yaml` file. The default is `default`.

3. Verify your setup by inspecting the `SubnetGroup` and `SecurityGroups` resources created as part of the installation of the package by running:

   ```
   kubectl get securitygroup
   kubectl get subnetgroup
   ```

When both resources report `SYNCED: True`, the AWS providers have connected to your AWS account and pulled down the information about each of the resources.

AWS Services concepts

This section introduces you to AWS Services concepts.

In this section:

- About the AWS Services package

About the AWS Services package

This topic tells you about the goal of the AWS Services package and some of its limitations.

Goals

The AWS Services package aims to provide simple and seamless integration into Tanzu Application Platform for a variety of services from AWS. The goal is to minimize the time to value so that users can both offer and consume the services that they want on Tanzu Application Platform with minimal effort.

Limitations

The AWS Services package has to accommodate a wide range of infrastructure and networking setups. Each setup has different infrastructure and configuration requirements.

Example setups include:

- A Tanzu Application Platform cluster running on AWS EKS in “VPC A” connecting to RDS PostgreSQL service instances running in “VPC A”
- A Tanzu Application Platform cluster running on AWS EKS in “VPC A” connecting to RDS PostgreSQL service instances running in “VPC B”
- A Tanzu Application Platform cluster running on AWS EKS in “VPC A” connecting to RDS MySQL service instances running in “VPC B”
- A Tanzu Application Platform cluster running on Azure AKS connecting to RDS MySQL service instances running in “VPC A”

If not handled carefully, accommodating these differences could lead to the package configuration becoming too complex.

To control the potential complexity, the AWS Services package makes the following compromises:

- You might have to complete one-time infrastructure setup tasks, for example, creating an RDS DBSubnetGroup.
- All service instances for each service type, such as RDS PostgreSQL, are created in the same VPC.
- There is no multi-region support.
- Instance-level configuration, such as instance class or engine version, is applied globally to all service instances of a service type.

As the AWS Services package matures and VMware learns more about how it is being used, VMware might remove some of these compromises if it can be achieved while keeping the experience as simple as possible. This is not guaranteed.

Other Considerations

The AWS Services package is not installed as part of any of the Tanzu Application Platform profiles. This is because not every user needs to integrate services from AWS into their Tanzu Application Platform cluster. However, the package is in the Tanzu Application Platform packageRepository, which means that you can install it using the same tooling, credentials, and image repositories that you use to install Tanzu Application Platform. See Install AWS Services.

You might not want to integrate all of the services supported by the package. Therefore, none of the services are enabled by default. It is up to service operators to enable the services they want using the Package values. For the list of services you can enable, see Supported AWS Services.

AWS Services tutorials

This section contains tutorials for how to use AWS Services.

In this section:

- Working with AWS Services

Working with AWS Services

In this tutorial you learn how application operators and application developers can use AWS Services on Tanzu Application Platform. You will learn how to discover, claim, and bind services to application workloads.

Prerequisites

Before starting this tutorial:

- VMware recommends that you read About the AWS Services package. The topic provides context about the goals of the package, and some of the considerations and compromises that were made as part of its development.
- Install AWS Services.

About this tutorial

Target user roles: Application Operator, Application Developer
Complexity: Basic
Estimated time: 15 minutes
Topics covered: AWS, RDS, PostgreSQL, MySQL, Classes, Claims
Learning outcomes: An understanding of how to work with RDS PostgreSQL and MySQL instances on Tanzu Application Platform using the AWS Services package

Step 1: Discover the list of available AWS services

To find out about available AWS services:

1. To discover the list of available services, run:

   ```
   tanzu service class list
   ```

   The expected output has two services: `postgresql-managed-aws` and `mysql-managed-aws`.

2. To learn more about the service, including which claim parameters are provided, run:

```
tanzu service class get CLASS-NAME
```

Where `CLASS-NAME` is one of the services listed in the previous step.

Step 2: Claim an instance of an AWS RDS service

To claim an instance of an AWS RDS service:

```
tanzu service class-claim create CLAIM-NAME --class CLASS-NAME
```

Where:

- `CLAIM-NAME` is the name you choose for your claim, for example, `rds-1`.
- `CLASS-NAME` is one of the services listed earlier.

It takes about 5 to 10 minutes for the service instance to be provisioned. You can watch the claim and wait for it to transition into a `READY: True` state to know when it is ready to use.

Step 3: Bind the service to a workload

After creating the claim, you can bind it to one or more of your application workloads.

Important

If you want to bind to more than one application workload, all application workloads must be in the same namespace. This is a known limitation. For more information, see Cannot claim and bind to the same service instance from across multiple namespaces.

1. Find the reference for the claim by running:

   ```
   tanzu service class-claim get CLAIM-NAME
   ```

   Where `CLAIM-NAME` is the name of the claim you want to bind your workload to, for example, `rds-1`.

   The reference is in the output under the heading Claim Reference.

2. Bind the claim to a workload of your choice by passing a reference to the claim to the `--service-ref` flag of the `tanzu apps workload create` command. For example:

   ```
   tanzu apps workload create my-workload --image my-registry/my-app-image --servi
   ce-ref db=services.apps.tanzu.vmware.com/v1alpha1:ClassClaim:rds-1
   ```

   You must pass the claim reference with a corresponding name that follows the format `--service-ref db=services.apps.tanzu.vmware.com/v1alpha1:ClassClaim:rds-1`. The `db=` prefix to this example reference is an arbitrary name for the reference.

AWS Services how-to guides

This section contains how-to guides for AWS Services.

In this section:

- Configure AWS Service Endpoint
- Troubleshoot AWS Services

Configure the AWS service endpoint

This topic describes how to configure the service endpoint that the providers included with the AWS Services package use.

Overview

By default, AWS providers make calls to the default service endpoint for each service in an AWS region. However, you can configure the providers to make calls to an endpoint of your choice.

Configure the endpoint by using a ProviderConfig resource

To configure the service endpoint through a `ProviderConfig` resource:

1. Update the `ProviderConfig` you created when installing the package. For example:

   ```
   ---
   apiVersion: aws.upbound.io/v1beta1
   kind: ProviderConfig
   metadata:
     name: custom-endpoint
   spec:
     endpoint:
       url:
         static: https://my-custom-aws-endpoint.com
         type: Static
   # ...
   ```

   For the full list of configuration options, see the Upbound documentation.

2. In your `aws-services-values.yaml` file, configure the AWS Services package to use the `ProviderConfig` you just configured. For example:

   ```
   # aws-services-values.yaml
   ---
   postgresql:
     provider_config_ref:
       name: custom-endpoint
   # ...
   ```

3. Update the AWS Services package:

   ```
   tanzu package installed update aws-services -n tap-install --values-file aws-se
   rvices-values.yaml
   ```

Troubleshoot AWS Services

This topic explains how you troubleshoot issues related to AWS Services on Tanzu Application Platform (commonly known as TAP).

Secret key name for Amazon MQ claims do not match the name used in the Spring Cloud Bindings library

Symptom:

When you create a claim for Amazon MQ (RabbitMQ), the resulting binding secret contains a key named `endpoint`. This does not match the key name that the Spring Cloud Bindings library expects,

which is `addresses`. As a result, when you bind Spring-based workloads to the Amazon MQ service, the connection is not established automatically.

Cause:

This issue was caused by a misconfiguration in the `CompositeResourceDefinition` and `Composition` for the Amazon MQ service. These resources have been updated to resolve the issue. However, Crossplane does not support changes to `connectionSecretKeys` in `CompositeResourceDefinition` resources.

Solution:

The following workaround is only required if you have upgraded Tanzu Application Platform from v1.8.0 or v1.8.1.

To workaround this issue:

1. Find the name of the Crossplane pod, for example:

   ```
   kubectl get pod -lapp=crossplane -n crossplane-system
   ```

2. Delete the pod, for example:

   ```
   kubectl delete pod CROSSPLANE-POD-NAME -n crossplane-system
   ```

   Where `CROSSPLANE-POD-NAME` is the name of the Crossplane pod you retrieved.

After you delete the pod, it is automatically recreated. This causes Crossplane to re-read the updated list of `connectionSecretKeys` from the `CompositeResourceDefinition`. New claims for Amazon MQ (RabbitMQ) will now contain the correct set of key names.

AWS Services reference

This section provides reference documentation for AWS Services.

In this section:

- Package values
- Supported Services
- Supported Topologies
- Version matrix

Package values for AWS Services

This topic lists the keys and values that you can use to configure the behavior of the AWS Services package.

Globals

The following table lists global configuration that applies across all services.

KEY	DEFAULT	TYPE	DESCRIPTION
ca_cert_data	`""`	string	PEM-encoded certificate data for the AWS Providers to trust TLS connections with a custom CA
globals.crossplane_system_namespace	`crossplane-system`	string	The name of the namespace in which Crossplane and the providers are deployed to

KEY	DEFAULT	TYPE	DESCRIPTION
globals.create_clusterroles	`true`	boolean	Specifies whether to create default ClusterRoles that grant `claim` permissions to all Tanzu Application Platform application operators
role_arn	""	string	The ARN for the role to be associated with the service account running the providers. Necessary when setting `spec.credentials.source` to `IRSA` in your `ProviderConfig`. For more information, see the Upbound documentation.

PostgreSQL

The following table lists configuration that applies to the `postgresql` service.

KEY	DEFAULT	TYPE	DESCRIPTION
postgresql.enabled	`false`	boolean	Enables the PostgreSQL service class
postgresql.infrastructure.security_groups	*n/a*	array	Security groups for your PostgreSQL databases to belong to
postgresql.infrastructure.subnet_group.name	`""`	string	Subnet group for your PostgreSQL databases
postgresql.instance_configuration.engine_version	`"13.7"`	string	The PostgreSQL version. For more information, see the AWS documentation.
postgresql.instance_configuration.instance_class	`"db.t3.micro"`	string	The instance type of the RDS instance. For more information, see the AWS documentation.
postgresql.instance_configuration.maintenance_window	`"Mon:00:00-Mon:03:00"`	string	The window to perform maintenance in. Syntax: `ddd:hh24:mi-ddd:hh24:mi`, for example, `Mon:00:00-Mon:03:00`. For more information, see the AWS documentation.
postgresql.instance_configuration.publicly_accessible	`false`	boolean	Controls whether your instances are publicly accessible
postgresql.instance_configuration.skip_final_snapshot	`false`	boolean	Determines whether a final snapshot is created before the instance is deleted. If you specify `true`, no snapshot is created. If you specify `false`, a snapshot called `final-snapshot-INSTANCE-NAME` is created before the instance is deleted.
postgresql.provider_config_ref.name	`"default"`	string	Name of your ProviderConfig for the `postgresql` service
postgresql.region	`"us-east-1"`	string	The AWS region to create databases in

MySQL

The following table lists configuration that applies to the `mysql` service.

KEY	DEFAULT	TYPE	DESCRIPTION
mysql.enabled	`false`	boolean	Enables the MySQL service class

KEY	DEFAULT	TYPE	DESCRIPTION
mysql.infrastructure.security_groups	*n/a*	array	Security groups for your MySQL databases to belong to
mysql.infrastructure.subnet_group.name	`""`	string	Subnet group for your MySQL databases
mysql.instance_configuration.engine_version	`"8.0"`	string	The MySQL version. For more information, see the AWS documentation.
mysql.instance_configuration.instance_class	`"db.t3.micro"`	string	The instance type of the RDS instance. For more information, see the AWS documentation.
mysql.instance_configuration.maintenance_window	`"Mon:00:00-Mon:03:00"`	string	The window to perform maintenance in. Syntax: `ddd:hh24:mi-ddd:hh24:mi`, for example, `Mon:00:00-Mon:03:00`. For more information, see the AWS documentation.
mysql.instance_configuration.publicly_accessible	`false`	boolean	Controls whether your instances are publicly accessible
mysql.instance_configuration.skip_final_snapshot	`false`	boolean	Determines whether a final snapshot is created before the instance is deleted. If you specify `true`, no snapshot is created. If you specify `false`, a snapshot called `final-snapshot-INSTANCE-NAME` is created before the instance is deleted.
mysql.provider_config_ref.name	`"default"`	string	Name of your ProviderConfig for the `mysql` service
mysql.region	`"us-east-1"`	string	The AWS region to create databases in

RabbitMQ

The following table lists configuration that applies to the `rabbitmq` service.

KEY	DEFAULT	TYPE	DESCRIPTION
rabbitmq.enabled	`false`	boolean	Enables the RabbitMQ service class
rabbitmq.infrastructure.security_groups	*n/a*	array	The security groups for your RabbitMQ brokers to belong to. Do not provide any security groups if you're setting `rabbitmq.instance_configuration.publicly_accessible` to true.
rabbitmq.infrastructure.subnet_id	`""`	string	The ID of the subnet for your RabbitMQ brokers to belong to
rabbitmq.instance_configuration.publicly_accessible	`false`	boolean	Controls if your instances are publicly accessible
rabbitmq.instance_configuration.engine_version	`3.11.20`	string	The RabbitMQ version. For more information, see the AWS documentation.
rabbitmq.instance_configuration.instance_class	`mq.t3.micro`	string	The instance type of the MQ broker. For more information, see AWS documentation.
rabbitmq.instance_configuration.maintenance_window_start_time.day_of_week	`MONDAY`	string	The day of the week to perform maintenance in. Possible values: `MONDAY`, `TUESDAY`, `WEDNESDAY`, `THURSDAY`, `FRIDAY`, `SATURDAY`, `SUNDAY`.

KEY	DEFAULT	TYPE	DESCRIPTION
rabbitmq.instance_configuration.maintenance_window_start_time.time_of_day	`"00:00"`	string	The time to perform maintenance in in 24-hour format
rabbitmq.instance_configuration.maintenance_window_start_time.time_zone	`UTC`	string	The time zone for the maintenance window
rabbitmq.provider_config_ref.name	`default`	string	The name of the ProviderConfig to use to create your RabbitMQ brokers
rabbitmq.region	`us-east-1`	string	The AWS region to create brokers in

Supported AWS services

This topic lists the services that the AWS Services package supports.

In Tanzu Application Platform v1.9.1, the AWS Services package supports the following AWS services:

- RDS PostgreSQL
- RDS MySQL
- Amazon MQ (RabbitMQ)

VMware plans to add more services to the package in future releases.

Supported topologies for AWS Services

This topic gives you the list of Tanzu Application Platform (commonly known as TAP) cluster to service instance Virtual Private Cloud (VPC) topologies that the AWS Services package supports. Each supported topology lists relevant package values configurations and one-time manual setup steps.

The topologies described in this topic are available for the PostgreSQL, MySQL, and RabbitMQ services.

Topology 1: service instance accessed by a workload in the same VPC

Topology 1 is a service instance in a VPC accessed by a workload in a Tanzu Application Platform cluster in the same VPC.

This topology is very similar to a database instance in a VPC accessed by an EC2 instance in the same VPC as described in the AWS documentation.

Key properties for topology 1

The key properties of this topology are:

- Uses subnets to separate where application workloads run and where service instances run
- Uses security groups to manage access between the subnets
- Service instances are not publicly accessible

This topology is recommended if your Tanzu Application Platform cluster is running in AWS.

Configuration tasks for topology 1

To configure the service from the AWS Services package for this type of topology you must:

- Manually create all required subnets and security groups in AWS.
- Add a rule to permit the TCP port from the subnet where the Tanzu Application Platform application workloads run to the subnet where the service instances run. Create the rule for TCP port 5432 for PostgreSQL and MySQL, or 5671 for RabbitMQ.
- For PostgreSQL and MySQL, create a database subnet group consisting of the subnets.

For instructions for these tasks, see the AWS documentation.

After completing configuration in AWS, you must configure your `aws-services-values.yaml` file using the following values when installing the package:

PostgreSQL

```
postgresql:
  enabled: true
  region: "REGION"
  infrastructure:
    subnet_group:
      name: "SUBNET-GROUP-NAME"
    security_groups:
      - id: "SECURITY-GROUP-ID"
```

MySQL

```
mysql:
  enabled: true
  region: "REGION"
  infrastructure:
    subnet_group:
      name: "SUBNET-GROUP-NAME"
    security_groups:
      - id: "SECURITY-GROUP-ID"
```

RabbitMQ

```
rabbitmq:
  enabled: true
  region: "REGION"
  infrastructure:
    subnet_id: "SUBNET-ID"
    security_groups:
      - id: "SECURITY-GROUP-ID"
```

Topology 2: service instance accessed by a workload external to AWS

Topology 2 is a service instance in a VPC accessed by a workload in a Tanzu Application Platform cluster running external to AWS.

This topology is very similar to a database instance in a VPC accessed by a client application through the Internet as described in the AWS documentation.

Key properties for topology 2

The key properties of this topology are:

- Uses a public subnet in which to run service instances

- Uses an Internet gateway to provide connectivity over the Internet
- Uses security groups to manage access to the subnet
- Service instances are publicly accessible over the Internet

This topology is recommended if your Tanzu Application Platform cluster is running external to AWS, for example, on-prem or in another cloud such as Azure.

Configuration tasks for topology 2

To configure the service from the AWS Services package for this type of topology you must:

- Manually create all required subnets and security groups in AWS.
- Create an Internet gateway.
- Add a rule to permit TCP port 5432 (PostgreSQL, MySQL) or 5671 (RabbitMQ) from the subnet where the Tanzu Application Platform application workloads run to the subnet where the service instances run.
- Create a database subnet group (PostgreSQL, MySQL) consisting of the subnets.

For instructions for these tasks, see the AWS documentation.

After completing configuration in AWS, you must configure your `aws-services-values.yaml` file using the following values when installing the package:

PostgreSQL

```
postgresql:
  enabled: true
  region: "REGION"
  infrastructure:
    subnet_group:
      name: "SUBNET-GROUP-NAME"
    security_groups:
      - id: "SECURITY-GROUP-ID"
  instance_configuration:
    publicly_accessible: true
```

MySQL

```
mysql:
  enabled: true
  region: "REGION"
  infrastructure:
    subnet_group:
      name: "SUBNET-GROUP-NAME"
    security_groups:
      - id: "SECURITY-GROUP-ID"
  instance_configuration:
    publicly_accessible: true
```

RabbitMQ

```
rabbitmq:
  enabled: true
  region: "REGION"
  infrastructure:
    subnet_id: "SUBNET-ID"
  instance_configuration:
    publicly_accessible: true
```

Version matrix for AWS Services

This topic provides you with a version matrix for the AWS Services package and its open source components in Tanzu Application Platform v1.9 (commonly known as TAP).

To view this information for another Tanzu Application Platform version, select the version from the drop-down menu at the top of this page.

The following table has the component versions for the AWS Services package.

Component	Version
AWS Services package	0.3.0
provider-aws	1.2.0

Note

Tanzu Application Platform patch releases are only added to the table when there is a change to one or more of the other versions in the table. Otherwise, the corresponding versions remain the same for each Tanzu Application Platform patch release.

Uninstall AWS Services

This topic tells you how to uninstall the AWS Services package from Tanzu Application Platform (commonly known as TAP).

Step 1: Prepare your infrastructure

Before uninstalling the package, you must decide whether to retain or delete the existing resources that have been claimed.

Failing to follow one of the following procedures for all of your resources leaves your Tanzu Application Platform in a state that might prevent you from reinstalling the AWS Services package in the future.

Retain the resources

If you want to keep a resource:

1. Find the Composite Resource associated with your claim by running:

   ```
   kubectl get classclaim CLASS-CLAIM-NAME -n CLASS-CLAIM-NAMESPACE -ojsonpath="{.status.provisionedResourceRef}"
   ```

   Where:

   - `CLASS-CLAIM-NAME` is the name of the claim.
   - `CLASS-CLAIM-NAMESPACE` is the namespace the claim is in.

   Example output for a PostgreSQL claim:

   ```
   {"apiVersion":"aws.database.tanzu.vmware.com/v1alpha1","kind":"XPostgreSQLInstance","name":"rds-2-r4mgc"}
   ```

2. Find the `Instance` associated with the Composite Resource by running:

```
kubectl get XR-API XR-NAME -ojsonpath="{.spec.resourceRefs}"
```

Where:

- `XR-API` is in the format `KIND.APIVERSION` using the `kind` and `apiVersion` from the output of the previous step. `APIVERSION` is the part of `apiVersion` before the `/`, for example, `aws.database.tanzu.vmware.com`.
- `XR-NAME` is the value of `name` from the output of the previous step.

For example:

```
$ kubectl get xpostgresqlinstance.aws.database.tanzu.vmware.com rds-2-r4mgc -oj
sonpath="{.spec.resourceRefs}"

[{"apiVersion":"rds.aws.upbound.io/v1beta1","kind":"Instance","name":"rds-2-r4m
gc-zc69h"}]
```

3. Open the `Instance` resource for editing by running:

   ```
   kubectl edit instance.rds.aws.upbound.io INSTANCE-NAME
   ```

   Where `INSTANCE-NAME` is the value of `name` from the output of the previous step.

   For example:

   ```
   $ kubectl edit instance.rds.aws.upbound.io rds-2-r4mgc-zc69h
   ```

4. Change the `Instance` resource `spec.deletionPolicy` field from `Delete` to `Orphan`:

   ```
   apiVersion: rds.aws.upbound.io/v1beta1
   kind: Instance
   metadata:
     # ...
   spec:
     deletionPolicy: Orphan
     # ...
   ```

5. Save, and close your editor.
6. Delete the claim by running:

   ```
   tanzu service class-claim delete CLAIM-NAME
   ```

Delete the resources

If you want to delete a resource:

1. Delete the corresponding claim by running:

   ```
   tanzu service class-claim delete CLAIM-NAME
   ```

2. Wait for the resource to disappear in the AWS console.

Step 2: Uninstall the AWS Services package

To uninstall the AWS Services package:

1. Confirm that you have the AWS Services package installed by running:

   ```
   tanzu package installed list -A
   ```

2. Search the `PACKAGE-NAME` column of the output for `aws.services.tanzu.vmware.com`, and record the name and namespace.
3. Uninstall the package:

   ```
   tanzu package installed delete PACKAGE-NAME -n PACKAGE-NAMESPACE
   ```

   Where `PACKAGE-NAME` and `PACKAGE-NAMESPACE` are the values you recorded in the previous step.

   For example:

   ```
   $ tanzu package installed delete aws-services -n tap-install
   ```

Step 3: Delete the `ProviderConfig`

You must delete the `ProviderConfig` you created after installing the AWS Services package to complete the uninstall.

Crossplane installs a finalizer when the `ProviderConfig` is created. To delete the `ProviderConfig` you must remove the finalizer. If you don't do this step, the `ProviderConfig` and its related Custom Resource Definition (CRD) remain in the cluster and prevent you from reinstalling the package in the future.

1. Open the `ProviderConfig` resource for editing by running:

   ```
   kubectl edit providerconfig.aws.upbound.io PROVIDER-CONFIG-NAME
   ```

   Where `PROVIDER-CONFIG-NAME` is the name you chose for your `ProviderConfig`.
2. In the `ProviderConfig`:
   1. Record the name and namespace of the `Secret` referenced in `spec.credentials`.
   2. Delete the `metadata.finalizers` entry. This allows the `ProviderConfig` to be deleted.
3. Save, and close your editor. The `ProviderConfig` is automatically deleted.
4. Verify the `ProviderConfig` has been removed by running:

   ```
   kubectl get providerconfig.aws.upbound.io
   ```

   The expected output is an error message like this:

   ```
   Error from server (NotFound): Unable to list "aws.upbound.io/v1beta1, Resource=
   providerconfigs": the server could not find the requested resource (get provide
   rconfigs.aws.upbound.io)
   ```
5. Delete the `Secret` by running:

   ```
   kubectl delete secret SECRET-NAME -n SECRET-NAMESPACE
   ```

   Where `SECRET-NAME` and `SECRET-NAMESPACE` are the values you recorded earlier.

Overview of Bitnami Services

Bitnami Services provides a set of backing services for Tanzu Application Platform (commonly known as TAP). The services are MySQL, PostgreSQL, RabbitMQ, Redis, MongoDB, and Kafka all of which are backed by the corresponding Bitnami Helm Chart.

Through integration with Crossplane and Services Toolkit, these six services are immediately ready for apps teams to consume, with no additional setup or configuration required from ops teams. This makes it incredibly quick and easy to get started working with services on Tanzu Application Platform.

Note

The Bitnami Services package provides unmanaged services that are not designed to support long lived instances. Therefore, there is no supported path to upgrade individual instances. Bitnami Services are instantiated using the configuration and version of the package at creation time and so upgrading the Bitnami Services package has no effect on existing instances. VMware discourages changing the `compositionUpdatePolicy` and `compositionRevisionRef` on the individual composite resources (XRs) because this might cause unintended side effects.

Getting started

If this is your first time working with Bitnami Services on Tanzu Application Platform, you can start with the tutorial Working with Bitnami Services. Otherwise, see the how-to guides and reference material.

Overview of Bitnami Services

Bitnami Services provides a set of backing services for Tanzu Application Platform (commonly known as TAP). The services are MySQL, PostgreSQL, RabbitMQ, Redis, MongoDB, and Kafka all of which are backed by the corresponding Bitnami Helm Chart.

Through integration with Crossplane and Services Toolkit, these six services are immediately ready for apps teams to consume, with no additional setup or configuration required from ops teams. This makes it incredibly quick and easy to get started working with services on Tanzu Application Platform.

Bitnami Services are instantiated using the configuration and version of the package at creation time and so upgrading the Bitnami Services package has no effect on existing instances. VMware discourages changing the `compositionUpdatePolicy` and `compositionRevisionRef` on the individual composite resources (XRs) because this might cause unintended side effects.

Getting started

If this is your first time working with Bitnami Services on Tanzu Application Platform, you can start with the tutorial Working with Bitnami Services. Otherwise, see the how-to guides and reference material.

Install Bitnami Services

This topic tells you how to install Bitnami Services from the Tanzu Application Platform (commonly known as TAP) package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install Bitnami Services. For more information about profiles, see Components and installation profiles.

Prerequisites

Before installing Bitnami Services, you must:

- Fulfill all prerequisites for installing Tanzu Application Platform
- Install Crossplane
- Install Services Toolkit

Install Bitnami Services

To install Bitnami Services:

1. See what versions of Bitnami Services are available to install by running:

   ```
   tanzu package available list -n tap-install bitnami.services.tanzu.vmware.com
   ```

   For example:

   ```
   $ tanzu package available list -n tap-install bitnami.services.tanzu.vmware.com
     NAME                               VERSION           RELEASED-AT
     bitnami.services.tanzu.vmware.com  0.1.0             2023-03-10 14:35:15 +000
   0 UTC
   ```

2. Install Bitnami Services by running:

   ```
   tanzu package install bitnami-services \
     --package bitnami.services.tanzu.vmware.com \
     --version VERSION-NUMBER \
     --namespace tap-install
   ```

   Where `VERSION-NUMBER` is the Bitnami Services version you want to install. For example, `0.1.0`.

3. Verify that the package installed by running:

   ```
   tanzu package installed get bitnami-services -n tap-install
   ```

   In the output, confirm that the `STATUS` value is `Reconcile succeeded`.

   For example:

   ```
   $ tanzu package installed get bitnami-services -n tap-install
   NAMESPACE:          tap-install
   NAME:               bitnami-services
   PACKAGE-NAME:       bitnami.services.tanzu.vmware.com
   PACKAGE-VERSION:    0.1.0
   STATUS:             Reconcile succeeded
   CONDITIONS:         - type: ReconcileSucceeded
     status: "True"
     reason: ""
     message: ""
   ```

Bitnami Services tutorials

This section contains tutorials for how to use Bitnami Services.

In this section:

- Working with Bitnami Services

Working with Bitnami Services

In this tutorial you learn how application operators can discover, claim, and bind services to application workloads.

Tanzu Application Platform has six services that are available in the Bitnami Services package. These are MySQL, PostgreSQL, RabbitMQ, Redis, MongoDB, and Kafka. The corresponding Bitnami Helm Chart backs each of these services.

About this tutorial

Target user role: Application Operator
Complexity: Basic
Estimated time: 15 minutes
Topics covered: Classes, Claims, Bitnami
Learning outcomes: An understanding of how work with the standard Bitnami services

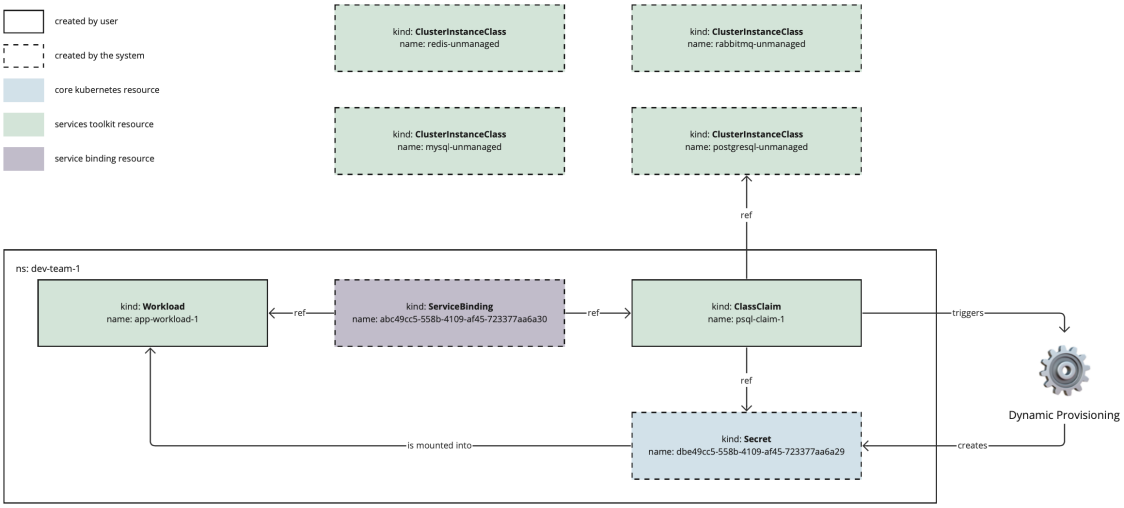
Prerequisites

To follow this tutorial, you must have:

- Access to a Tanzu Application Platform cluster v1.5.0 and later
- The Tanzu services CLI plug-in v0.6.0 and later

Concepts

The following diagram provides an overview of the elements you will use during this tutorial and how they all fit together.



In this diagram:

- There are only two elements that require user input, which are creating a `ClassClaim` and creating a `Workload`. The workload is configured to refer to the class claim`.

- The life cycles of the `ClassClaim` and the `Workload` are separate. This allows you to update one without affecting the other.
- The dynamic provisioning process is simplified. This is intentional because Application Operators and Developers do not need to know about the inner workings and configurations of service instances.

Procedure

The following steps explain how to work with Bitnami Services.

Step 1: Discover services

Application teams can discover the range of services on offer to them by running:

```
tanzu service class list
```

The expected output is similar to the following:

```
  NAME                  DESCRIPTION
  kafka-unmanaged       Kafka by Bitnami
  mongodb-unmanaged     MongoDB by Bitnami
  mysql-unmanaged       MySQL by Bitnami
  postgresql-unmanaged  PostgreSQL by Bitnami
  rabbitmq-unmanaged    RabbitMQ by Bitnami
  redis-unmanaged       Redis by Bitnami
```

Here the output shows six classes. These are the six services available in the Bitnami Services package. You can see from the names and descriptions that they are all *unmanaged* services. This implies that the resulting service instances run on cluster, that is, they are not a managed service running in the cloud. Other classes might be listed here as well.

As an Application Operator, you review the classes on offer and choose one that meets your requirements.

You can learn and discover more about a class by running:

```
tanzu service class get postgresql-unmanaged
```

Example output:

```
NAME:           postgresql-unmanaged
DESCRIPTION:    PostgreSQL by Bitnami
READY:          true

PARAMETERS:
  KEY        DESCRIPTION                                                TYPE     DEF
AULT  REQUIRED
  storageGB  The desired storage capacity of the database, in Gigabytes.  integer  1
false
```

The output shows the name and a short description for the class, its current status, and the parameters. The parameters represent the set of configuration options that are available to application teams.

The `postgresql-unmanaged` class here has one parameter, which is `storageGB`. You can also see that it is not required to pass this parameter when creating a claim for the class, in which case the default value of `1` is used.

Step 2: Claim services

In this example, you have an application workload that requires a PostgreSQL database to function correctly. You can claim the PostgreSQL Bitnami Service to obtain such a database.

To create the claim in a namespace named `dev-team-1`, you must first create the namespace by running:

```
kubectl create namespace dev-team-1
```

You can use the `tanzu service class-claim create` command to create a claim for the `postgresql-unmanaged` class, then bind your application workload to the resulting claim. In this example, you are also choosing to override the default value of `1` for the `storageGB` parameter, setting it instead to `3`. You can override any of the options as you see fit.

```
tanzu service class-claim create psql-1 --class postgresql-unmanaged --parameter stora
geGB=3 -n dev-team-1
```

Example output:

```
Creating claim 'psql-1' in namespace 'dev-team-1'.
Please run `tanzu service class-claim get psql-1 --namespace dev-team-1` to see the pr
ogress of create.
```

As the output states, you can then confirm the status of the claim by using the `tanzu service class-claim get` command as follows:

```
tanzu service class-claim get psql-1 --namespace dev-team-1
```

Example output:

```
Name: psql-1
Namespace: dev-team-1
Claim Reference: services.apps.tanzu.vmware.com/v1alpha1:ClassClaim:psql-1
Class Reference:
  Name: postgresql-unmanaged
Parameters:
  storageGB: 3
Status:
  Ready: True
  Claimed Resource:
    Name: 7974379c-7b4d-41c3-af57-f4f1ae08c65d
    Namespace: dev-team-1
    Group:
    Version: v1
    Kind: Secret
```

It might take a moment or two before the claim reports `Ready: True`. After the claim is ready, you then have a successful claim for a PostgreSQL database configured to your needs with 3 GB of storage.

Step 3: Bind the claim to a workload

After creating the claim, you can bind it to one or more of your application workloads.

Important

If binding to more than one application workload then all application workloads must exist in the same namespace. This is a known limitation. For more information, see

Cannot claim and bind to the same service instance from across multiple namespaces.

1. Find the reference for the claim by running the following command.

   ```
   tanzu service class-claim get psql-1
   ```

   The reference is in the output under the heading Claim Reference.

2. Bind the claim to a workload of your choice by pass a reference to the claim to the `--service-ref` flag of the `tanzu apps workload create` command. For example:

   ```
   tanzu apps workload create my-workload --image my-registry/my-app-image --servi
   ce-ref db=services.apps.tanzu.vmware.com/v1alpha1:ClassClaim:psql-1
   ```

   You must pass the claim reference with a corresponding name that follows the format `--service-ref db=services.apps.tanzu.vmware.com/v1alpha1:ClassClaim:psql-1`. The `db=` prefix to this example reference is an arbitrary name for the reference.

Bitnami Services how-to guides

This section contains how-to guides for Bitnami Services.

In this section:

- Configure private registry and VMware Tanzu Application Catalog integration for Bitnami Services
- Obtain credentials for VMware Tanzu Application Catalog integration
- Upgrading to Tanzu Kubernetes releases v1.26 or later
- Troubleshoot Bitnami Services

Configure private registry and VMware Tanzu Application Catalog integration for Bitnami Services

This topic tells you how to integrate Bitnami Services with private registries or with VMware Tanzu Application Catalog. You can configure this globally for all services, or on a per-service basis.

Prerequisites

Before you integrate Bitnami Services with a private registry or VMware Tanzu Application Catalog, you must:

- Have your Helm Chart repository URL in the format `oci://REGISTRY-HOSTNAME/REPOSITORY-PATH/charts`. Some VMware Tanzu Application Catalog instances append the operating system to the repository URL, in which case, use the URL format `oci://REGISTRY-HOSTNAME/REPOSITORY-PATH/charts/centos-7`.
- Have the credentials to access the private registry.

For how to obtain both of these prerequisites for VMware Tanzu Application Catalog integration, see Obtain credentials for VMware Tanzu Application Catalog integration.

Procedure

1. Create two Kubernetes `Secrets`, one with credentials to pull Helm charts and the other with credentials to pull images. The following examples put these in the `default` namespace, but you can choose to place them in any namespace you prefer.

```
$ kubectl create secret generic tac-chart-pull \
  -n default \
  --from-literal=username='USERNAME' \
  --from-literal=password='TOKEN'
```

```
$ kubectl create secret docker-registry tac-container-pull \
  -n default \
  --docker-server='REGISTRY-HOSTNAME' \
  --docker-username='USERNAME' \
  --docker-password='TOKEN'
```

2. Apply the configuration either to all Bitnami services or to one specific service.
    - **Apply configuration to all Bitnami services:**
        1. Add the following to your `tap-values.yaml` file:

```
bitnami_services:
  globals:
    helm_chart:
      repo: oci://REGISTRY-HOSTNAME/REPOSITORY-PATH/charts # Updat
e this value.
      chart_pull_secret_ref:
        name: tac-chart-pull
        namespace: default
      container_pull_secret_ref:
        name: tac-container-pull
        namespace: default
```

        2. Update Tanzu Application Platform by running:

```
tanzu package installed update tap -p tap.tanzu.vmware.com --value
s-file tap-values.yaml -n tap-install
```

    - **Apply configuration to one specific Bitnami service:**
        1. Add the following to your `tap-values.yaml` file:

```
bitnami_services:
  mysql: # Choose from mysql, postgresql, rabbitmq, redis, mongod
b, and kafka.
    helm_chart:
      repo: oci://REGISTRY-HOSTNAME/REPOSITORY-PATH/charts # Updat
e this value.
      chart_pull_secret_ref:
        name: tac-chart-pull
        namespace: default
      container_pull_secret_ref:
        name: tac-container-pull
        namespace: default
```

        2. Update Tanzu Application Platform by running:

```
tanzu package installed update tap -p tap.tanzu.vmware.com --value
s-file tap-values.yaml -n tap-install
```

3. If your VMware Tanzu Application Catalog instance does not have the default version of a given chart or you want to use a different version, configure the version for the chart by

updating the `helm_chart.version` value for the service. For example:

```
bitnami_services:
  mysql: # Choose from mysql, postgresql, rabbitmq, redis, mongodb, and kafka.
    helm_chart:
      version: VERSION
```

Known issue

As of Tanzu Application Platform v1.5.0 there is a known issue that occurs if you try to configure private registry integration for the Bitnami services after having already created a claim for one or more of the Bitnami services using the default configuration. The issue is that the updated private registry configuration does not appear to take effect. This is due to caching behavior in the system which is not currently accounted for during configuration updates.

Workaround

There is a temporary workaround to this issue, which is to delete the `provider-helm-*` pods in the `crossplane-system` namespace and wait for new pods to come back online after having applied updated registry configuration.

Obtain credentials for VMware Tanzu Application Catalog integration with Bitnami Services

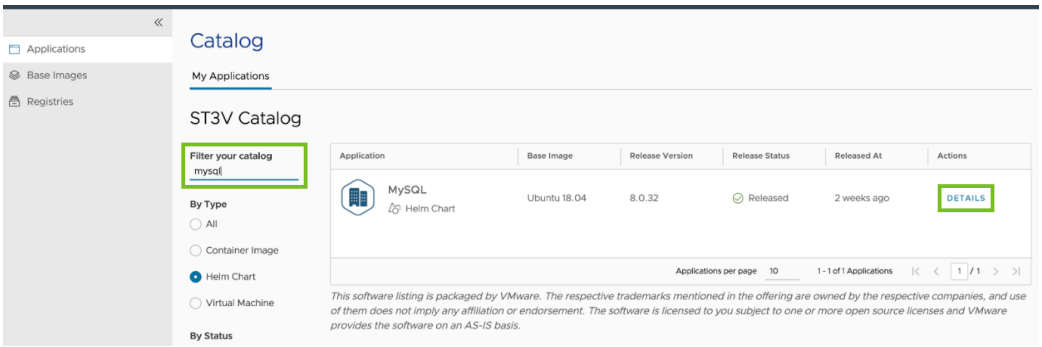
This topic tells you how to obtain credentials for VMware Tanzu Application Catalog to use when following the procedure in Configure private registry and VMware Tanzu Application Catalog integration for Bitnami Services.

Prerequisites

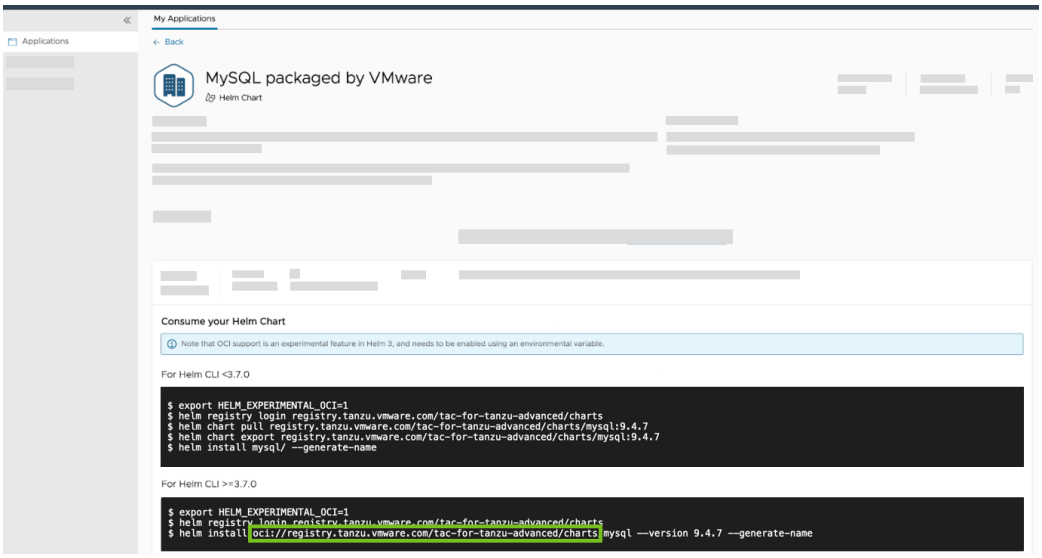
Before obtaining credentials, you must have a VMware Tanzu Application Catalog instance that can create access tokens from within the VMware Tanzu Application Catalog UI.

Obtain the Helm chart repository for VMware Tanzu Application Catalog

1. In VMware Tanzu Application Catalog, navigate to the **Applications** side tab.
2. Under **Filter your catalog**, search for Helm Charts in your catalog, for example, `MySQL`, and click **Details** for one of the charts you found:

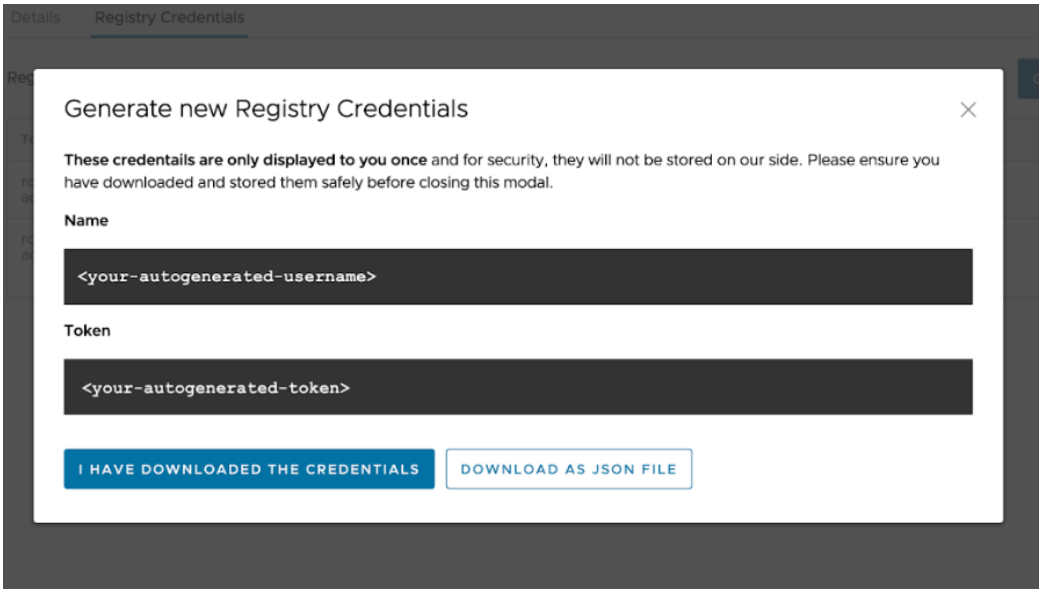


3. Take note of the repository shown under **For Helm CLI >= 3.7.0**. You must include the `oci://` prefix as shown on the page:



Obtain pull credentials for VMware Tanzu Application Catalog

1. In VMware Tanzu Application Catalog, navigate to the **Registries** side tab:
2. Click on the registry that contains your Helm Charts and container images and record the **Registry URL**.
3. Click the **Registry Credentials** tab.
4. Click **Generate New Credentials**.
5. Record the user name and token you are presented with.



You can now take the repository, user name, and token and use it to configure VMware Tanzu Application Catalog integration with the Bitnami services by following the steps in Configure Private Registry and VMware Tanzu Application Catalog Integration for Bitnami Services.

Upgrading to Tanzu Kubernetes releases v1.26 or later

This topic describes how to update your existing Bitnami Services service instances if you upgraded to Tanzu Kubernetes releases v1.26 and later.

Tanzu Kubernetes releases v1.26 and later enforces a restricted Pod Security Standard (PSS) for all pods running on the cluster. This change affects your running services.

New services claimed on Tanzu Application Platform v1.7 and later run with no issues in a restricted PSS. Existing services claimed on Tanzu Application Platform v1.6 will fail to start. To resolve the issue for existing instances, you must update CompositionRevision references for any existing Bitnami Services service instances.

Update existing services

To repair your existing services, upgrade their corresponding managed resources to the latest composition revision:

1. Find the managed resource associated with your claim by running:

   ```
   kubectl get classclaim CLASS-CLAIM-NAME -n CLASS-CLAIM-NAMESPACE -ojsonpath="{.
   status.provisionedResourceRef}"
   ```

   Where:

   - `CLASS-CLAIM-NAME` is the name of your claim.
   - `CLASS-CLAIM-NAMESPACE` is the namespace your claim is in.

   Example output for a MongoDB claim:

   ```
   {"apiVersion":"bitnami.database.tanzu.vmware.com/v1alpha1","kind":"XMongoDBInst
   ance","name":"mongodb-zfjr5"}
   ```

2. Find the newest composition revision for your resource type by running:

   ```
   kubectl get compositionrevisions
   ```

   Example output:

   ```
   NAME                                                          REVISION   XR-
   KIND               XR-APIVERSION                              AGE
   ...
   xmongodbinstances.bitnami.database.tanzu.vmware.com-734d138   4          XMo
   ngoDBInstance      bitnami.database.tanzu.vmware.com/v1alpha1 3h4m
   xmongodbinstances.bitnami.database.tanzu.vmware.com-889eaeb   1          XMo
   ngoDBInstance      bitnami.database.tanzu.vmware.com/v1alpha1 3h29m
   xmongodbinstances.bitnami.database.tanzu.vmware.com-d869e8c   2          XMo
   ngoDBInstance      bitnami.database.tanzu.vmware.com/v1alpha1 3h29m
   xmongodbinstances.bitnami.database.tanzu.vmware.com-f1f3fe9   3          XMo
   ngoDBInstance      bitnami.database.tanzu.vmware.com/v1alpha1 3h5m
   ...
   ```

   Record the name of the highest revision. In the above output, this is revision 4 (`xmongodbinstances.bitnami.database.tanzu.vmware.com-734d138`).

3. Open your managed resource for editing by running:

   ```
   kubectl edit RESOURCE-API RESOURCE-NAME
   ```

   Where:

   - `RESOURCE-API` is in the format `KIND.APIVERSION` using the `kind` and `apiVersion` from the output of the `kubectl get classclaim` command earlier. `APIVERSION` is the part of `apiVersion` before the `/`, for example, `bitnami.database.tanzu.vmware.com`.

- `RESOURCE-NAME` is the value of `name` from the output of the `kubectl get classclaim` command earlier.

For example:

```
$ kubectl edit xmongodbinstance.bitnami.database.tanzu.vmware.com mongodb-zfjr5
```

4. Change the resource `compositionRevisionRef` to point to the new composition revision. For example:

```
apiVersion: bitnami.database.tanzu.vmware.com/v1alpha1
kind: XMongoDBInstance
metadata:
  # ...
spec:
  compositionRef:
    name: xmongodbinstances.bitnami.database.tanzu.vmware.com
  compositionRevisionRef:
    name: xmongodbinstances.bitnami.database.tanzu.vmware.com-734d138
```

5. Save, and close your editor.
6. Verify that the resource is ready by running:

```
kubectl get RESOURCE-API RESOURCE-NAME
```

For example:

```
$ kubectl get xmongodbinstance.bitnami.database.tanzu.vmware.com mongodb-zfjr5

NAME            SYNCED   READY   COMPOSITION
AGE
mongodb-zfjr5   True     True    xmongodbinstance.bitnami.database.tanzu.vmwar
e.com   3h24m
```

Troubleshoot Bitnami Services

This topic explains how you troubleshoot issues related to Bitnami Services on Tanzu Application Platform (commonly known as TAP).

Private registry or VMware Tanzu Application Catalog configuration does not take effect

Symptom:

If you configure private registry integration for the Bitnami services after creating a claim for a Bitnami service using the default configuration, the updated private registry configuration does not appear to take effect.

Cause:

This is due to caching behavior in the system that is not accounted for during configuration updates.

Solution:

Delete the `provider-helm-*` pods in the `crossplane-system` namespace and wait for new pods to come back online after having applied the updated registry configuration.

Services aren't starting after upgrading to Tanzu Kubernetes releases v1.26

Symptom:

After upgrading to Tanzu Kubernetes releases v1.26, Bitnami services are not starting. When you inspect a `Statefulset` or `Replicaset` associated with the service, you see an error message about an issue with the Pod Security Standard for the cluster:

```
Error creating: pods "xxx" is forbidden: violates PodSecurity "restricted:latest": ...
```

Cause:

Tanzu Kubernetes releases v1.26 and later enforces a `restricted` Pod Security Standard. This prevents services created with Tanzu Application Platform v1.6 or earlier from starting.

Solution:

Follow the steps in Upgrading to Tanzu Kubernetes releases v1.26 or later.

Bitnami Services reference

This section provides reference documentation for Bitnami Services.

In this section:

- Dependencies
- Package values
- Version matrix

Dependencies for Bitnami Services

Bitnami Services is an integration package, which means that it provides configuration for other Tanzu Application Platform (commonly known as TAP) components. As such, it has a number of dependencies that must be met before you can use it.

The dependencies for Bitnami Services are:

- **Crossplane and the two providers** `provider-helm` **and** `provider-kubernetes`: See Install Crossplane
- **Services Toolkit**: See Install Services Toolkit

These dependencies are met if you install Tanzu Application Platform using the full, iterate, or run profiles.

Package values for Bitnami Services

This topic lists the keys and values that you can use to configure the behavior of the Bitnami Services package. You can apply configuration globally to all services using the `globals` key, or on a per-service basis using the `mysql`, `postgresql`, `rabbitmq`, `redis`, `mongodb`, and `kafka` keys.

If you are applying configuration to Tanzu Application Platform through the use of profiles and the `tap-values.yaml`, all configuration must exist under the `bitnami_services` top-level key.

For example:

```
bitnami_services:
  globals:
    helm_chart:
```

```
      # If you choose to use a custom Helm Chart repo, it's possible you'll also need
to configure specific versions
      # for each Chart as well, see example configuration below for postgresql.
      repo: https://charts.mycompany.example.com
  mysql:
    enabled: false
  postgresql:
    helm_chart:
      version: 12.2.6
    instance_class:
      name: company-redis
      description: My company postgres
  rabbitmq:
    instance_class:
      name: company-redis
      description: My company rabbit
  redis:
    instance_class:
      name: company-redis
      description: My company redis
```

Globals

The following table lists configuration that applies to all services.

KEY	DEFAULT	TYPE	DESCRIPTION
globals.create_clusterroles	`true`	boolean	Optional: Specifies whether to create default ClusterRoles that grant `claim` permissions to all Tanzu Application Platform Application operators.
globals.helm_chart.chart_pull_secret_ref.name	`""`	string	Name of the pull secret. Can be overridden by individual services.
globals.helm_chart.chart_pull_secret_ref.namespace	`""`	string	Namespace of the pull secret. Can be overridden by individual services.
globals.helm_chart.container_pull_secret_ref.name	`""`	string	Name of the secret. Can be overridden by individual services.
globals.helm_chart.container_pull_secret_ref.namespace	`""`	string	Namespace of the secret. Can be overridden by individual services.
globals.helm_chart.repo	`https://charts.bitnami.com/bitnami`	string	Optional: Repository hosting the Helm charts used to provision the instances of all services. Can be overridden by individual services.
globals.shared_namespace	`""`	string	Optional: Name of the namespace that is shared by all provisioned instances of all services. By default, each instance is provisioned in its own dedicated namespace. Cannot be set if `claim_namespace` is configured. Can be overridden by individual services.
globals.claim_namespace	`false`	boolean	Optional: Specifies whether to create the Service resources inside the same namespace as the claim. By default, each instance is provisioned in its own dedicated namespace. Cannot be set to `true` if `shared_namespace` is configured. Can be overridden by individual services.

MySQL

The following table lists configuration that applies to the `mysql` service.

KEY	DEFAULT	TYPE	DESCRIPTION
mysql.defaults.storage_size_gb	`1`	integer	Optional: The amount of storage to give each MySQL instance by default, in Gigabytes.
mysql.enabled	`true`	boolean	Optional: Provide developers an offering for unmanaged MySQL instances.
mysql.helm_chart.repo	`""`	string	Optional: Repository hosting the Helm chart used to provision MySQL instances.
mysql.helm_chart.version	`9.5.0`	string	Optional: Version of the Helm chart used to provision MySQL instances.
mysql.helm_chart.chart_pull_secret_ref.name	`""`	string	Name of the pull secret.
mysql.helm_chart.chart_pull_secret_ref.namespace	`""`	string	Namespace of the pull secret.
mysql.helm_chart.container_pull_secret_ref.name	`""`	string	Name of the secret. Can be overridden by individual services.
mysql.helm_chart.container_pull_secret_ref.namespace	`""`	string	Namespace of the secret. Can be overridden by individual services.
mysql.instance_class.description	`MySQL by Bitnami`	string	Optional: Description of the ClusterInstanceClass that developers use to provision and claim MySQL instances.
mysql.instance_class.name	`mysql-unmanaged`	string	Optional: Name of the ClusterInstanceClass that developers use to provision and claim MySQL instances.
mysql.shared_namespace	`""`	string	Optional: Name of the namespace that is shared by all provisioned MySQL instances. By default, each instance is provisioned in its own dedicated namespace. Cannot be set if `claim_namespace` is configured.
mysql.claim_namespace	`false`	boolean	Optional: Specifies whether to create the MySQL resources inside the same namespace as the claim. By default, each instance is provisioned in its own dedicated namespace. Cannot be set to `true` if `shared_namespace` is configured.

PostgreSQL

The following table lists configuration that applies to the `postgresql` service.

KEY	DEFAULT	TYPE	DESCRIPTION
postgresql.enabled	`true`	boolean	Optional: Provide developers an offering for unmanaged PostgreSQL instances.
postgresql.helm_chart.chart_pull_secret_ref.name	`""`	string	Name of the pull secret.
postgresql.helm_chart.chart_pull_secret_ref.namespace	`""`	string	Namespace of the pull secret.

KEY	DEFAULT	TYPE	DESCRIPTION
postgresql.helm_chart.container_pull_secret_ref.name	""	string	Name of the secret. Can be overridden by individual services.
postgresql.helm_chart.container_pull_secret_ref.namespace	""	string	Namespace of the secret. Can be overridden by individual services.
postgresql.helm_chart.repo	""	string	Optional: Repository hosting the Helm chart used to provision PostgreSQL instances.
postgresql.helm_chart.version	12.2.0	string	Optional: Version of the Helm chart used to provision PostgreSQL instances.
postgresql.instance_class.description	PostgreSQL by Bitnami	string	Optional: Description of the ClusterInstanceClass that developers use to provision and claim PostgreSQL instances.
postgresql.instance_class.name	postgresql-unmanaged	string	Optional: Name of the ClusterInstanceClass that developers use to provision and claim PostgreSQL instances.
postgresql.shared_namespace	""	string	Optional: Name of the namespace that is shared by all provisioned PostgreSQL instances. By default, each instance is provisioned in its own dedicated namespace.
postgresql.claim_namespace	false	boolean	Optional: Specifies whether to create the PostgreSQL resources inside the same namespace as the claim. By default, each instance is provisioned in its own dedicated namespace. Cannot be set to `true` if `shared_namespace` is configured.
postgresql.defaults.storage_size_gb	1	integer	Optional: The amount of storage to give each PostgreSQL instance by default, in Gigabytes.

RabbitMQ

The following table lists configuration that applies to the `rabbitmq` service.

KEY	DEFAULT	TYPE	DESCRIPTION
rabbitmq.enabled	true	boolean	Optional: Provide developers an offering for unmanaged RabbitMQ instances
rabbitmq.helm_chart.container_pull_secret_ref.name	""	string	Name of the secret. Can be overridden by individual services.
rabbitmq.helm_chart.container_pull_secret_ref.namespace	""	string	Namespace of the secret. Can be overridden by individual services.
rabbitmq.helm_chart.repo	""	string	Optional: Repository hosting the Helm chart used to provision RabbitMQ instances.
rabbitmq.helm_chart.version	11.10.0	string	Optional: Version of the Helm chart used to provision RabbitMQ instances.
rabbitmq.helm_chart.chart_pull_secret_ref.name	""	string	Name of the pull secret.
rabbitmq.helm_chart.chart_pull_secret_ref.namespace	""	string	Namespace of the pull secret.

KEY	DEFAULT	TYPE	DESCRIPTION
rabbitmq.instance_class.description	`RabbitMQ by Bitnami`	string	Optional: Description of the ClusterInstanceClass that developers use to provision and claim RabbitMQ instances.
rabbitmq.instance_class.name	`rabbitmq-unmanaged`	string	Optional: Name of the ClusterInstanceClass that developers use to provision and claim RabbitMQ instances.
rabbitmq.shared_namespace	`""`	string	Optional: Name of the namespace that is shared by all provisioned RabbitMQ instances. By default, each instance is provisioned in its own dedicated namespace.
rabbitmq.claim_namespace	`false`	boolean	Optional: Specifies whether to create the RabbitMQ resources inside the same namespace as the claim. By default, each instance is provisioned in its own dedicated namespace. Cannot be set to `true` if `shared_namespace` is configured.
rabbitmq.defaults.replica_count	`1`	integer	Optional: The number of replicas to create for each RabbitMQ instance by default.
rabbitmq.defaults.storage_size_gb	`1`	integer	Optional: The amount of storage to give each RabbitMQ instance by default, in Gigabytes.

Redis

The following table lists configuration that applies to the `redis` service.

KEY	DEFAULT	TYPE	DESCRIPTION
redis.instance_class.description	`Redis by Bitnami`	string	Optional: Description of the ClusterInstanceClass that is used by developers to provision and claim Redis instances.
redis.instance_class.name	`redis-unmanaged`	string	Optional: Name of the ClusterInstanceClass that is used by developers to provision and claim Redis instances.
redis.shared_namespace	`""`	string	Optional: Name of the namespace that is shared by all provisioned Redis instances. By default, each instance is provisioned in its own dedicated namespace.
redis.claim_namespace	`false`	boolean	Optional: Specifies whether to create the Redis resources inside the same namespace as the claim. By default, each instance is provisioned in its own dedicated namespace. Cannot be set to `true` if `shared_namespace` is configured.
redis.defaults.storage_size_gb	`1`	integer	Optional: The amount of storage to give each Redis instance by default, in Gigabytes.
redis.enabled	`true`	boolean	Optional: Provide developers an offering for unmanaged Redis instances.
redis.helm_chart.chart_pull_secret_ref.name	`""`	string	Name of the pull secret.
redis.helm_chart.chart_pull_secret_ref.namespace	`""`	string	Namespace of the pull secret.
redis.helm_chart.container_pull_secret_ref.name	`""`	string	Name of the secret. Can be overridden by individual services.
redis.helm_chart.container_pull_secret_ref.namespace	`""`	string	Namespace of the secret. Can be overridden by individual services.

KEY	DEFAULT	TYPE	DESCRIPTION
redis.helm_chart.repo	""	string	Optional: Repository hosting the Helm chart used to provision Redis instances.
redis.helm_chart.version	17.8.0	string	Optional: Version of the Helm chart used to provision Redis instances.

MongoDB

The following table lists configuration that applies to the `mongodb` service.

KEY	DEFAULT	TYPE	DESCRIPTION
mongodb.instance_class.description	MongoDB by Bitnami	string	Optional: Description of the ClusterInstanceClass that is used by developers to provision and claim MongoDB instances.
mongodb.instance_class.name	mongodb-unmanaged	string	Optional: Name of the ClusterInstanceClass that is used by developers to provision and claim MongoDB instances.
mongodb.shared_namespace	""	string	Optional: Name of the namespace that is shared by all provisioned MongoDB instances. By default, each instance is provisioned in its own dedicated namespace. Cannot be set if `claim_namespace` is configured.
mongodb.claim_namespace	false	boolean	Optional: Specifies whether to create the MongoDB resources inside the same namespace as the claim. By default, each instance is provisioned in its own dedicated namespace. Cannot be set to `true` if `shared_namespace` is configured.
mongodb.defaults.storage_size_gb	1	integer	Optional: The amount of storage in Gigabytes to give each MongoDB instance by default.
mongodb.enabled	true	boolean	Optional: Provide developers an offering for unmanaged MongoDB instances.
mongodb.helm_chart.chart_pull_secret_ref.name	""	string	Name of the pull secret.
mongodb.helm_chart.chart_pull_secret_ref.namespace	""	string	Namespace of the pull secret.
mongodb.helm_chart.container_pull_secret_ref.name	""	string	Name of the secret. Can be overridden by individual services.
mongodb.helm_chart.container_pull_secret_ref.namespace	""	string	Namespace of the secret. Can be overridden by individual services.
mongodb.helm_chart.repo	""	string	Optional: Repository hosting the Helm chart used to provision MongoDB instances.
mongodb.helm_chart.version	13.13.1	string	Optional: Version of the Helm chart used to provision MongoDB instances.

Kafka

The following table lists configuration that applies to the `kafka` service.

KEY	DEFAULT	TYPE	DESCRIPTION
kafka.instance_class.description	`Kafka by Bitnami`	string	Optional: Description of the ClusterInstanceClass that is used by developers to provision and claim Kafka instances.
kafka.instance_class.name	`kafka-unmanaged`	string	Optional: Name of the ClusterInstanceClass that is used by developers to provision and claim Kafka instances.
kafka.shared_namespace	`""`	string	Optional: Name of the namespace that is shared by all provisioned Kafka instances. By default, each instance is provisioned in its own dedicated namespace. Cannot be set if `claim_namespace` is configured.
kafka.claim_namespace	`false`	boolean	Optional: Specifies whether to create the Kafka resources inside the same namespace as the claim. By default, each instance is provisioned in its own dedicated namespace. Cannot be set to `true` if `shared_namespace` is configured.
kafka.defaults.storage_size_gb	`1`	integer	Optional: The amount of storage in Gigabytes to give each Kafka instance by default.
kafka.enabled	`true`	boolean	Optional: Provide developers an offering for unmanaged Kafka instances.
kafka.helm_chart.chart_pull_secret_ref.name	`""`	string	Name of the pull secret.
kafka.helm_chart.chart_pull_secret_ref.namespace	`""`	string	Namespace of the pull secret.
kafka.helm_chart.container_pull_secret_ref.name	`""`	string	Name of the secret. Can be overridden by individual services.
kafka.helm_chart.container_pull_secret_ref.namespace	`""`	string	Namespace of the secret. Can be overridden by individual services.
kafka.helm_chart.repo	`""`	string	Optional: Repository hosting the Helm chart used to provision Kafka instances.
kafka.helm_chart.version	`22.0.0`	string	Optional: Version of the Helm chart used to provision Kafka instances.

Version matrix for Bitnami Services

This topic provides you with a version matrix for the Bitnami Services package and its open source components in Tanzu Application Platform v1.9 (commonly known as TAP).

To view this information for another Tanzu Application Platform version, select the version from the drop-down menu at the top of this page.

The following table has the component versions for the Bitnami Services package.

Component	Version
Bitnami Services package	0.5.0
MySQL Chart	9.5.0
PostgreSQL Chart	12.2.0
RabbitMQ Chart	11.10.0
Redis Chart	17.8.0

Component	Version
MongoDB Chart	13.13.1
Kafka Chart	22.0.0

Note

Tanzu Application Platform patch releases are only added to the table when there is a change to one or more of the other versions in the table. Otherwise, the corresponding versions remain the same for each Tanzu Application Platform patch release.

Overview of Cartographer Conventions

This topic describes an overview of Cartographer Conventions and how you can use it with Tanzu Application Platform.

Overview

Cartographer Conventions provides a means for operators to express their knowledge about how applications can run on Kubernetes as a convention. Cartographer Conventions supports defining and applying conventions to pods. It applies these opinions to fleets of developer workloads as they are deployed to the platform, saving operator and developer time.

The service is composed of two components

- **convention controller:** The convention service's convention controller provides the metadata to the convention server and executes the updates to a PodTemplateSpec in accordance with convention server's requests.
- **convention server:** The convention server receives and evaluates metadata associated with a workload and requests updates to the PodTemplateSpec associated with that workload. You can have one or more convention servers for a single controller instance.

About applying conventions

The convention server uses criteria defined in the convention to discover whether the configuration of a workload must change. The server receives the OCI metadata from the convention controller. If the metadata meets the criteria defined by the convention server, the conventions are applied. A convention can apply to all workloads regardless of metadata.

Applying conventions by using image metadata

You can define conventions to target workloads by using properties of their OCI metadata.

Conventions can use this information to only apply changes to the configuration of workloads when they match specific criteria. Such as, Spring Boot or .Net apps, or Spring Boot v2.3+. Targeted conventions can ensure that uniformity across specific workload types deployed on the cluster.

You can use all the metadata details of an image when evaluating workloads. To see the metadata details, use the Docker CLI command:

```
docker image inspect IMAGE`.
```

Note

Depending on how the image was built, metadata might not be available to reliably identify the image type and match the criteria for a convention server. Images built with Cloud Native Buildpacks reliably include rich descriptive metadata. Images built by some other process might not include the same metadata.

Applying conventions without using image metadata

Conventions can apply to workloads without targeting build service metadata. Examples of possible uses of this type of convention include:

- appending a logging or metrics sidecar,
- adding environment variables, or
- adding cached volumes.

These kinds of conventions ensure that infrastructure uniformity exists across workloads deployed on the cluster while reducing developer toil.

Important

Adding a sidecar alone does not make the log or metrics collection work. This requires having collector agents deployed and accessible from the Kubernetes cluster, and configuring required access by using role-based access control (RBAC) policy.

Note

Depending on how the image was built, metadata might not be available to reliably identify the image type and match the criteria for a convention server. Images built with Cloud Native Buildpacks reliably include rich descriptive metadata. Images built by some other process might not include the same metadata.

Applying conventions without using image metadata

Conventions can apply to workloads without targeting build service metadata. Examples of possible uses of this type of convention include:

- appending a logging or metrics sidecar,
- adding environment variables, or
- adding cached volumes.

These kinds of conventions ensure that infrastructure uniformity exists across workloads deployed on the cluster while reducing developer toil.

Important

Adding a sidecar alone does not make the log or metrics collection work. This requires having collector agents deployed and accessible from the Kubernetes cluster, and configuring required access by using role-based access control (RBAC) policy.

Install Cartographer Conventions

This topic tells you how to install Cartographer Conventions from the Tanzu Application Platform (commonly known as TAP) package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install Source Controller. For more information about profiles, see Components and installation profiles.

Prerequisites

Before installing Source Controller:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- Install cert-manager on the cluster. For more information, see Install cert-manager.

Install

To install Source Controller:

1. List version information for the package by running:

```
tanzu package available list cartographer.conventions.apps.tanzu.vmware.com --n
amespace tap-install
```

   For example:

```
$ tanzu package available list cartographer.conventions.apps.tanzu.vmware.com -
-namespace tap-install
- Retrieving package versions for cartographer.conventions.apps.tanzu.vmware.co
m...
  NAME                                            VERSION        RELEASED-AT
  cartographer.conventions.apps.tanzu.vmware.com  0.8.0-build.2  2024-02-27 10:
22:43 -0500 EST
```

2. (Optional) Gather the values schema:

```
tanzu package available get cartographer.conventions.apps.tanzu.vmware.com/VERS
ION-NUMBER --values-schema --namespace tap-install
```

   Where `VERSION-NUMBER` is the version of the package listed in step 1 above.

   For example:

```
tanzu package available get cartographer.conventions.apps.tanzu.vmware.com/0.8.
0-build.2 --values-schema --namespace tap-install

  KEY               DEFAULT  TYPE    DESCRIPTION
  aws_iam_role_arn  ""       string  Optional: Arn role that has access to pull
images from ECR container registry
  ca_cert_data      ""       string  Optional: PEM Encoded certificate data for
image registries with private CA.
  resources                          Optional: Cartographer Conventions control
ler resource limit configuration
```

3. (Optional) Create a file named `cartographer-conventions-values.yaml` to override the default installation settings. You can configure the following fields:

   - `ca_cert_data`: Enables Cartographer Conventions controller to connect to image registries that use self-signed or private certificate authorities. If a certificate error `x509: certificate signed by unknown authority` occurs, use this option to trust additional certificate authorities.

     To provide a custom certificate, add the PEM-encoded CA certificate data to `source-controller-values.yaml`. For example:

```
ca_cert_data: |
    -----BEGIN CERTIFICATE-----
    MIICpTCCAYUCBgkqhkiG9w0BBQ0wMzAbBgkqhkiG9w0BBQwwDgQIYg9x6gkCAggA
    ...
    9TlA7A4FFpQqbhAuAVH6KQ8WMZIrVxJSQ03c9lKVkI62wQ==
    -----END CERTIFICATE-----
```

- `aws_iam_role_arn`: Annotates the Cartographer Conventions controller service with an AWS Identity and Access Management (IAM) role. This allows Cartographer Conventions controllerto pull images from Amazon Elastic Container Registry (ECR).

  To add the AWS IAM role Amazon Resource Name (ARN) to the Cartographer Conventions controller service, add the ARN to `cartographer-conventions-values.yaml`. For example:

  ```
  aws_iam_role_arn: "eks.amazonaws.com/role-arn: arn:aws:iam::112233445566:
  role/cartographer-conventions-controller-manager"
  ```

- `resources`: Allows updating the default resource configuration for the Cartographer Conventions controller. By default Cartographer Convention controller resource configuration is set as following:

  ```
  resources:
   limits:
     cpu: 100m
     memory: 512Mi
   requests:
     cpu: 100m
     memory: 20Mi
  ```

  To update the controller's default resource configuration, add the desired configuration to `cartographer-conventions-values.yaml`. For example:

  ```
  resources:
    limits:
       cpu: 100m
       memory: 1Gi
  ```

4. Install the package by running:

   ```
   tanzu package install cartographer-conventions \
     --package cartographer.conventions.apps.tanzu.vmware.com \
     --version VERSION-NUMBER \
     --namespace tap-install \
     --values-file VALUES-FILE
   ```

   Where:

   - `VERSION-NUMBER` is the version of the package listed in step 1 above.
   - `VALUES-FILE` is the path to the file created in step 3.

   For example:

   ```
   $ tanzu package install cartographer-conventions
       --package cartographer.conventions.apps.tanzu.vmware.com
       --version 0.8.0-build.2
       --namespace tap-install
       --values-file cartogrpaher-conventions-values.yaml

   4:16:45PM: Creating service account 'cartographer-conventions-tap-install-sa'
   4:16:45PM: Creating cluster admin role 'cartographer-conventions-tap-install-cl
   uster-role'
   4:16:45PM: Creating cluster role binding 'cartographer-conventions-tap-install-
   cluster-rolebinding'
   4:16:45PM: Creating secret 'cartographer-conventions-tap-install-values'
   4:16:45PM: Creating overlay secrets
   4:16:45PM: Creating package install resource
   4:16:45PM: Waiting for PackageInstall reconciliation for 'cartographer-conventi
   ons'
   ```

Service                         -    create  -       reconcile  -   -
        | Op:      19 create, 0 delete, 0 update, 0 noop, 0 exists
        | Wait to: 19 reconcile, 0 delete, 0 noop
```

```
        | 8:16:48PM: ---- applying 7 changes [0/19 done] ----
        | ...
        | 8:17:07PM: ok: reconcile deployment/cartographer-conventions-controll
er-manager (apps/v1) namespace: conventions-system
        | 8:17:07PM: ---- applying complete [19/19 done] ----
        | 8:17:07PM: ---- waiting complete [19/19 done] ----
        | Succeeded
4:17:07PM: Deploy succeeded
```

5. Verify the package installation by running:

   ```
   tanzu package installed get cartographer-conventions -n tap-install
   ```

   For example:

   ```
   tanzu package installed get cartographer-conventions -n tap-install

   NAMESPACE:          tap-install
   NAME:               cartographer-conventions
   PACKAGE-NAME:       cartographer.conventions.apps.tanzu.vmware.com
   PACKAGE-VERSION:    0.8.0-build.2
   STATUS:             Reconcile succeeded
   CONDITIONS:         - status: "True"
     type: ReconcileSucceeded
   ```

   Verify that `STATUS` is `Reconcile succeeded`:

   ```
   kubectl get pods -n conventions-system
   ```

   For example:

   ```
   $ kubectl get pods -n source-system
   NAME                                                        READY   STATUS
   RESTARTS   AGE
   cartographer-conventions-controller-manager-6cc74788-2z2v9   1/1     Running
   0          5m6s
   ```

   Verify that `STATUS` is `Running`.

Create conventions with Cartographer Conventions

This topic describes how you can create and deploy custom conventions to the Tanzu Application Platform by using Cartographer Conventions.

Introduction

Tanzu Application Platform helps developers transform their code into containerized workloads with a URL. The Supply Chain Choreographer for Tanzu manages this transformation. For more information, see Supply Chain Choreographer.

Cartographer Conventions is a key component of the supply chain compositions the choreographer calls into action. Cartographer Conventions enables people in operational roles to efficiently apply their expertise. They can specify the runtime best practices, policies, and conventions of their organization to workloads as they are created on the platform. The power of this component becomes evident when the conventions of an organization are applied consistently, at scale, and without hindering the velocity of application developers.

Opinions and policies vary from organization to organization. Cartographer Convention supports the creation of custom conventions to meet the unique operational needs and requirements of an organization.

Before jumping into the details of creating a custom convention, you can view two distinct components of Cartographer Conventions:

- Convention controller
- Convention server

Convention server

The convention server is the component that applies a convention already defined on the server. For a golang example of creating a convention server to add Spring Boot conventions, see spring-convention-server in GitHub. The resource that structures the request body of the request and response from the server is the PodConventionContext.

The `PodConventionContext` is a webhooks.conventions.carto.run/v1alpha1 type that defines the structure used to communicate internally by the webhook convention server. It ***does not exist*** on the Kubernetes API Server.

`PodConventionContext` is a wrapper for two types:

- `PodConventionContextSpec` which acts as a wrapper for a `PodTemplateSpec` and a list of `ImageConfigs` provided in the request body of the server.
- `PodConventionContextStatus` which is a status type used to represent the current status of the context retrieved by the request.

For information about an example `PodConventionContext`, see PodConventionContext in GitHub. For information about a Convention server and the structure of these types, see OpenAPI Spec in GitHub.

How the convention server works

Each convention server can host one or more conventions. The application of each convention by a convention server are controlled conditionally. The conditional criteria governing the application of a convention is customizable and are based on the evaluation of a custom Kubernetes resource called PodIntent. PodIntent is the vehicle by which Cartographer Conventions as a whole delivers its value.

A PodIntent is created, or updated if already existing, when a workload is run by using a Tanzu Application Platform supply chain. The custom resource includes both the PodTemplateSpec and the OCI image metadata associated with a workload. See the Kubernetes documentation. The conditional criteria for a convention are based on any property or value found in the PodTemplateSpec or the Open Containers Initiative (OCI) image metadata available in the PodIntent.

If a convention's criteria are met, the convention server enriches the PodTemplateSpec in the PodIntent. The convention server also updates the `status` section of the PodIntent with the name of the convention that's applied. You can figure out after the fact which conventions were applied to the workload.

To provide flexibility in how conventions are organized, you can deploy multiple convention servers. Each server can contain a convention or set of conventions focused on a specific class of runtime modifications, on a specific language framework, and so on. How the conventions are organized, grouped, and deployed is up to you and the needs of your organization.

Convention servers deployed to the cluster does not take action unless triggered to do so by the second component of Cartographer Conventions, the Convention service's controller.

Convention controller

The convention controller is the orchestrator of one or many convention servers deployed to the cluster. There are resources available on the `conventions.carto.run/v1aplha1` API that allow the controller to carry out its functions. These resources include:

- ClusterPodConvention `ClusterPodConvention` is a resource type that allows the conventions author to register a webhook server with the controller using its `spec.webhook` field.

  ```
  ...
  spec:
    selectorTarget: PodTemplateSpec # optional field with options, defaults to Po
  dTemplateSpec
    selectors: # optional, defaults to match all workloads
    - <metav1.LabelSelector>
    webhook:
      certificate:
        name: sample-cert
        namespace: sample-conventions
      clientConfig:
        <admissionregistrationv1.WebhookClientConfig>
  ```

- PodIntent

  `PodIntent` is a `conventions.carto.run/v1alpha1` resource type that is continuously reconciled and applies decorations to a workload `PodTemplateSpec` exposing the enriched `PodTemplateSpec` on its status. Whenever the status of the `PodIntent` is updated, no side effects are caused on the cluster.

As key types defined on the `conventions.carto.run` API, the ClusterPodConvention`and`PodIntent`resources are both present on the Kubernetes API Server and are queried using`clusterpodconventions.conventions.carto.run`for the former and`podintents.conventions.carto.run` for the later.

How the convention services's controller works

When the Supply Chain Choreographer creates or updates a PodIntent for a workload, the convention controller retrieves the OCI image metadata from the repository containing the workload's images and sets it in the PodIntent.

The convention controller then uses a webhook architecture to pass the PodIntent to each convention server deployed to the cluster. The controller orchestrates the processing of the PodIntent by the convention servers sequentially, based on the `priority` value that's set on the convention server. For more information, see ClusterPodConvention.

After all convention servers are finished processing a PodIntent for a workload, the convention controller updates the PodIntent with the latest version of the PodTemplateSpec and sets `PodIntent.status.conditions[].status=True` where `PodIntent.status.conditions[].type=Ready`. This status change signals the Supply Chain Choreographer that Cartographer Conventions is finished with its work. The status change also executes whatever steps are waiting in the supply chain.

Getting started

With this high-level understanding of Cartographer Conventions components, you can create and deploy a custom convention.

Note

This topic covers developing conventions using GOLANG, but this is done using other languages by following the specifications.

Prerequisites

The following prerequisites must be met before a convention is developed and deployed:

- The Kubernetes CLI tool (kubectl) CLI is installed. For more information, see the Kubernetes documentation.
- Tanzu Application Platform prerequisites are installed. For more information, see Prerequisites
- Tanzu Application Platform components are installed. For more information, see the Installing the Tanzu CLI.
- The default supply chain is installed. Download Supply Chain Security Tools for VMware Tanzu from Tanzu Network.
- Your kubeconfig context is set to the Tanzu Application Platform-enabled cluster:

  ```
  kubectl config use-context CONTEXT_NAME
  ```

- You use GitHub to install the ko CLI. See the google/ko GitHub repository. These instructions use `ko` to build an image. If there is an existing image or build process, `ko` is optional.)

Define convention criteria

The `server.go` file contains the configuration for the server and the logic the server applies when a workload matches the defined criteria. For example, adding a Prometheus sidecar to web applications, or adding a `workload-type=spring-boot` label to any workload that has metadata, indicating it is a Spring Boot app.

Important

For this example, the package `model` defines resource types.

1. The example `server.go` configures the `ConventionHandler` to ingest the webhook requests from the convention controller. See PodConventionContext. Here the handler must only deal with the existing PodTemplateSpec and ImageConfig.

   ```
   ...
   import (
     corev1 "k8s.io/api/core/v1"
   )
   ...
   func ConventionHandler(template *corev1.PodTemplateSpec, images []model.ImageCo
   nfig) ([]string, error) {
      // Create custom conventions
   }
   ...
   ```

   Where:

   - `template` is the predefined `PodTemplateSpec` that the convention edits. For more information about `PodTemplateSpec`, see the Kubernetes documentation.

- `images` are the ImageConfig used as reference to make decisions in the conventions. In this example, the type was created within the `model` package.

2. The example `server.go` also configures the convention server to listen for requests:

```
...
import (
    "context"
    "fmt"
    "log"
    "net/http"
    "os"
    ...
)
...
func main() {
    ctx := context.Background()
    port := os.Getenv("PORT")
    if port == "" {
        port = "9000"
    }
    http.HandleFunc("/", webhook.ServerHandler(convention.ConventionHandler))
    log.Fatal(webhook.NewConventionServer(ctx, fmt.Sprintf(":%s", port)))
}
...
```

Where:

- `PORT` is a possible environment variable, for this example, defined in the Deployment.
- `ServerHandler` is the *handler* function called when any request comes to the server.
- `NewConventionServer` is the function in charge of configuring and creating the *http webhook* server.
- `port` is the calculated port of the server to listen for requests. It must match the Deployment if the `PORT` variable is not defined in it.
- The `path` or pattern (default to `/`) is the convention server's default path. If it is changed, it must be changed in the ClusterPodConvention.

Note

The *Server Handler*, `func ConventionHandler(...)`, and the configure or start web server, `func NewConventionServer(...)`, is defined in the convention controller in the `webhook` package, but you can use a custom one.

3. Creating the *Server Handler*, which handles the request from the convention controller with the PodConventionContext serialized to JSON.

```
package webhook
...
func ServerHandler(conventionHandler func(template *corev1.PodTemplateSpec, ima
ges []model.ImageConfig) ([]string, error)) http.HandlerFunc {
    return func(w http.ResponseWriter, r *http.Request) {
        ...
        // Check request method
        ...
        // Decode the PodConventionContext
        podConventionContext := &model.PodConventionContext{}
```

```
        err = json.Unmarshal(body, &podConventionContext)
        if err != nil {
            w.WriteHeader(http.StatusBadRequest)
            return
        }
        // Validate the PodTemplateSpec and ImageConfig
        ...
        // Apply the conventions
        pts := podConventionContext.Spec.Template.DeepCopy()
        appliedConventions, err := conventionHandler(pts, podConventionContext.
Spec.Images)
        if err != nil {
            w.WriteHeader(http.StatusInternalServerError)
            return
        }
        // Update the applied conventions and status with the new PodTemplateSp
ec
        podConventionContext.Status.AppliedConventions = appliedConventions
        podConventionContext.Status.Template = *pts
        // Return the updated PodConventionContext
        w.Header().Set("Content-Type", "application/json")
        w.WriteHeader(http.StatusOK)
        json.NewEncoder(w).Encode(podConventionContext)
    }
}
...
```

4. Configure and start the web server by defining the `NewConventionServer` function, which starts the server with the defined port and current context. The server uses the `.crt` and `.key` files to handle *TLS* traffic.

```
package webhook
...
// Watch handles the security by certificates.
type certWatcher struct {
    CrtFile string
    KeyFile string

    m       sync.Mutex
    keyPair *tls.Certificate
}
func (w *certWatcher) Load() error {
    // Creates a X509KeyPair from PEM encoded client certificate and private ke
y.
    ...
}
func (w *certWatcher) GetCertificate() *tls.Certificate {
    w.m.Lock()
    defer w.m.Unlock()

    return w.keyPair
}
...
func NewConventionServer(ctx context.Context, addr string) error {
    // Define a health check endpoint to readiness and liveness probes.
    http.HandleFunc("/healthz", func(w http.ResponseWriter, r *http.Request) {
        w.WriteHeader(http.StatusOK)
    })

    if err := watcher.Load(); err != nil {
        return err
    }
    // Defines the server with the TLS configuration.
    server := &http.Server{
        Addr: addr,
```

```
        TLSConfig: &tls.Config{
            GetCertificate: func(_ *tls.ClientHelloInfo) (*tls.Certificate, err
or) {
                cert := watcher.GetCertificate()
                return cert, nil
            },
            PreferServerCipherSuites: true,
            MinVersion:               tls.VersionTLS13,
        },
        BaseContext: func(_ net.Listener) context.Context {
            return ctx
        },
    }
    go func() {
        <-ctx.Done()
        server.Close()
    }()

    return server.ListenAndServeTLS("", "")
}
```

Define the convention behavior

Any property or value within the PodTemplateSpec or OCI image metadata associated with a workload defines the criteria for applying conventions. See PodTemplateSpec in the Kubernetes documentation. The following are a few examples.

Matching criteria by labels or annotations

The `conventions.carto.run/v1alpha1` API allows convention authors to use the `selectorTarget` field which complements the `ClusterPodConvention` matchers to specify whether to consider labels on either one of the following available options:

- PodTemplateSpec

  ```
  ...
  template:
    metadata:
      labels:
        awesome-label: awesome-value
      annotations:
        awesome-annotation: awesome-value
  ...
  ```

- PodIntent

  ```
    ...
    kind: PodIntent
    metadata:
      name: test-pod
      labels:
        environment: production
        ...
  ```

The `selectorTarget` field is configured on the ClusterPodConvention as follows:

```
...
spec:
  selectorTarget: PodIntent # optional, defaults to PodTemplateSpec
  selectors: # optional, defaults to match all workloads
  - <metav1.LabelSelector>
  webhook:
```

```
  certificate:
    name: sample-cert
    namespace: sample-conventions
  clientConfig:
    <admissionregistrationv1.WebhookClientConfig>
```

If you do not provide a value for this optional field while using the `conventions.carto.run/v1alpha1` API, the default value is set to `PodTemplateSpec` without the conventions author explicitly doing so.

Matching criteria by environment variables

When using environment variables to define whether the convention is applicable, it must be present in the PodTemplateSpec, spec, containers, and env to validate the value.

- PodTemplateSpec

  ```
  ...
  template:
    spec:
      containers:
        - name: awesome-container
          env:
  ...
  ```

- Handler

  ```
  package convention
  ...
  func conventionHandler(template *corev1.PodTemplateSpec, images []model.ImageCo
  nfig) ([]string, error) {
      if len(template.Spec.Containers[0].Env) == 0 {
          template.Spec.Containers[0].Env = append(template.Spec.Containers[0].En
  v, corev1.EnvVar{
              Name: "MY_AWESOME_VAR",
              Value: "MY_AWESOME_VALUE",
          })
          return []string{"awesome-envs-convention"}, nil
      }
      return []string{}, nil
      ...
  }
  ```

Matching criteria by image metadata

For each image contained within the PodTemplateSpec, the convention controller fetches the OCI image metadata and known bill of materials (BOMs), providing it to the convention server as ImageConfig. This metadata is introspected to make decisions about how to configure the PodTemplateSpec.

Configure and install the convention server

The `server.yaml` defines the Kubernetes components that enable the convention server in the cluster. The next definitions are within the file.

1. A `namespace` is created for the convention server components and has the required objects to run the server. It's used in the ClusterPodConvention section to indicate to the controller where the server is.

   ```
   ...
   ---
   apiVersion: v1
   ```

```
kind: Namespace
metadata:
  name: awesome-convention
---
...
```

2. (Optional) A certificate manager `Issuer` is created to issue the> certificate needed for TLS communication.

```
...
---
# The following manifests contain a self-signed issuer CR and a certificate CR.
# More document can be found at https://docs.cert-manager.io
apiVersion: cert-manager.io/v1
kind: Issuer
metadata:
  name: awesome-selfsigned-issuer
  namespace: awesome-convention
spec:
  selfSigned: {}
---
...
```

3. (Optional) A self-signed `Certificate` is created.

```
...
---
apiVersion: cert-manager.io/v1
kind: Certificate
metadata:
  name: awesome-webhook-cert
  namespace: awesome-convention
spec:
  subject:
    organizations:
    - vmware
    organizationalUnits:
    - tanzu
  commonName: awesome-webhook.awesome-convention.svc
  dnsNames:
  - awesome-webhook.awesome-convention.svc
  - awesome-webhook.awesome-convention.svc.cluster.local
  issuerRef:
    kind: Issuer
    name: awesome-selfsigned-issuer
  secretName: awesome-webhook-cert
  revisionHistoryLimit: 10
---
...
```

4. A Kubernetes `Deployment` is created to run the webhook from. The Service uses the container port defined by the `Deployment` to expose the server.

```
...
---
apiVersion: apps/v1
kind: Deployment
metadata:
  name: awesome-webhook
  namespace: awesome-convention
spec:
  replicas: 1
  selector:
    matchLabels:
```

```
    app: awesome-webhook
  template:
    metadata:
      labels:
        app: awesome-webhook
    spec:
      containers:
      - name: webhook
        # Set the prebuilt image of the convention or use ko to build an image
from code.
        # see https://github.com/google/ko
        image: ko://awesome-repo/awesome-user/awesome-convention
      env:
      - name: PORT
        value: "8443"
      ports:
      - containerPort: 8443
        name: webhook
      livenessProbe:
        httpGet:
          scheme: HTTPS
          port: webhook
          path: /healthz
      readinessProbe:
        httpGet:
          scheme: HTTPS
          port: webhook
          path: /healthz
      volumeMounts:
      - name: certs
        mountPath: /config/certs
        readOnly: true
    volumes:
    - name: certs
      secret:
        defaultMode: 420
        secretName: awesome-webhook-cert
---
...
```

5. A Kubernetes `Service` to expose the convention deployment is created. For this example, the exposed port is the default `443`. If you change the port, the ClusterPodConvention must be updated.

```
...
---
apiVersion: v1
kind: Service
metadata:
  name: awesome-webhook
  namespace: awesome-convention
  labels:
    app: awesome-webhook
spec:
  selector:
    app: awesome-webhook
  ports:
    - protocol: TCP
      port: 443
      targetPort: webhook
---
...
```

6. The ClusterPodConvention adds the convention to the cluster to make it available for the convention controller:

Important

The `annotations` block is only needed if you use a self-signed certificate. See the cert-manager documentation.

```
...
---
apiVersion: conventions.carto.run/v1alpha1
kind: ClusterPodConvention
metadata:
  name: awesome-convention
  annotations:
    conventions.carto.run/inject-ca-from: "awesome-convention/awesome-webhook-c
ert"
spec:
  webhook:
    clientConfig:
      service:
        name: awesome-webhook
        namespace: awesome-convention
        # path: "/" # default
        # port: 443 # default
```

Deploy a convention server

To deploy a convention server:

1. Build and install the convention.
    - To build and deploy the convention, use the ko tool on GitHub. It compiles your Go code into a Docker image and pushes it to the registry `KO_DOCKER_REGISTRY`.

      ```
      ko apply -f dist/server.yaml
      ```

    - If a different tool builds the image, the configuration is also applied by using either kubectl or `kapp`, setting the correct image in the Deployment descriptor.

      kubectl

      ```
      kubectl apply -f server.yaml
      ```

      kapp

      ```
      kapp deploy -y -a awesome-convention -f server.yaml
      ```

2. Verify the convention server. To verify the status of the convention server, confirm the running convention pods:
    - If the server is running, `kubectl get all -n awesome-convention` returns output such as:

      ```
      NAME                                    READY   STATUS    RESTARTS   A
      GE
      pod/awesome-webhook-1234567890-12345    1/1     Running   0          8
      h

```

Next Steps

Keep Exploring:

- Try to use different matching criteria for the conventions or enhance the supply chain with multiple conventions.

Troubleshoot Cartographer Conventions

This topic describes how you can troubleshoot Cartographer Conventions.

No server in the cluster

Symptoms

- When a `PodIntent` is submitted, no `convention` is applied.

Cause

When there are no `convention servers` (ClusterPodConvention) deployed in the cluster or none of the existing convention servers applied any conventions, the `PodIntent` is not being mutated.

Solution

Deploy a `convention server` (ClusterPodConvention) in the cluster.

Server with wrong certificates configured

Symptoms

- When a `PodIntent` is submitted, the `conventions` are not applied.
- The `convention-controller` logs report an error `failed to get CABundle` as follows:

```
{
"level": "error",
"ts": 1638222343.6839523,
"logger": "controllers.PodIntent.PodIntent.ResolveConventions",
"msg": "failed to get CABundle",
"ClusterPodConvention": "base-convention",
"error": "unable to find valid certificaterequests for certificate \"convention
-template/webhook-certificate\"",
"stacktrace": "reflect.Value.Call\n\treflect/value.go:339\ngithub.com/vmware-la

pkg/internal/controller.(*Controller).Start.func2.2\n\tsigs.k8s.io/controller-r
untime@v0.10.3/pkg/internal/controller/controller.go:227"
```

Cause

`convention server` (ClusterPodConvention) is configured with the wrong certificates. The `convention-controller` cannot figure out the CA Bundle to perform the request to the server.

Solution

Ensure that the `convention server` (ClusterPodConvention) is configured with the correct certificates. To do so, verify the value of annotation `conventions.carto.run/inject-ca-from` which must be set to the used Certificate.

Important

Do not set annotation `conventions.carto.run/inject-ca-from` if no certificate is used.

Server fails when processing a request

Symptoms

- When a `PodIntent` is submitted, the `convention` is not applied.
- The `convention-controller` logs reports `failed to apply convention` error like this.

```
{"level":"error","ts":1638205387.8813763,"logger":"controllers.PodIntent.PodInt

```

- When a `PodIntent` status message is updated with `failed to apply convention from source base-convention: Post "https://webhook.convention-template.svc:443/?timeout=30s": EOF`.

Cause

An unmanaged error occurs in the `convention server` when processing a request.

Solution

1. Inspect the `convention server` logs to identify the cause of the error:
    1. To retrieve the `convention server` logs:

        ```
        kubectl -n convention-template logs deployment/webhook
        ```

        Where:

        - The convention server was deployed as a `Deployment`
        - `webhook` is the name of the convention server `Deployment`.

    - `convention-template` is the namespace where the convention server is deployed.

2. Identify the error and deploy a fixed version of `convention server`.
    - The new deployment is not applied to the existing `PodIntent`s. It is only applied to the new `PodIntent`s.
    - To apply new deployment to exiting `PodIntent`, you must update the `PodIntent`, so the reconciler applies if it matches the criteria.

Connection refused due to unsecured connection

Symptoms

- When a `PodIntent` is submitted, the `convention` is not applied.
- The `convention-controller` logs reports a connection refused error as follows:

```
{"level":"error","ts":1638202791.5734537,"logger":"controllers.PodIntent.PodInt
ent.ApplyConventions","msg":"failed to apply convention","Convention":{"Nam
e":"base-convention","Selectors":null,"Priority":"Normal","ClientConfig":{"serv
ice":{"namespace":"convention-template","name":"webhook","port":443},"caBundl
e":"..."}},"error":"Post \"https://webhook.convention-template.svc:443/?timeout

```

- The `convention server` fails to start due to `server gave HTTP response to HTTPS client`:
    - When checking the `convention server` events by running:

```
kubectl -n convention-template describe pod webhook-594d75d69b-4w4s8
```

    Where:

    - The convention server was deployed as a `Deployment`
    - `webhook-594d75d69b-4w4s8` is the name of the `convention server` Pod.
    - `convention-template` is the namespace where the convention server is deployed.

    For example:

```
Name:         webhook-594d75d69b-4w4s8
Namespace:    convention-template
```

```
...

Warning  BackOff    4m22s (x32 over 11m)   kubelet            Back-off restartin
g failed container
```

Cause

When a `convention server` is provided without using Transport Layer Security (TLS) but the `Deployment` is configured to use TLS, Kubernetes fails to deploy the `Pod` because of the `liveness probe`.

Solution

1. Deploy a `convention server` with TLS enabled.
2. Create `ClusterPodConvention` resource for the convention server with annotation `conventions.carto.run/inject-ca-from` as a pointer to the deployed `Certificate` resource.

Self-signed certificate authority (CA) not propagated to the Convention Service

Symptoms

The self-signed certificate authority (CA) for a registry is not propagated to the Convention Service.

Cause

When you provide the self-signed certificate authority (CA) for a registry through `convention-controller.ca_cert_data`, it cannot be propagated to the Convention Service.

Solution

Define the CA by using the available `.shared.ca_cert_data` top-level key to supply the CA to the Convention Service.

No imagePullSecrets configured

Symptoms

When a PodIntent is submitted:

- No convention is applied.
- You see an `unauthorized to access repository` or `fetching metadata for Images failed` error when you inspect the workload.

Cause

The errors are seen when a `workload` is created in a developer namespace where `imagePullSecrets` are not defined on the `default` serviceAccount or on the preferred serviceAccount.

Solution

Add the `imagePullSecrets` name to the default serviceAccount or the preferred serviceAccount.

For example:

```
kind: ServiceAccount
metadata:
  name: default
  namespace: my-workload-namespace
imagePullSecrets:
  - name: registry-credentials # ensure this secret is defined
secrets:
- name: registry-credentials
```

`OOMKilled` convention controller

Symptoms

While processing workloads with large SBOM, the Cartographer Convention controller manager pod can fail with the status `CrashLoopBackOff` or `OOMKilled`.

To work around this problem you can increase the memory limit to `512Mi` to fix the pod crash.

For example:

```
NAME                                                    READY   STATUS
RESTARTS          AGE
cartographer-conventions-controller-manager-ff4cdf59d-5nzl5   0/1     CrashLoopBackOff
1292 (109s ago)   5d3h
```

The following is an example controller pod status:

```
containerStatuses:
  - containerID: containerd://b7b7159a9e00ef726944d642a1b649108bba610b34d8d10f9b5270ea
25d3db94
    image: sha256:9827e8e5b30d47c9373a1907dc5e7e15a76d2a4581e803eb6f2cb24e3a9ea62e
    imageID: my.image.registry.com/tanzu-application-platform/tap-packages@sha256:3cd1
ae92f534ff935fbaf992b8308aa3dac3d1b6cbc8cf8a856451c8c92540f66
    lastState:
      terminated:
        containerID: containerd://b7b7159a9e00ef726944d642a1b649108bba610b34d8d10f9b52
70ea25d3db94
        exitCode: 137
        finishedAt: "2023-11-06T21:02:56Z"
        reason: OOMKilled
```

```
        startedAt: "2023-11-06T21:02:10Z"
    name: manager
```

Cause

This error usually occurs when a `workload` image, built by the supply chain, contains a large SBOM. The default resource limit set during installation might not be large enough to process the pod conventions which can lead to the controller pod crashing.

Solution

To increase the Cartographer Convention controller manager memory limit via the TAP values.yaml. For example:

- To increase the memory limit for convention server, see Increase the memory limit for convention server.
- To increase the memory limit for convention webhook servers, such as app-live-view-conventions, spring-boot-webhook, and developer-conventions/webhook, see Increase the memory limit for convention webhook servers.

Increase the memory limit for convention server

To increase the memory limit, add the desired resource limit under key `cartographer_conventions` in the TAP value.yaml:

```
cartographer_conventions:
  resource:
    memory: 512Mi
```

1. Update Tanzu Application Platform by running:

   ```
   tanzu package installed update tap -p tap.tanzu.vmware.com -v 1.9.1  --values-f
   ile tap-values.yaml -n tap-install
   ```

For information about the package customization, see Customize your package installation.

Increase the memory limit for convention webhook servers

You might need to increase the memory limit for the following convention webhook servers:

- app-live-view-conventions
- spring-boot-webhook
- developer-conventions/webhook

Use this procedure to increase the memory limit:

1. Create a `Secret` with the following ytt overlay.

   ```
   apiVersion: v1
   kind: Secret
   metadata:
   name: patch-app-live-view-conventions
   namespace: tap-install
   stringData:
   patch-conventions-controller.yaml: |
     #@ load("@ytt:overlay", "overlay")

     #@overlay/match by=overlay.subset({"kind":"Deployment", "metadata":{"name":"a
   ppliveview-webhook", "namespace": "app-live-view-conventions"}})
   ```

```
  ---
  spec:
    template:
      spec:
        containers:
          #@overlay/match by=overlay.subset({"name": "webhook"})
          - name: webhook
            resources:
              limits:
                memory: 512Mi
---
apiVersion: v1
kind: Secret
metadata:
name: patch-spring-boot-conventions
namespace: tap-install
stringData:
patch-conventions-controller.yaml: |
  #@ load("@ytt:overlay", "overlay")

  #@overlay/match by=overlay.subset({"kind":"Deployment", "metadata":{"name":"s
pring-boot-webhook", "namespace": "spring-boot-convention"}})
  ---
  spec:
    template:
      spec:
        containers:
          #@overlay/match by=overlay.subset({"name": "webhook"})
          - name: webhook
            resources:
              limits:
                memory: 512Mi
---
apiVersion: v1
kind: Secret
metadata:
name: patch-developer-conventions
namespace: tap-install
stringData:
patch-conventions-controller.yaml: |
  #@ load("@ytt:overlay", "overlay")

  #@overlay/match by=overlay.subset({"kind":"Deployment", "metadata":{"name":"w
ebhook", "namespace": "developer-conventions"}})
  ---
  spec:
    template:
      spec:
        containers:
          #@overlay/match by=overlay.subset({"name": "webhook"})
          - name: webhook
            resources:
              limits:
                memory: 512Mi
```

2. Update the Tanzu Application Platform values YAML file to include a `package_overlays` field:

```
package_overlays:
- name: appliveview-conventions
secrets:
- name: patch-app-live-view-conventions
- name: spring-boot-conventions
secrets:
- name: patch-spring-boot-conventions
```

```
- name: developer-conventions
secrets:
- name: patch-developer-conventions
```

3. Update Tanzu Application Platform by running:

```
tanzu package installed update tap -p tap.tanzu.vmware.com -v 1.9.1  --values-f
ile tap-values.yaml -n tap-install
```

For information about the package customization, see Customize your package installation.

Convention Service Resources for Cartographer Conventions

This reference topic describes the convention service resources you can use with Cartographer Conventions.

Overview

There are several resources involved in the application of conventions to workloads and these are typically consumed by platform developers and operators rather than by application developers.

- ClusterPodConvention

  The following is an example `conventions.carto.run/v1alpha1` type:

  ```
  ---
  apiVersion: conventions.carto.run/v1alpha1
  kind: ClusterPodConvention
  metadata:
  name: sample
  spec:
  selectorTarget: PodTemplateSpec # optional field with options, defaults to PodT
  emplateSpec
  selectors: # optional, defaults to match all workloads
  - <metav1.LabelSelector>
  webhook:
    certificate:
      name: sample-cert
      namespace: sample-conventions
    clientConfig:
      <admissionregistrationv1.WebhookClientConfig>
  ```

  A `ClusterPodConvention` can target a one or more workloads of different types. You can apply multiple conventions to a single workload. It is at the discretion of the “Conventions Author” how a convention is applied.

  To list out available conventions in your cluster, run the following `kubectl`command

  ```
  $ kubectl get clusterpodconventions.conventions.carto.run

    NAME                     AGE
    appliveview-sample       23h
    developer-conventions    23h
    spring-boot-convention   23h
  ```

- PodIntent

  The following is an example `conventions.carto.run/v1alpha1` resource:

```
apiVersion: conventions.carto.run/v1alpha1
kind: PodIntent
metadata:
name: sample
spec:
imagePullSecrets: <[]corev1.LocalObjectReference> # optional
serviceAccountName: <string> # optional, defaults to 'default'
template:
  <corev1.PodTemplateSpec>
status:
observedGeneration: 1 # reflected from .metadata.generation
conditions:
- <metav1.Condition>
template: # enriched PodTemplateSpec
  <corev1.PodTemplateSpec>
```

To list out available `PodIntent` resources in your cluster, run the following kubectl command

```
# specify relevant namespace
kubectl get podintents.conventions.carto.run -n my-apps

NAME            READY   REASON               AGE
spring-sample   True    ConventionsApplied   8m5s
```

When a`PodIntent` is created, the `PodIntent` reconciler lists all `ClusterPodConventions` resources and applies them serially. To ensure that the consistency of the enriched PodTemplateSpec, the list of `ClusterPodConventions`is sorted alphabetically by name before applying the conventions.

Tip : *You can use strategic naming to control the order in which the conventions are applied.*

After the conventions are applied, the `Ready` status condition on the `PodIntent` resource is used to indicate whether it is applied. A list of all applied conventions is stored under the annotation `conventions.carto.run/applied-conventions`.

There are also a few other resources available to the `Conventions Author` that are not persisted in your cluster, including:

- ImageConfig
- PodConventionContextSpec
- PodConventionContextStatus
- PodConventionContext
- BOM

Collecting Logs from the Controller

A successful deployment of the convention service creates it's resources on the following `conventions-system` namespace:

```
$ kubectl get all -n conventions-system
  NAME                                                              READY   STATUS
RESTARTS   AGE
  ...
  pod/cartographer-conventions-controller-manager-76fd86789f-lzh86   1/1     Running
0          20h

  NAME                                                                 TYPE        CL
USTER-IP     EXTERNAL-IP   PORT(S)    AGE
```

```
  ...
  service/cartographer-conventions-controller-manager-metrics-service   ClusterIP   1
0.0.250.231   <none>        8443/TCP   20h
  service/cartographer-conventions-webhook-service                      ClusterIP   1
0.0.6.254     <none>        443/TCP    20h
  ...

  NAME                                                          READY   UP-TO-DATE   A
VAILABLE   AGE
  ...
  deployment.apps/cartographer-conventions-controller-manager   1/1     1            1
20h

  NAME                                                                    DESIRED   C
URRENT   READY   AGE
  ...
  replicaset.apps/cartographer-conventions-controller-manager-76fd86789f   1         1
1       20h
```

In order to examine logs from the cartographer conventions controller to help identify issues, inspect the cartographer conventions controller manager pod as follows

```
 kubectl -n conventions-system logs -l control-plane=controller-manager
...
{"level":"info","ts":"2023-02-06T20:49:19.850086032Z","logger":"MetricsReconciler","ms

```

Convention Service Resources for Cartographer Conventions

This reference topic describes the convention service resources you can use with Cartographer Conventions.

Overview

There are several resources involved in the application of conventions to workloads and these are typically consumed by platform developers and operators rather than by application developers.

- ClusterPodConvention

  The following is an example `conventions.carto.run/v1alpha1` type:

  ```
  ---
  apiVersion: conventions.carto.run/v1alpha1
  kind: ClusterPodConvention
  metadata:
  name: sample
  ```

```
spec:
selectorTarget: PodTemplateSpec # optional field with options, defaults to PodT
emplateSpec
selectors: # optional, defaults to match all workloads
- <metav1.LabelSelector>
webhook:
  certificate:
    name: sample-cert
    namespace: sample-conventions
  clientConfig:
    <admissionregistrationv1.WebhookClientConfig>
```

A `ClusterPodConvention` can target a one or more workloads of different types. You can apply multiple conventions to a single workload. It is at the discretion of the “Conventions Author” how a convention is applied.

To list out available conventions in your cluster, run the following `kubectl`command

```
$ kubectl get clusterpodconventions.conventions.carto.run

  NAME                     AGE
  appliveview-sample       23h
  developer-conventions    23h
  spring-boot-convention   23h
```

- PodIntent

  The following is an example `conventions.carto.run/v1alpha1` resource:

```
apiVersion: conventions.carto.run/v1alpha1
kind: PodIntent
metadata:
name: sample
spec:
imagePullSecrets: <[]corev1.LocalObjectReference> # optional
serviceAccountName: <string> # optional, defaults to 'default'
template:
  <corev1.PodTemplateSpec>
status:
observedGeneration: 1 # reflected from .metadata.generation
conditions:
- <metav1.Condition>
template: # enriched PodTemplateSpec
  <corev1.PodTemplateSpec>
```

  To list out available `PodIntent` resources in your cluster, run the following kubectl command

```
# specify relevant namespace
kubectl get podintents.conventions.carto.run -n my-apps

NAME            READY   REASON               AGE
spring-sample   True    ConventionsApplied   8m5s
```

  When a`PodIntent` is created, the `PodIntent` reconciler lists all `ClusterPodConventions` resources and applies them serially. To ensure that the consistency of the enriched PodTemplateSpec, the list of `ClusterPodConventions`is sorted alphabetically by name before applying the conventions.

  Tip : *You can use strategic naming to control the order in which the conventions are applied.*

After the conventions are applied, the `Ready` status condition on the `PodIntent` resource is used to indicate whether it is applied. A list of all applied conventions is stored under the annotation `conventions.carto.run/applied-conventions`.

There are also a few other resources available to the `Conventions Author` that are not persisted in your cluster, including:

- ImageConfig
- PodConventionContextSpec
- PodConventionContextStatus
- PodConventionContext
- BOM

Collecting Logs from the Controller

A successful deployment of the convention service creates it's resources on the following `conventions-system` namespace:

```
$ kubectl get all -n conventions-system
  NAME                                                              READY   STATUS
RESTARTS   AGE
  ...
  pod/cartographer-conventions-controller-manager-76fd86789f-lzh86   1/1     Running
0          20h

  NAME                                                                 TYPE        CL
USTER-IP     EXTERNAL-IP   PORT(S)    AGE
  ...
  service/cartographer-conventions-controller-manager-metrics-service   ClusterIP   1
0.0.250.231   <none>        8443/TCP   20h
  service/cartographer-conventions-webhook-service                      ClusterIP   1
0.0.6.254     <none>        443/TCP    20h
  ...

  NAME                                                          READY   UP-TO-DATE   A
VAILABLE   AGE
  ...
  deployment.apps/cartographer-conventions-controller-manager   1/1     1            1
20h

  NAME                                                                    DESIRED   C
URRENT   READY   AGE
  ...
  replicaset.apps/cartographer-conventions-controller-manager-76fd86789f   1         1
1       20h
```

In order to examine logs from the cartographer conventions controller to help identify issues, inspect the cartographer conventions controller manager pod as follows

```
 kubectl -n conventions-system logs -l control-plane=controller-manager
...
{"level":"info","ts":"2023-02-06T20:49:19.855086032Z","logger":"MetricsReconciler","ms

...
```

ImageConfig for Cartographer Conventions

This reference topic describes the ImageConfig object you can use with Cartographer Conventions.

Overview

The image configuration object holds the name of the image, the BOM, and the OCI image configuration with image metadata from the repository.

OCI image configuration contains the metadata from the image repository.

The BOM represents the content of the image and may be zero or more per image.

```
{
  "name": "oci-image-name",
  "boms": [{
      "name": "bom-name",
      "raw": "`a byte array`"
  }],
  "config": {
      {

        }
        ]
    }
  }
}
```

PodConventionContextSpec for Cartographer Conventions

This reference topic describes the `PodConventionContextSpec` you can use with Cartographer Conventions.

Overview

The Pod convention context specification is a wrapper of the PodTemplateSpec and the ImageConfig provided in the request body of the server. It represents the original `PodTemplateSpec`. For more information on `PodTemplateSpec`, see the Kubernetes documentation.

```
{
"template": {
    "metadata": {
        ...
    },
    "spec": {
        ...
    }
},
"imageConfig": {
    ...
  "name": "oci-image-name",
  "config": {
        ...
    }
  }
}
```

PodConventionContextStatus for Cartographer Conventions

This reference topic describes the `PodConventionContextStatus` status type that you can use with Cartographer Conventions.

Overview

The Pod convention context status type is used to represent the current status of the context retrieved by the request. It holds the applied conventions by the server and the modified version of the `PodTemplateSpec`. For more information about `PodTemplateSpec`, see the Kubernetes documentation.

The field `.template` is populated with the enriched PodTemplateSpec. The field `.appliedConventions` is populated with the names of any applied conventions.

```
{
    "template": {
        "metadata": {
            ...
        },
        "spec": {
            ...
        }
    },
    "appliedConventions": [
        "convention-1",
        "convention-2",
        "convention-4"
    ]
}
```

yaml version:

```
---
apiVersion: webhooks.conventions.carto.run/v1alpha1
kind: PodConventionContext
metadata:
  name: sample # the name of the ClusterPodConvention
spec: # the request
  imageConfig:
  template:
    <corev1.PodTemplateSpec>
status: # the response
  appliedConventions: # list of names of conventions applied
  - my-convention
  template:
  spec:
      containers:
      - name : workload
        image: helloworld-go-mod
```

PodConventionContext for Cartographer Conventions

This reference topic describes the `PodConventionContext` that you can use with Cartographer Conventions.

Overview

The Pod convention context is the body of the webhook request and response. The specification is provided by the convention controller and the status is set by the convention server.

The context is a wrapper of the individual object description in an API (TypeMeta), the persistent metadata of a resource (ObjectMeta), the PodConventionContextSpec and the PodConventionContextStatus.

PodConventionContext Objects

In the `PodConventionContext` API resource:

- Object path `.spec.template` field defines the `PodTemplateSpec` to be enriched by conventions. For more information about `PodTemplateSpec`, see the Kubernetes documentation.
- Object path `.spec.imageConfig[]` field defines ImageConfig. Each entry of it is populated with the name of the image (`.spec.imageConfig[].image`) and its OCI metadata (`.spec.imageConfig[].config`). These entries are generated for each image referenced in PodTemplateSpec (`.spec.template`).

The following is an example of a `PodConventionContext` resource request received by the convention server. This resource is generated for a Go language-based application image in GitHub. It is built with Cloud Native Paketo Buildpacks that use Go mod for dependency management.

```
---
apiVersion: webhooks.conventions.carto.run/v1alpha1
kind: PodConventionContext
metadata:
  name: sample # the name of the ClusterPodConvention
spec: # the request
  imageConfig: # one entry per image referenced by the PodTemplateSpec
  - image: sample/go-based-image
    boms:
    - name: cnb-app:.../sbom.cdx.json
      raw: ...
    config:
      entrypoint:
      - "/cnb/process/web"
      domainname: ""
      architecture: "amd64"
      image: "sha256:05b698a4949db54fdb36ea431477867abf51054abd0cbfcfd1bb81cda1842288"
      labels:
        "io.buildpacks.stack.distro.version": "18.04"
        "io.buildpacks.stack.homepage": "https://github.com/paketo-buildpacks/stacks"
        "io.buildpacks.stack.id": "io.buildpacks.stacks.bionic"
        "io.buildpacks.stack.maintainer": "Paketo Buildpacks"
        "io.buildpacks.stack.distro.name": "Ubuntu"
        "io.buildpacks.stack.metadata": `{"app":[{"sha":"sha256:ea4ec23266a3af1204fd64
3de0f3572dd8dbb5697a5ef15bdae844777c19bf8f"}],
        "buildpacks":[{"key":"paketo-buildpac`...,
        "io.buildpacks.build.metadata": `{"bom":[{"name":"go","metadata":{"licenses":
[],"name":"Go","sha256":"7fef8ba6a0786143efcce66b0bbfbfbab02afeef522b4e09833c5b550d7
`...
  template:
    spec:
      containers:
      - name : workload
        image: helloworld-go-mod
```

PodConventionContext Structure

This section introduces more information about the image configuration in `PodConventionContext`. The convention-controller passes this information for each image in good faith. The controller is not the source of the metadata, and there is no guarantee that the information is correct.

The `config` field in the image configuration passes through the OCI Image metadata in GitHub loaded from the registry for the image.

The `boms` field in the image configuration passes through the BOMs of the image. Conventions might parse the BOMs they want to inspect. There is no guarantee that an image contains a BOM or that the BOM is in a certain format.

ClusterPodConvention for Cartographer Conventions

This reference topic describes the `ClusterPodConvention` that you can use with Cartographer Conventions.

Overview

A `ClusterPodConvention` defines how to connect to convention servers. It provides a way to apply a set of conventions to a PodTemplateSpec and artifact metadata. A convention typically focuses on a particular application framework, but might be cross cutting. Applied conventions must be pure functions.

Define conventions

Webhook servers are the only way to define conventions.

```
apiVersion: conventions.carto.run/v1alpha1
kind: ClusterPodConvention
metadata:
  name: base-convention
  annotations:
    conventions.carto.run/inject-ca-from: "convention-template/webhook-cert"
spec:
  selectorTarget: PodTemplateSpec # optional, defaults to PodTemplateSpec; field optio
ns include PodTemplateSpec|PodIntent
  webhook:
    clientConfig:
      service:
        name: webhook
        namespace: convention-template
```

PodIntent for Cartographer Conventions

This reference topic describes `PodIntent` that you can use with Cartographer Conventions.

Overview

The conditional criteria governing the application of a convention is customizable and is based on the evaluation of a custom Kubernetes resource called PodIntent.

`PodIntent` applies conventions to a workload. A PodIntent is created, or updated, when a workload is run by using a Tanzu Application Platform supply chain.

The `.spec.template`'s PodTemplateSpec is enriched by the conventions and exposed as the `.status.template`s PodTemplateSpec. A log of which sources and conventions are applied is captured with the `conventions.carto.run/applied-conventions` annotation on the PodTemplateSpec.

```
apiVersion: conventions.carto.run/v1alpha1
kind: PodIntent
metadata:
  name: sample
spec:
  template:
```

```
    spec:
      containers:
      - name: workload
        image: ubuntu
```

BOM for Cartographer Conventions

This reference topic describes the `BOM` structure you can use with Cartographer Conventions.

Overview

The `BOM` is a type/structure wrapping a Software Bill of Materials (SBOM) describing the software components and their dependencies.

Structure

The structure of the `BOM` is defined as follows:

```
{
  "name": "BOM-NAME",
  "raw": "BYTE-ARRAY"
}
```

Where:

- `BOM-NAME` is the prefix `cnb-sbom:`, followed by the location of the BOM definition in the layer for a cloud native buildpack (CNB) SBOM. For example: `cnb-sbom:/layers/sbom/launch/paketo-buildpacks_executable-jar/sbom.cdx.json`. For a non-CNB SBOM, the value of `name` might change.
- `BYTE-ARRAY`: The content of the BOM. The content may be in any format or encoding. Consult the name to infer how the content is structured.

The convention controller forwards BOMs to the convention servers that it can discover from known sources, including:

- CNB-SBOM

Overview of cert-manager

cert-manager adds certificates and certificate issuers as resource types to Kubernetes clusters. It also helps you to obtain, renew, and use those certificates. For more information about cert-manager, see cert-manager documentation.

The cert-manager package allows you to, optionally, configure a number of `ClusterIssuer`. When you install Tanzu Application Platform by using profiles, a self-signed `ClusterIssuer` is included by default.

As of `cert-manager.tanzu.vmware.com/2.0.0`, versioning departs from the upstream, open-source project's version. The contained cert-manager version is reflected in `Package.spec.includedSoftware`. You can identify the version of cert-manager as follows:

```
kubectl get package -n tap-install cert-manager.tanzu.vmware.com.2.0.0 -ojsonpath='{.s
pec.includedSoftware}' | jq
[
 {
   "description": "X.509 certificate management for Kubernetes and OpenShift",
   "displayName": "cert-manager",
   "version": "1.9.1"
```

```
 }
]
```

Caution

ACME HTTP01 challenges can fail under certain conditions. For more information, see ACME challenges.

Caution

ACME HTTP01 challenges can fail under certain conditions. For more information, see ACME challenges.

Install cert-manager

This topic tells you how to install cert-manager from the Tanzu Application Platform (commonly known as TAP) package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install cert-manager. For more information about profiles, see Components and installation profiles.

The cert-manager package installs cert-manager and, optionally, a number of `ClusterIssuer`.

To install cert-manager with a self-signed `ClusterIssuer` from the Tanzu Application Platform package repository:

1. List version information for the package by running:

```
tanzu package available list cert-manager.tanzu.vmware.com -n tap-install
```

For example:

```
$ tanzu package available list cert-manager.tanzu.vmware.com -n tap-install
/ Retrieving package versions for cert-manager.tanzu.vmware.com...
  NAME                           VERSION           RELEASED-AT
  cert-manager.tanzu.vmware.com  2.0.0             ...
```

2. Discover available configuration for the package by running:

```
tanzu package available get cert-manager.tanzu.vmware.com/2.0.0 --namespace tap
-install --values-schema
```

For example:

```
$ tanzu package available get cert-manager.tanzu.vmware.com/2.0.0 --namespace t
ap-install --values-schema

KEY                    DEFAULT  TYPE    DESCRIPTION
certManager.pspNames   []       array   PodSecurityPolicy names which cert-manag
er is allowed to use
issuers                []       array   The ClusterIssuers to install - default:
[]
namespace                       string  Cert-manager's namespace - also used as
its cluster resource namespace
https://cert-manager.io/v1.9-docs/faq/cluster-resource/
```

3. Create a file named `cert-manager-rbac.yaml` by using the following sample:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: cert-manager-tap-install-cluster-admin-role
rules:
- apiGroups:
  - '*'
  resources:
  - '*'
  verbs:
  - '*'
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: cert-manager-tap-install-cluster-admin-role-binding
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: cert-manager-tap-install-cluster-admin-role
subjects:
- kind: ServiceAccount
  name: cert-manager-tap-install-sa
  namespace: tap-install
---
apiVersion: v1
kind: ServiceAccount
metadata:
  name: cert-manager-tap-install-sa
  namespace: tap-install
```

Apply the configuration:

```
kubectl apply -f cert-manager-rbac.yaml
```

4. Create a file named `cert-manager-install.yaml` by using the following sample:

```
---
apiVersion: packaging.carvel.dev/v1alpha1
kind: PackageInstall
metadata:
  name: cert-manager
  namespace: tap-install
spec:
  serviceAccountName: cert-manager-tap-install-sa
  packageRef:
    refName: cert-manager.tanzu.vmware.com
    versionSelection:
      constraints: "VERSION-NUMBER"
      prereleases: {}
  values:
    - secretRef:
        name: cert-manager-values

---
apiVersion: v1
kind: Secret
metadata:
  name: cert-manager-values
  namespace: tap-install
stringData:
  values.yaml: |
    issuers:
      - name: tap-ingress-selfsigned
        self_signed: {}
```

   Where:

   - `VERSION-NUMBER` is the version of the package listed earlier.
   - Secret `cert-manager-values` contains your configuration of the cert-manager package.

   Apply the configuration:

```
kubectl apply -f cert-manager-install.yaml
```

5. Verify the package installation:

```
tanzu package installed get cert-manager -n tap-install
```

   For example:

```
$ tanzu package installed get cert-manager -n tap-install
/ Retrieving installation details for cert-manager...
NAME:                    cert-manager
PACKAGE-NAME:            cert-manager.tanzu.vmware.com
PACKAGE-VERSION:         2.0.0
STATUS:                  Reconcile succeeded
CONDITIONS:              [{ReconcileSucceeded True}]
USEFUL-ERROR-MESSAGE:
```

   Verify that `STATUS` is `Reconcile succeeded`

6. Verify that cert-manager is up and running:

```
kubectl get deployment -n cert-manager
```

For example:

```
$ kubectl get deployment -n cert-manager
NAME                      READY   UP-TO-DATE   AVAILABLE   AGE
cert-manager              1/1     1            1           5m
cert-manager-cainjector   1/1     1            1           5m
cert-manager-webhook      1/1     1            1           5m
```

7. Verify that the self-signed `ClusterIssuer` is present:

```
kubectl get clusterissuer
```

For example:

```
$ kubectl get clusterissuer
NAME                                READY   AGE
tap-ingress-selfsigned              True    5m
tap-ingress-selfsigned-bootstrap    True    5m
...
```

ACME challenges

cert-manager.io provides APIs for managing certificates on Kubernetes. It is one of the most popular extensions for Kubernetes and has found ubiquitous adoption. Automatic Certificate Management Environment (commonly called ACME) is a protocol for automatically obtaining certificates from certificate authorities. LetsEncrypt has designed and pioneered ACME and is one of the most-popular ACME-style, public CA.

You can use ACME with either an HTTP01 or a DNS01 challenge. In both cases the certificate requester must prove ownership of the domain either by answering a plain HTTP request or by setting a DNS record.

When using cert-manager's `(Cluster)Issuer` with an ACME HTTP01 challenge solver, a `Pod` is run and exposed to the network by using ingress. The `Pod` receives the challenge from the CA and responds. If the challenge is solved successfully, the certificate is issued.

When using cert-manager's `(Cluster)Issuer` with an ACME DNS01 challenge solver, the owner of the domain answers the challenge by setting a `TXT` record under the domain name. If the challenge is solved successfully, the certificate is issued.

Working with DNS01 challenges is harder than with HTTP01 challenges, but can work in situations where HTTP01 can't.

HTTP01 challenges can fail

All of components' images of Tanzu Application Platform are relocated to and pulled from a private registry. This also applies to `cert-manager.tanzu.vmware.com`, including the ACME HTTP01 solver `Pod`'s image.

Due to the design of cert-manager's `(Cluster)Issuer` resources, it is not easy to provide them with credentials to your private registry in a way that works consistently across all namespaces in your cluster.

You can deeply integrate a cluster with a private registry so that image pull secrets don't have to be provided explicitely. This is a common practice with popular cloud-based Kubernetes providers such as GKE, AKS and EKS.

As a result, ACME HTTP01 challenges can fail when your cluster is not deeply integrated with your private registry. In that case VMware recommends the following workarounds:

- (Recommended) Use DNS01 challenges
- Provide your `(Cluster)Issuer` with a `ServiceAccount` by using its pod template so that it can pull from your registry. For example:

```
---
apiVersion: v1
kind: ServiceAccount
metadata:
 name: tap-acme-http01-solver
 namespace: #! ...
imagePullSecrets:
 - registry-credentials

---
apiVersion: cert-manager.io/v1
kind: ClusterIssuer
metadata: #! ...
spec:
 #! ...
 acme:
   solvers:
     - http01:
         ingress:
           podTemplate:
             spec:
               serviceAccountName: tap-acme-http01-solver
```

  The challenge lies in ensuring that the same `ServiceAccount` is available in every namespace that obtains `Certificates` from the `ClusterIssuer`.

Overview of Cloud Native Runtimes

This topic gives you an overview what Cloud Native Runtimes is and how you can use it with Tanzu Application Platform.

Overview

Cloud Native Runtimes is enterprise supported Knative, with Carvel tools for deployment and Contour for networking. Cloud Native Runtimes offers everything Knative does and some extras that make it ideal for cloud-native application development. Cloud Native Runtimes gives developers environmental simplicity and administrators deployment control. It works on any Kubernetes cluster running Kubernetes v1.26 and later.

The Cloud Native Runtimes component documentation consists of the following sections:

- How-to guides give you steps to solve a specific problem.
- Reference give you specific information, such as the Cloud Native Runtimes Compatibility Matrix.

Cloud Native Runtimes uses Knative Serving to provide:

- Automatic pod scaling
- Traffic splitting by code release version

Kubernetes Developers must know:	Cloud Native Runtimes Developers must know:
Pods	Pods

Kubernetes Developers must know:	Cloud Native Runtimes Developers must know:
Deployment and Rollout Progress	Knative Service
Service (networking model)	*n/a*
Ingress	*n/a*
Labels and selectors	*n/a*

Cloud Native Runtimes increases administrator control and support.

Administrators can:

- Manage infrastructure costs with request driven autoscaling
- Test deployments with traffic splitting by code version
- Use Carvel command tools to simplify deployment
- Receive Enterprise Support when they need it

Cloud Native Runtimes works well with these use cases:

- Batch Jobs Processing
- AI and ML
- Application or Network Monitoring
- IOT
- Serverless application architectures

For more information about the software related to Cloud Native Runtimes, see:

- Knative Documentation Home - Knative
- Carvel Tools Suite Documentation Carvel - Home
- Contour Networking Documentation Contour

Cloud Native Runtimes how-to guides

This topic lists the how-to guides available for Cloud Native Runtimes, commonly known as CNRs.

- Configure Cloud Native Runtimes with VMware NSX Advanced Load Balancer
- Cloud Native Runtimes for App Operators
- Configuring observability for Cloud Native Runtimes
- Configure garbage collection for the Knative revisions
- Configure an external DNS for Cloud Native Runtimes
- Customizing Cloud Native Runtimes
- Installing Cloud Native Runtimes with your existing Contour installation
- Cloud Native Runtimes AutoTLS how-to guides
- Configuring Cloud Native Runtimes with Tanzu Service Mesh
- Troubleshooting Cloud Native Runtimes
- Use your existing TLS Certificate for Cloud Native Runtimes

Cloud Native Runtimes for app operators

This topic outlines topics related to installing, updating, and uninstalling Cloud Native Runtimes.

Overview

The following topics are related to app operator tasks:

- Install Cloud Native Runtimes on Tanzu Application Platform without a Profile
- Manage Knative Serving Resources
- Uninstall Cloud Native Runtimes
- Upgrade Cloud Native Runtimes
- Verify Cloud Native Runtimes Installation

Install Cloud Native Runtimes

This topic describes how you can install Cloud Native Runtimes, commonly known as CNRs, from the Tanzu Application Platform package repository.

Note

Use the instructions in this topic if you do not want to use a profile to install packages. The full profile includes Cloud Native Runtimes. For more information about profiles, see Installing the Tanzu Application Platform Package and Profiles.

Prerequisites

Before installing Cloud Native Runtimes:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- Contour is installed in the cluster. You can install Contour from the Tanzu Application package repository. If you have have an existing Contour installation, see Installing Cloud Native Runtimes with an Existing Contour Installation.
- By default, Tanzu Application Platform installs and uses a self-signed certificate authority for issuing TLS certificates to components by using ingress issuer. For more information, see Ingress Certificates. To install Cloud Native Runtimes, you must set the `shared.ingress_domain` or `cnrs.domain_name` property when you set `ingress_issuer`. For example:

  ```
  shared:
  ingress_domain: "foo.bar.com"
  ```

  or

  ```
  cnrs:
  domain_name: "foo.bar.com"
  ```

  If the domain name is not available or not what you want, you can set the domain name to any valid value if no process relies on the domain name resolving to the envoy IP. VMware discourages this for production environments. Another alternative to bypass setting domain name is to deactivate auto-TLS. For more information, see Disabling Automatic TLS Certificate Provisioning.

Install

To install Cloud Native Runtimes:

1. List version information for the package by running:

   ```
   tanzu package available list cnrs.tanzu.vmware.com --namespace tap-install
   ```

   For example:

   ```
   tanzu package available list cnrs.tanzu.vmware.com --namespace tap-install

     NAME                    VERSION  RELEASED-AT
     cnrs.tanzu.vmware.com   2.4.0    2023-06-05 19:00:00 -0500 -05
   ```

2. (Optional) Make changes to the default installation settings:

   1. Gather the values schema.

      ```
      tanzu package available get cnrs.tanzu.vmware.com/2.4.0 --values-schema -
      n tap-install
      ```

   2. Create a `cnr-values.yaml` file by using the following example as a guide to configure Cloud Native Runtimes:

      Note

      For most installations, you can leave the `cnr-values.yaml` empty, and use the default values.

      ```
      ---
      # Configures the domain that Knative Services will use
      domain_name: "mydomain.com"
      ```

      Configuration Notes:

      - If you are using a single-node cluster, such as kind, set the `lite.enable: true` option to lower CPU and memory requests for resources. To deactivate pod disruption budgets on Knative Serving, if high availability is not indispensable in your development environment, you can set `pbd.enable` to `false`.
      - Cloud Native Runtimes reuses the existing `tanzu-system-ingress` Contour installation for external and internal access when installed in the `full` profile. To use a separate Contour installation for system-internal traffic, set `cnrs.contour.internal.namespace` to the namespace of your separate Contour installation.
      - If you install Cloud Native Runtimes with the default value of `true` for the `allow_manual_configmap_update` configuration, you can only update some ConfigMaps manually. To update all ConfigMaps using overlays, change this value to `false`.

3. Install the package by running:

   ```
   tanzu package install cloud-native-runtimes \
     --package cnrs.tanzu.vmware.com \
     --version 2.4.0 \
     --namespace tap-install \
   ```

```
  --values-file cnr-values.yaml \
  --poll-timeout 30m
```

For example:

```
tanzu package install cloud-native-runtimes \
  --package cnrs.tanzu.vmware.com \
  --version 2.4.0 \
  --namespace tap-install \
  --values-file cnr-values.yaml \
  --poll-timeout 30m

| Installing package 'cnrs.tanzu.vmware.com'
| Getting package metadata for 'cnrs.tanzu.vmware.com'
| Creating service account 'cloud-native-runtimes-tap-install-sa'
| Creating cluster admin role 'cloud-native-runtimes-tap-install-cluster-role'
| Creating cluster role binding 'cloud-native-runtimes-tap-install-cluster-role
binding'
- Creating package resource
- Package install status: Reconciling

 Added installed package 'cloud-native-runtimes' in namespace 'tap-install'
```

4. Verify the package install by running:

```
tanzu package installed get cloud-native-runtimes -n tap-install
```

For example:

```
tanzu package installed get cloud-native-runtimes -n tap-install

Retrieving installation details for cloud-native-runtimes...
NAME:                    cloud-native-runtimes
PACKAGE-NAME:            cnrs.tanzu.vmware.com
PACKAGE-VERSION:         2.4.0
STATUS:                  Reconcile succeeded
CONDITIONS:              [{ReconcileSucceeded True  }]
USEFUL-ERROR-MESSAGE:
```

Verify that `STATUS` is `Reconcile succeeded`.

Verify Your Installation

This topic tells you how to verify your Cloud Native Runtimes, commonly known as Cloud Native Runtimes, installation. You can verify that your Cloud Native Runtimes installation was successful by testing Knative Serving.

Prerequisites

1. Create a namespace and environment variable where you want to create Knative services. Run:

Note

This step covers configuring a namespace to run Knative services. If you rely on a SupplyChain to deploy Knative services into your cluster, skip this step because namespace configuration is covered when developer namespaces are set up to use installed packages. For more information, see Set up developer namespaces to use your installed packages. Otherwise, you must

complete the following steps for each namespace where you create Knative services.

```
export WORKLOAD_NAMESPACE='cnr-demo'
kubectl create namespace ${WORKLOAD_NAMESPACE}
```

2. Configure a namespace to use Cloud Native Runtimes. If you relocated images to another registry during Tanzu Application Platform installation, you must grant service accounts that run Knative services using Cloud Native Runtimes access to the image pull secrets. This includes the `default` service account in a namespace, which is created automatically but not associated with any image pull secrets. Without these credentials, attempts to start a service fail with a timeout and the pods report that they are unable to pull the `queue-proxy` image.

    1. Create an image pull secret in the namespace that Knative services run and fill it from the `tap-registry` secret mentioned in Add the Tanzu Application Platform package repository. Run the following commands to create an empty secret and annotate it as a target of the secretgen controller:

        ```
        kubectl create secret generic pull-secret --from-literal=.dockerconfigjso
        n={} --type=kubernetes.io/dockerconfigjson -n ${WORKLOAD_NAMESPACE}

        kubectl annotate secret pull-secret secretgen.carvel.dev/image-pull-secre
        t="" -n ${WORKLOAD_NAMESPACE}
        ```

    2. After you create a `pull-secret` secret in the same namespace as the service account, run the following command to add the secret to the service account:

        ```
        kubectl patch serviceaccount default -p '{"imagePullSecrets": [{"name":
        "pull-secret"}]}' -n ${WORKLOAD_NAMESPACE}
        ```

    3. Verify that a service account is correctly configured by running:

        ```
        kubectl describe serviceaccount default -n ${WORKLOAD_NAMESPACE}
        ```

        For example:

        ```
        kubectl describe sa default -n cnr-demo
        Name:                default
        Namespace:           cnr-demo
        Labels:              <none>
        Annotations:         <none>
        Image pull secrets:  pull-secret
        Mountable secrets:   default-token-xh6p4
        Tokens:              default-token-xh6p4
        Events:              <none>
        ```

        The service account has access to the `pull-secret` image pull secret.

Verify that `STATUS` is `Reconcile succeeded`.

Verify Knative Serving installation

To verify the installation of Knative Serving

1. Create a namespace and environment variable for the test. Run:

    ```
    export WORKLOAD_NAMESPACE='cnr-demo'
    ```

```
kubectl create namespace ${WORKLOAD_NAMESPACE}
```

2. Test Knative Serving by creating a test service. See Verifying Knative Serving.
3. Delete the namespace that you created for the demo. Run:

```
kubectl delete namespaces ${WORKLOAD_NAMESPACE}
unset WORKLOAD_NAMESPACE
```

Verify Knative Serving for Cloud Native Runtimes

This topic tells you how to verify that Knative Serving was installed for Cloud Native Runtimes, commonly known as CNRs.

Overview of verifying Knative Serving

To verify that Knative Serving was installed, create an example Knative service and test it.

The following procedure shows you how to create an example Knative service using the Cloud Native Runtimes sample app, `hello-yeti`. This sample is custom built for Cloud Native Runtimes and is stored in the VMware Harbor registry.

Note

If you do not have access to the Harbor registry, you can use the Hello World - Go sample app in the Knative documentation.

Prerequisites

Before you verify Knative Serving, you must have a namespace where you want to deploy Knative services. This namespace is referred to as `${WORKLOAD_NAMESPACE}` in this tutorial. See Verifying Your Installation.

Test Knative Serving

To create an example Knative service and use it to test Knative Serving:

1. If you are verifying on Tanzu Mission Control or vSphere 7.0 with Tanzu, then create a role binding in the `${WORKLOAD_NAMESPACE}` namespace. Run:

```
kubectl apply -n "${WORKLOAD_NAMESPACE}" -f - << EOF
---
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: ${WORKLOAD_NAMESPACE}-psp
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: cnr-restricted
subjects:
- kind: Group
  name: system:serviceaccounts:${WORKLOAD_NAMESPACE}
EOF
```

2. Deploy the sample app using the `kn` CLI. Run:

```
kn service create hello-yeti -n ${WORKLOAD_NAMESPACE} \
  --image projects.registry.vmware.com/tanzu_serverless/hello-yeti@sha256:17d64
0edc48776cfc604a14fbabf1b4f88443acc580052eef3a753751ee31652 --env TARGET='hello
-yeti'
```

If you are verifying on Tanzu Mission Control or vSphere 7.0 with Tanzu, add `--user 1001` to the command above to run it as a non-root user.

3. Run one of these commands to retrieve the external address for your ingress, depending on your IaaS:

IaaS	Command
Tanzu Kubernetes Grid on AWS	`export EXTERNAL_ADDRESS=$(kubectl get service envoy -n tanzu-system-ingress -ojsonpath="{.status.loadBalancer.ingress[0].hostname}")`
Tanzu Mission Control on AWS	`export EXTERNAL_ADDRESS=$(kubectl get service envoy -n tanzu-system-ingress -ojsonpath="{.status.loadBalancer.ingress[0].hostname}")`
Amazon Elastic Kubernetes Service	`export EXTERNAL_ADDRESS=$(kubectl get service envoy -n tanzu-system-ingress -ojsonpath="{.status.loadBalancer.ingress[0].hostname}")`
vSphere 7.0 on Tanzu	`export EXTERNAL_ADDRESS=$(kubectl get service envoy -n tanzu-system-ingress -ojsonpath="{.status.loadBalancer.ingress[0].ip}")`
Tanzu Kubernetes Grid on vSphere, Azure, or Google Cloud Platform (GCP)	`export EXTERNAL_ADDRESS=$(kubectl get service envoy -n tanzu-system-ingress -ojsonpath="{.status.loadBalancer.ingress[0].ip}")`
Tanzu Kubernetes Grid Integrated Edition	`export EXTERNAL_ADDRESS=$(kubectl get service envoy -n tanzu-system-ingress -ojsonpath="{.status.loadBalancer.ingress[0].ip}")`
Tanzu Mission Control on vSphere	`export EXTERNAL_ADDRESS=$(kubectl get service envoy -n tanzu-system-ingress -ojsonpath="{.status.loadBalancer.ingress[0].ip}")`
Azure Kubernetes Service	`export EXTERNAL_ADDRESS=$(kubectl get service envoy -n tanzu-system-ingress -ojsonpath="{.status.loadBalancer.ingress[0].ip}")`
Google Kubernetes Engine	`export EXTERNAL_ADDRESS=$(kubectl get service envoy -n tanzu-system-ingress -ojsonpath="{.status.loadBalancer.ingress[0].ip}")`
Docker desktop	`export EXTERNAL_ADDRESS='localhost:8080'` And set up port-forwarding in a separate terminal: `kubectl -n tanzu-system-ingress port-forward svc/envoy 8080:80`

4. Connect to the app. Verify the URL for the Knative service.

   Run:

```
kn service list -n ${WORKLOAD_NAMESPACE}
```

   The result is something like this:

```
NAME           URL                                                        LAT
EST               AGE   CONDITIONS   READY   REASON
hello-yeti     https://hello-yeti.${WORKLOAD_NAMESPACE}.svc.cluster.local   hel
lo-yeti-00001     6s    3 OK / 3     True
```

Now, take the host name from the URL and set it in an environment variable `KSERVICE_HOSTNAME` like so:

```
export KSERVICE_HOSTNAME="hello-yeti.${WORKLOAD_NAMESPACE}.svc.cluster.local"
```

Then, connect to the app:

```
curl https://${KSERVICE_HOSTNAME} -k --resolve ${KSERVICE_HOSTNAME}:443:${EXTER
NAL_ADDRESS}
```

Note

If you configured DNS locally by using `/etc/hosts` or externally, the `--resolve` flag is omitted, or you can use a web browser.

On success, you see a reply from our mascot, Carl the Yeti.

Delete the Example Knative Service

After verifying your serving installation, delete the example Knative service and unset the environment variable:

1. Run:

   ```
   kn service delete hello-yeti -n ${WORKLOAD_NAMESPACE}
   unset EXTERNAL_ADDRESS
   unset KSERVICE_HOSTNAME
   ```

2. If you created port forwarding in step 3, terminate that process.

Knative Serving resource management

This topic tells you how to configure the memory and CPU allocation of resources in the `knative-serving` namespace.

Overview

By default, Knative deployments are allocated a predefined amount of CPU and memory. These default allocations support general use cases, but you might adjust the allocations for the following reasons:

- **Performance Optimization**: Customize resource allocations to help fine-tune the load for specific workloads to improve response times and throughput.
- **Cost Efficiency**: Customize resources to avoid over-provisioning or under-provisioning and verify efficient resource use.
- **Improved Stability**: Control resource allocation to prevent any deployment from consuming excessive resources and increase the stability of the entire cluster.

You can tailor the memory and CPU of Knative system controllers by using the Cloud Native Runtimes `resource_management` config option.

Configuring memory and cpu requests and limits for Knative Serving resources

To configure the memory and CPU allocation for the deployments in the `knative-serving` namespace, you must specify the `resource_management` config option on Cloud Native Runtimes. You can only configure the following deployments:

- `activator`
- `autoscaler`
- `autoscaler-hpa`
- `controller`
- `net-certmanager-controller`
- `net-certmanager-webhook`
- `net-contour-controller`
- `webhook`

Example: updating the activator deployment

The following example shows how to adjust the CPU and memory requests and limits by using the `resource_management` option of the Knative `activator` deployment. By default, the `activator` deployment has the following resources:

```
resources:
    requests:
        cpu: 300m
        memory: 60Mi
    limits:
        cpu: 1000m
        memory: 600Mi
```

Specify the following resources to the activator pod:

```
cnrs:
  resource_management:
    - name: NAME
      requests:
        memory: MEMORY
        cpu: CPU
      limits:
        memory: MEMORY
        cpu: CPU
```

Where:

- `NAME` represents the name of the deployment you want to configure.
- `requests` specifies the amount of resources that are allocated to the pods of this deployment:
    - `MEMORY` is how many megabytes of memory you want to request.
    - `CPU` is how many CPU cores, 100 millicpu units, you want to request.
- `limits` sets the maximum amount of resources that the pods can use:
    - `MEMORY` is the limit of how many megabytes of memory that the pods can use.
    - `CPU` is the limit of how many CPU cores, 100 millicpu units, pods can use.

Note

> You can provide any of the resource units supported by Kubernetes as explained in the Kubernetes documentation.

After updating Cloud Native Runtimes, get the deployment information to confirm the `activator` deployment updated:

```
kubectl get deployment activator -n knative-serving -o=jsonpath='{.spec.template.spec.
containers[?(@.name=="activator")].resources}'

{"limits":{"cpu":"1","memory":"1000Mi"},"requests":{"cpu":"100m","memory":"100Mi"}}
```

All fields, such as the request and limits of CPUs, and the memory's request and limits, are optional, except for the deployment's name, causing it to use the default values specified for these deployments.

For example, to change only the limit and the memory's request of the Knative `controller`, you can provide the following configuration to `resource_management`:

```
cnrs:
  resource_management:
    - name: "controller"
      requests:
        memory: "130M"
      limits:
        cpu: "0.5"
```

Upgrading Cloud Native Runtimes

This topic tells you how to upgrade Cloud Native Runtimes for Tanzu to the latest version.

Overview

New versions of Cloud Native Runtimes are available from the Tanzu Application Platform package repository, and you can upgrade as part of upgrading Tanzu Application Platform.

Prerequisites

The following prerequisites are required to upgrade Cloud Native Runtimes:

- An updated Tanzu Application Platform package repository with the version of Cloud Native Runtimes you want to upgrade to. For more information, see Upgrade your Tanzu Application Platform.

Upgrade Cloud Native Runtimes

To upgrade the Cloud Native Runtimes PackageInstall specifically, run:

```
tanzu package installed update cloud-native-runtimes \
  --package cnrs.tanzu.vmware.com \
  --version CNR-VERSION \
  --namespace tap-install \
  --values-file cnr-values.yaml
```

Where `CNR-VERSION` is the latest version of Cloud Native Runtimes available as part of the new Tanzu Application Platform package repository.

Uninstall Cloud Native Runtimes

This topic tells you how to uninstall Cloud Native Runtimes.

Overview

Cloud Native Runtimes is part of the Tanzu Application Platform package repository. For information about uninstalling the entire Tanzu Application Platform package repository, see Uninstall your Tanzu Application Platform by using Tanzu CLI.

Uninstall

To uninstall Cloud Native Runtimes:

1. Delete the installed package:

```
tanzu package installed delete cloud-native-runtimes --namespace tap-install
```

Cloud Native Runtimes AutoTLS how-to guides

This topic lists how-to guides related to AutoTLS.

Overview

This topic describes the scenarios related to autoTLS:

- Setting up AutoTLS
- Deactivate autoTLS
- Deactivate HTTP-to-HTTPS redirection
- Configure Custom Issuer or ClusterIssuer
- Configure wildcard certificates

Securing your web workloads in Cloud Native Runtimes

This topic gives you an overview of securing HTTP connections using TLS certificates in Cloud Native Runtimes, commonly known as CNRs, for VMware Tanzu Application Platform and helps you configure Transport Layer Security (TLS).

Prerequisites

Ensure that you have the Tanzu Application Platform, Cloud Native Runtimes for VMware Tanzu, Contour, and cert-manager installed.

Overview of Cloud Native Runtimes TLS configurations

This section describes default configuration, custom configuration, obtaining, and renewing TLS certificates with Cloud Native Runtimes.

Default TLS configuration in Cloud Native Runtimes

When installing Tanzu Application Platform by using profiles, the cert-manager package is used to facilitate the acquisition, management, and renewal of TLS certificates.

Cloud Native Runtimes automatically acquires TLS certificates for workloads through the shared ingress issuer integrated into the Tanzu Application Platform. The `shared.ingress_issuer` configuration value in Tanzu Application Platform specifies the ingress issuer and it refers to a `cert-manager.io/v1/ClusterIssuer`.

By default, the ingress issuer is self-signed and has limits. For more information about the shared ingress issuer, see the following Tanzu Application Platform documentation:

- Secure exposed ingress endpoints in Tanzu Application Platform

The following TLS features are in Cloud Native Runtimes by default:

- **Auto-TLS**

  Cloud Native Runtimes has the Auto-TLS feature enabled by default. It uses the cert-manager package to automate the process of certificate issuance and management. Auto-TLS takes care of requesting, renewing, and configuring TLS certificates for each domain that you configure in your Cloud Native Runtimes settings.

- **Automatic HTTPS Redirection**

  By default, Cloud Native Runtimes automatically redirects HTTP traffic to HTTPS for secured services. This ensures that all communication with your applications is encrypted and providing a secure experience for your users.

- **One certificate per hostname**

  Cloud Native Runtimes issues a unique certificate for each host name associated with a Knative Service.

Custom TLS configuration in Cloud Native Runtimes

While the default ingress issuer is suitable for testing and evaluation purposes, VMware recommends replacing it with your own issuer for production environments.

There are a few ways to customize TLS configuration in Cloud Native Runtimes:

Replace the shared ingress issuer at the Tanzu Application Platform's level

You have the flexibility to replace Tanzu Application Platform's default ingress issuer with any other `certificate authority` that is compliant with cert-manager ClusterIssuer. For information about how to replace the default ingress issuer, see Replacing the default ingress issuer.

Cloud Native Runtimes uses the issuer specified by the `shared.ingress_issuer` configuration value to issue certificates for your workload automatically.

Designate another ingress issuer for your workloads in Cloud Native Runtimes only

You can have a shared ingress issuer at the Tanzu Application Platform's level and designate another issuer used by Cloud Native Runtimes to issue TLS certificates for your workloads. This allows you to customize TLS settings for Cloud Native Runtimes while maintaining a global configuration for other components.

You can designate an ingress issuer for Cloud Native Runtimes by specifying the `cnrs.ingress_issuer` configuration value. The ingress or TLS configuration for Cloud Native Runtimes takes precedence over the shared ingress issuer.

For information about designating another ingress issuer for your workloads, see Configure Cloud Native Runtimes to use a custom Issuer or ClusterIssuer for details.

Provide an existing TLS certificate for your workloads in Cloud Native Runtimes

If you manually generated a TLS certificate and want to provide it to Cloud Native Runtimes instead of using an ingress issuer, you can follow the instructions in Use your existing TLS Certificate for Cloud Native Runtimes.

Resources on custom TLS configuration for Cloud Native Runtimes

The following resources are helpful for custom TLS configuration for Cloud Native Runtimes:

- Configure Cloud Native Runtimes to use a custom Issuer or ClusterIssuer
- Use wildcard certificates with Cloud Native Runtimes
- Use your existing TLS Certificate for Cloud Native Runtimes
- Deactivate HTTP-to-HTTPS redirection
- Opt out from any ingress issuer and deactivate automatic TLS feature

Opt out from an ingress issuer and deactivate automatic TLS feature

This topic tells you how to opt out from an ingress issuer and deactivate the automatic TLS feature for Cloud Native Runtimes, commonly known as CNRs.

Deactivate TLS

You can deactivate automatic TLS certificate provisioning in Cloud Native Runtimes by setting the `ingress_issuer` property to an empty string as follows:

```
cnrs:
    ingress_issuer: ""
```

Update your Tanzu Application Platform installation accordingly after following the step mentioned earlier.

```
tanzu package installed update tap -p tap.tanzu.vmware.com -v ${TAP-VERSION} --values-
file tap-values.yaml -n tap-install
```

Where `TAP-VERSION` is the version of Tanzu Application Platform you want to update to.

Deactivate HTTP-to-HTTPS redirection

This topic tells you how to deactivate HTTP-to-HTTPS redirection with Cloud Native Runtimes.

Overview

When you designate an ingress issuer for your workloads by setting either the `shared.ingress_issuer` or `cnrs.ingress_issuer` configuration value, in your `tap-values.yaml` file, the auto-TLS feature is enabled in Cloud Native Runtimes. When the auto-TLS is enabled, Cloud Native Runtimes automatically redirects traffic from HTTP to HTTPS. However, there can be situations where you want to opt out of this behavior and continue serving content over HTTP. To do this, you must deactivate the HTTPS redirection feature.

To deactivate HTTP-to-HTTPS redirection in Cloud Native Runtimes, you must edit your configuration values file:

1. Configure Cloud Native Runtimes to deactivate https redirection:

```
cnrs:
   https_redirection: false
```

2. Update your Tanzu Application Platform installation:

```
tanzu package installed update tap -p tap.tanzu.vmware.com -v ${TAP_VERSION} --
values-file tap-values.yaml -n tap-install
```

3. Verify that the HTTP-to-HTTPS redirection is deactivated by accessing your workload using the HTTP protocol. You can access the service without being redirected to HTTPS. Use a web browser or a tool like `curl` to test the behavior:

```
curl -I http://your-workload.your-domain.com
```

   The response shows an HTTP status code without redirection to HTTPS.

Configure Cloud Native Runtimes to use a custom Issuer or ClusterIssuer

This topic tells you how to configure Cloud Native Runtimes to use a custom Issuer or ClusterIssuer.

Overview

The ability to opt out of the shared ingress issuer and use a custom Issuer or ClusterIssuer for Cloud Native Runtimes provides greater flexibility, security, isolation, and integration with existing infrastructure, allowing you to tailor the TLS configurations to your specific needs and requirements.

The following example explains how to opt out of the shared ingress issuer and use Let's Encrypt with the HTTP01 challenge type. The HTTP01 challenge requires that your load balancer is reachable from the Internet by using HTTP. With the HTTP01 challenge type, a certificate is provisioned for each service.

Configure a custom issuer

You have the flexibility to replace Tanzu Application Platform's default ingress issuer with any other `certificate authority` that is compliant with cert-manager ClusterIssuer. For more information, see the cert-manager documentation. For information about how to replace the default ingress issuer, see Replacing the default ingress issuer.

To configure Cloud Native Runtimes to use a custom Issuer or ClusterIssuer with the HTTP01 challenge:

1. Create a custom Issuer or ClusterIssuer with the Certificate Authority (CA) that you want and configurations. Here's an example YAML configuration for a custom ClusterIssuer using Let's Encrypt with the HTTP01 challenge:

```
apiVersion: cert-manager.io/v1
kind: ClusterIssuer
metadata:
  name: letsencrypt-http01-issuer
spec:
  acme:
     email: YOUR-EMAIL
     server: https://acme-v02.api.letsencrypt.org/directory
     privateKeySecretRef:
```

```
      name: letsencrypt-http01-issuer-account-key
    solvers:
      - http01:
          ingress:
            class: contour
```

Where `YOUR-EMAIL` is your email address.

Specify the ingress class you are using in your Tanzu Application Platform cluster, which is `contour`.

2. Save the configuration from the previous step in a file called `issuer-letsencrypt-http01.yaml`.

Note

To test this feature, you can set `spec.acme.server` to `https://acme-staging-v02.api.letsencrypt.org/directory`. This is the staging URL, which generates self-signed certificates. It is useful for testing without worrying about hitting quotas for your actual domain.

3. Apply the Issuer or ClusterIssuer configuration to your cluster:

```
kubectl apply -f issuer-letsencrypt-http01.yaml
```

Configure Cloud Native Runtimes to use a custom issuer

To configure Cloud Native Runtimes to use a custom issuer:

1. Configure Cloud Native Runtimes to use a custom Issuer or ClusterIssuer for issuing certificates by updating your `tap-values.yaml` file with the following snippet of YAML.

```
cnrs:
   ingress_issuer: "letsencrypt-http01-issuer"
```

2. Update Tanzu Application Platform.

   To update the Tanzu Application Platform installation with the changes to the values file, run:

```
tanzu package installed update tap -p tap.tanzu.vmware.com -v ${TAP_VERSION} --
values-file tap-values.yaml -n tap-install
```

Verify the issuance of certificates

To verify your certificate:

1. Verify that your ClusterIssuer was created and properly issuing certificates, by running:

```
kubectl get clusterissuer letsencrypt-http01-issuer
```

2. Confirm the status of the certificate by running the following command. You see the certificate in a `Ready` state.

```
kubectl get certificate -n DEVELOPER-NAMESPACE
```

   You see the certificate in a `Ready` state.

Where `DEVELOPER-NAMESPACE` is the namespace that you want to use.

3. You can access your workload using the domain you specified with `curl` or a web browser and verify that it is using a TLS certificate issued by the custom Issuer or ClusterIssuer.

```
tanzu apps workload get WORKLOAD-NAME --namespace DEVELOPER-NAMESPACE
kubectl get ksvc WORKLOAD-NAME -n DEVELOPER-NAMESPACE -o jsonpath='{.status.ur
l}'
```

Where:

- `DEVELOPER-NAMESPACE` is the namespace that you want to use.
- `WORKLOAD-NAME` is the name of the workload you want to use.

For information about how to troubleshoot failures related to the certificate, see the cert-manager documentation.

Use wildcard certificates with Cloud Native Runtimes

This section describes how to configure, use, and verify wildcard certificates with Cloud Native Runtimes.

Cloud Native Runtimes uses the cert-manager package by default to automate the process of obtaining, managing, and renewing TLS certificates for your services.

cert-manager is a Kubernetes-native component that works with different `certificate authorities` (CAs) like Let's Encrypt and others, to manage certificates within your Kubernetes cluster. As part of Tanzu Application Platform predefined profile installation, cert-manager package is deployed to the cluster.

Configure an issuer for wildcard certificates

Any other `cert-manager.io/v1/ClusterIssuer` can replace Tanzu Application Platform's default ingress issuer. This topic uses Let's Encrypt as an example of how to set up a custom ingress issuer that issues wildcard certificates.

The Let's Encrypt documentation states that the DNS01 challenge is required to validate wildcard domains. This topic provides instructions for configuring Cloud Native Runtimes to use wildcard certificates with the DNS01 challenge only.

To configure an issuer for wildcard certificates:

1. Create a cert-manager custom Issuer or ClusterIssuer for the DNS01 challenge.

   You must create a custom Issuer or ClusterIssuer with the DNS01 solver configured for your specific DNS provider. For more information about supported DNS01 providers, see the cert-manager documentation for instructions for configuring cert-manager for all the supported DNS providers.

   The following example uses Let's Encrypt and Google Cloud DNS:

```
apiVersion: cert-manager.io/v1
kind: ClusterIssuer
metadata:
  name: letsencrypt-dns-wildcard
spec:
  acme:
    server: https://acme-v02.api.letsencrypt.org/directory
    # This will register an issuer with LetsEncrypt.
    email: YOUR-EMAIL
    privateKeySecretRef:
```

```
      # Set privateKeySecretRef to any unused secret name.
      name: letsencrypt-dns-wildcard-account-key
    solvers:
    - dns01:
        cloudDNS:
          # Set this to your GCP project id
          project: PROJECT-ID
          # This is the secret used to access the service account
          serviceAccountSecretRef:
            name: cloud-dns-key
            key: key.json
```

Where:

- `YOUR-EMAIL` is the email associated with your DNS provider.
- `PROJECT-ID` is the ID of the GCP project.

2. Save the configuration from the previous step in a file called `issuer-wildcard.yaml`.

   When using cert-manager to obtain wildcard certificates, you typically must provide credentials, especially when using the DNS01 challenge. The DNS01 challenge requires cert-manager to create and delete DNS records for domain validation during the certificate issuance process. To perform these actions, cert-manager needs access to your DNS provider's API, which requires authentication using API keys, access tokens, or other credentials. See Supported DNS01 providers in the cert-manager documentation.

   Note

   To test this feature, you can set `spec.acme.server` to `https://acme-staging-v02.api.letsencrypt.org/directory`. This is the staging URL, which generates self-signed certificates. It is useful for testing without worrying about hitting quotas for your actual domain.

3. Apply the file you saved in the previous section to your cluster:

```
kubectl apply -f issuer-wildcard.yaml
```

Configure Cloud Native Runtimes to use wildcard certificates

To use wildcard certificates:

1. Configure Cloud Native Runtimes to use the custom Issuer or ClusterIssuer and indicate in which namespaces to create wildcard certificates.

   Note

   If no value is passed to `cnrs.namespace_selector`, only per service certificates are generated instead of wildcard certificates.

   You achieve this by adding the following YAML to your `tap-values.yaml` file.

```
cnrs:
  ingress_issuer: "letsencrypt-dns-wildcard"
  namespace_selector:
    matchExpressions:
```

```
    - key: apps.tanzu.vmware.com/tap-ns
      operator: Exists
```

This configuration tells Cloud Native Runtimes which custom Issuer or ClusterIssuer is used for issuing the wildcard certificate. When a Knative Service is created or updated with this configuration, Cloud Native Runtimes requests and uses the wildcard certificate from the specified custom Issuer or ClusterIssuer.

In Cloud Native Runtimes, the per-namespace certificate manager operates by using the namespace labels to verify which namespaces require a certificate to be generated. This example specifies that only namespaces labeled with `apps.tanzu.vmware.com/tap-ns` have corresponding wildcard certificates created for them.

If you are using the suggested namespace selector, label your developer namespace with `apps.tanzu.vmware.com/tap-ns`. Run:

```
kubectl label namespace DEV-NAMESPACE "apps.tanzu.vmware.com/tap-ns"
```

To remove a label from a namespace, run:

```
kubectl label namespace DEV-NAMESPACE "apps.tanzu.vmware.com/tap-ns"- --overwri
te
```

2. Update Tanzu Application Platform.

   To update the Tanzu Application Platform installation with the changes to the values file, run:

   ```
   tanzu package installed update tap -p tap.tanzu.vmware.com -v ${TAP_VERSION} --
   values-file tap-values.yaml -n tap-install
   ```

Verify the issuance of wildcard certificates

Verify that your ClusterIssuer was created and properly issuing certificates.

1. To verify your ClusterIssuer, run:

   ```
   kubectl get clusterissuer letsencrypt-dns-wildcard
   ```

2. Confirm the status of the certificate by running the following command. You see the certificate in a `Ready` state.

   ```
   kubectl get certificate -n DEVELOPER-NAMESPACE
   ```

   You see the certificate in a `Ready` state.

   Where `DEVELOPER-NAMESPACE` is the namespace you want to use.

3. You can access your workload using the domain you specified with `curl` or a web browser, and verify that it is using a TLS certificate issued by the custom Issuer or ClusterIssuer.

   ```
   tanzu apps workload get WORKLOAD-NAME --namespace DEVELOPER-NAMESPACE
   kubectl get ksvc WORKLOAD-NAME -n DEVELOPER-NAMESPACE -o jsonpath='{.status.ur
   l}'
   ```

   Where:

   - `DEVELOPER-NAMESPACE` is the namespace you want to use.
   - `WORKLOAD-NAME` is the name of the workload you want to use.

For details about how to troubleshoot failures related to the certificate, see the cert-manager documentation.

Configure garbage collection for the Knative revisions

This topic tells you about current Garbage collection defaults for Knative Revisions and you can update them in Tanzu Application Platform.

Overview

You can configure garbage collection with Knative. For more information, see the Knative documentation.

The current configuration sets the following defaults to mark Knative revisions for garbage collection:

```
  * `retain-since-create-time: "48h"`: Any revision created with an age of 2 days is c
onsidered for garbage collection.
  * `retain-since-last-active-time: "15h"`: Revision that was last active at least 15
hours ago is considered for garbage collection.
  * `min-non-active-revisions: "2"`: The minimum number of inactive Revisions to retai
n.
  * `max-non-active-revisions: "5"`: The maximum number of inactive Revisions to retai
n.
```

Update default values for Knative Garbage Collection

To update default values for Knative Garbage Collection:

1. Create an overlay with the following contents:

   ```
   apiVersion: v1
   kind: Secret
   metadata:
   name: cnr-overlay-gc-cm
   namespace: tap-install #! namespace where tap is installed
   stringData:
   overlay-gc-cm.yaml: |
     #@ load("@ytt:overlay", "overlay")
     #@overlay/match by=overlay.subset({"kind":"ConfigMap","metadata":{"name":"con
   fig-gc"}})
     ---
     data:
       #@overlay/match missing_ok=True
       retain-since-create-time: "48h"
       #@overlay/match missing_ok=True
       retain-since-last-active-time: "15h"
       #@overlay/match missing_ok=True
       min-non-active-revisions: "2"
       #@overlay/match missing_ok=True
       max-non-active-revisions: "5"
   ```

2. Update Tanzu Application Platform values.

   ```
   package_overlays:
   - name: cnrs
     secrets:
       - name: cnr-overlay-gc-cm
   ```

3. Update Tanzu Application Platform Package.

```
tanzu package installed update tap -p tap.tanzu.vmware.com --values-file tap-va
lues.YAML  -n tap-install
```

4. Verify that the overlay was applied by running following commands:

```
kubectl get configmap config-gc --namespace knative-serving --output jsonpath="
{.data.retain-since-create-time}"
kubectl get configmap config-gc --namespace knative-serving --output jsonpath="
{.data.retain-since-last-active-time}"
kubectl get configmap config-gc --namespace knative-serving --output jsonpath="
{.data.min-non-active-revisions}"
kubectl get configmap config-gc --namespace knative-serving --output jsonpath="
{.data.max-non-active-revisions}"
```

Configure Cloud Native Runtimes with VMware NSX Advanced Load Balancer

This topic tells you how to configure Cloud Native Runtimes, commonly known as CNRs, with VMware NSX Advanced Load Balancer, formerly known as Avi Networks.

Overview

You can configure Cloud Native Runtimes to integrate with VMware NSX Advanced Load Balancer. VMware NSX Advanced Load Balancer is a multi-cloud platform that delivers features such as load balancing, security, and container ingress services.

The NSX Advanced Load Balancer Controller provides a control plane while the NSX Advanced Load Balance Service Engines provide a data plane. The Service Engines forward incoming traffic to your Kubernetes cluster's Envoy pods, which Contour creates and manages.

For information about VMware NSX Advanced Load Balancer, see VMware NSX Advanced Load Balancer Documentation.

Prerequisites

To integrate VMware NSX Advanced Load Balancer with Cloud Native Runtimes, you must first install Cloud Native Runtimes:

- If you have not already installed Cloud Native Runtimes, see Installing Cloud Native Runtimes.
- If you already have a Contour installation on your cluster, see Installing Cloud Native Runtimes with an Existing Contour Installation.

Integrate VMware NSX Advanced Load Balancer with Cloud Native Runtimes

To configure Cloud Native Runtimes with VMware NSX Advanced Load Balancer:

1. Deploy the NSX Advanced Load Balancer Controller on a supported infrastructure provider. For a list of NSX Advanced Load Balancer supported providers, see Installation Guides.
2. Deploy the Avi Kubernetes operator to your Kubernetes cluster where Cloud Native Runtimes is hosted. For more information, see the Avi Kubernetes Operator documentation.
3. Connect to a test app and verify that it is reachable. Run:

```
"curl -H KNATIVE-SERVICE-DOMAIN" ENVOY-IP
```

Where:

- `KNATIVE-SERVICE-DOMAIN` is the name of your domain.
- `ENVOY-IP` is the IP address of your Envoy instance.

For information about deploying a sample application and connecting to the application, see Test Knative Serving.

4. (Optional) Create a DNS record that configures your KService URL to point to the Avi Service Engines, and resolve to the external IP of the Envoy. You can create a DNS record on any platform that supports DNS services. For more information, see the documentation for your DNS service platform.

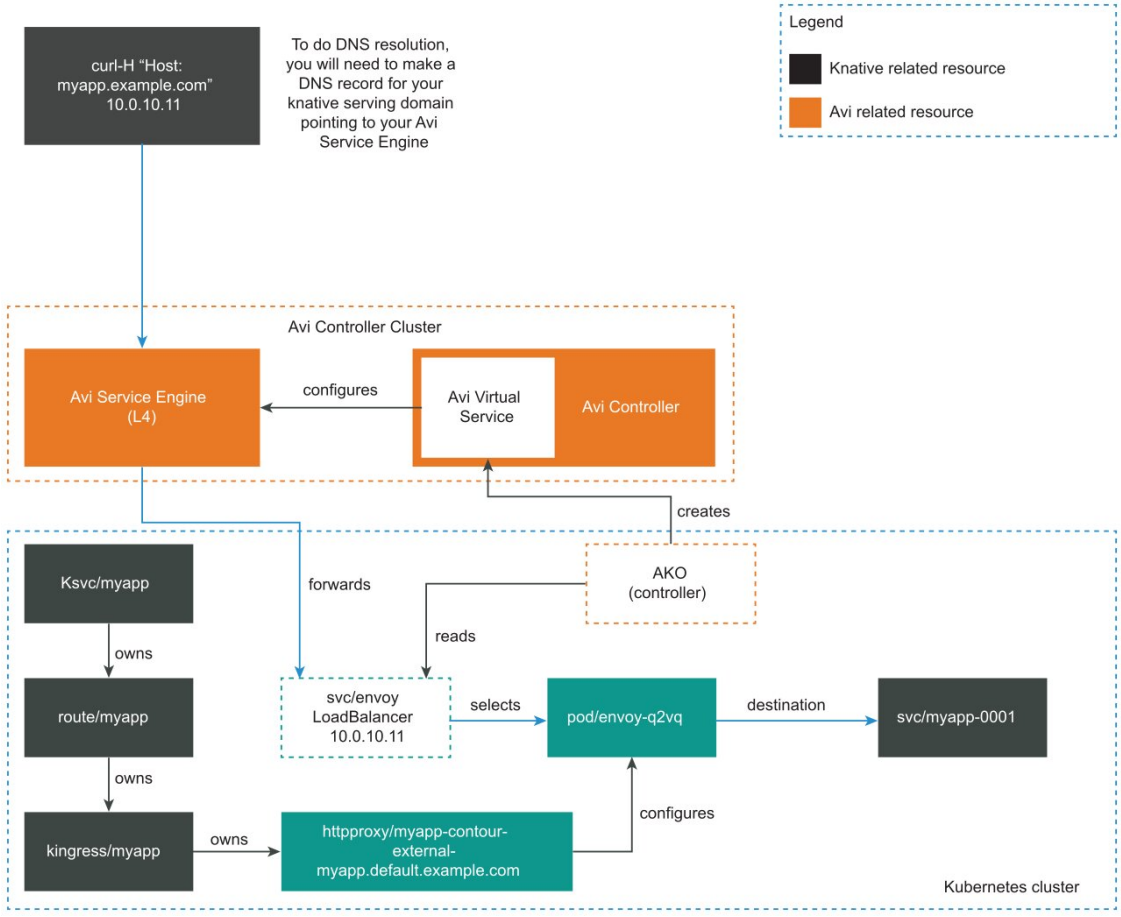
   To get the KService URL, run:

   ```
   kn route describe APP-NAME | grep "URL"
   ```

   To get Envoy's external IP, follow step 3 in Test Knative Serving.

About Routing with VMware NSX Advanced Load Balancer and Cloud Native Runtimes

The following diagram shows how VMware NSX Advanced Load Balancer integrates with Cloud Native Runtimes:



When Contour creates a Kubernetes LoadBalancer service for Envoy, the Avi Kubernetes operator (AKO) sees the new LoadBalancer service. Then NSX Advanced Load Balancer Controller creates a

Virtual Service. For information about LoadBalancer services, see Type LoadBalancer in the Kubernetes documentation.

For each Envoy service, NSX Advanced Load Balancer Controller creates a corresponding Virtual Service. See Virtual Services in the VMware NSX Advanced Load Balancer documentation.

After NSX Advanced Load Balancer Controller creates a Virtual Service, the Controller configures the Service Engines to forward traffic to the Envoy pods. The Envoy pods route traffic based on incoming requests, including traffic splitting and path based routing.

The NSX Advanced Load Balancer Controller provides Envoy with an external IP address so that apps are reachable by the app developer.

Note

VMware NSX Advanced Load Balancer does not interact directly with any Cloud Native Runtimes resources. VMware NSX Advanced Load Balancer forwards all incoming traffic to Envoy.

Installing Cloud Native Runtimes with your existing Contour installation

This topic describes how you can configure Cloud Native Runtimes, commonly known as CNRs, with your existing Contour instance. Cloud Native Runtimes uses Contour to manage internal and external access to the services in a cluster.

About using Contour with Cloud Native Runtimes

Follow the instructions in this topic if:

- You installed Contour as part of Tanzu Application Platform and want to configure Cloud Native Runtimes to use it.
- You see an error about `an existing Contour installation` when you install the Cloud Native Runtimes package.

Cloud Native Runtimes needs two instances of Contour:

- An instance for exposing services outside the cluster
- An instance for services that are private in your network

If installed as part of a Tanzu Application Platform profile, by default Cloud Native Runtimes use the Contour instance installed in the namespace `tanzu-system-ingress` for both internal and external traffic.

If you already use a Contour instance to route requests from clients outside and inside the cluster, you can use your own Contour if it matches the Contour version used by Tanzu Application Platform.

You can use the same single instance of Contour for both internal and external traffic. However, this causes Contour to handle internal and external traffic the same way. For example, if the Contour instance is configured to be accessible from clients outside the cluster, then any internal traffic is also accessible from outside the cluster. Tanzu Application Platform only supports using a single Contour instance for both internal and external traffic.

In all of these cases, Cloud Native Runtimes uses the Tanzu Application Platform's Contour `CustomResourceDefinition`s.

Prerequisites

The following prerequisites are required to configure Cloud Native Runtimes with an existing Contour installation:

- Contour version v1.25.2, the Contour version that is installed as part of Tanzu Application Platform. To identify your cluster's Contour version, see Identify Your Contour Version.
- Contour `CustomResourceDefinition`s versions:

Resource Name	Version
`contourdeployments.projectcontour.io`	v1alpha1
`contourconfigurations.projectcontour.io`	v1alpha1
`extensionservices.projectcontour.io`	v1alpha1
`httpproxies.projectcontour.io`	v1
`tlscertificatedelegations.projectcontour.io`	v1

Identify your Contour version

To identify your cluster's Contour version, run:

```
export CONTOUR_NAMESPACE=CONTOUR-NAMESPACE
export CONTOUR_DEPLOYMENT=$(kubectl get deployment --namespace $CONTOUR_NAMESPACE --ou
tput name)
kubectl get $CONTOUR_DEPLOYMENT --namespace $CONTOUR_NAMESPACE --output jsonpath="{.sp
ec.template.spec.containers[].image}"
kubectl get crds extensionservices.projectcontour.io --output jsonpath="{.status.store
dVersions}"
kubectl get crds httpproxies.projectcontour.io --output jsonpath="{.status.storedVersi
ons}"
kubectl get crds tlscertificatedelegations.projectcontour.io --output jsonpath="{.stat
us.storedVersions}"
```

Where `CONTOUR-NAMESPACE` is the namespace where Contour is installed on your Kubernetes cluster.

Install Cloud Native Runtimes on a cluster with your existing Contour instance

To install Cloud Native Runtimes on a cluster with an existing Contour instance, you can add values to your `cnr-values.yaml` file so that Cloud Native Runtimes uses your Contour instance.

An example of a `cnr-values.yaml` file where Cloud Native Runtimes uses the Contour version in a different namespace:

```
---
contour:
  external:
    namespace: "tanzu-system-ingress"
  internal:
    namespace: "tanzu-system-ingress"
```

Note

If your Contour instance is removed or configured incorrectly, apps running on Cloud Native Runtimes lose connectivity.

Customizing Cloud Native Runtimes

This topic tells you how to customize your Cloud Native Runtimes installation.

Overview

There are many package configuration options exposed through data values that allows you to customize your Cloud Native Runtimes installation.

To yield all the configuration options available in a Cloud Native Runtimes package version:

```
export CNR_VERSION=2.4.0
tanzu package available get cnrs.tanzu.vmware.com/${CNR_VERSION} --values-schema -n ta
p-install
```

Customizing Cloud Native Runtimes

Besides using the out-of-the-box options to configure your package, you can use ytt overlays to further customize your installation. For information about how to customize any Tanzu Application Platform package, see Customize your package installation.

The following example shows how to update the Knative ConfigMap `config-logging` to override the logging level of the Knative Serving controller to `debug`:

1. Create a Kubernetes secret containing the ytt overlay by applying the following configuration to your cluster.

   ```
   kubectl apply -n tap-install -f - << EOF
   apiVersion: v1
   kind: Secret
   metadata:
    name: cnrs-patch
   stringData:
    patch.yaml: |
      #@ load("@ytt:overlay", "overlay")
      #@overlay/match by=overlay.subset({"kind":"ConfigMap","metadata":{"name":"co
   nfig-logging","namespace":"knative-serving"}})
      ---
      data:
        #@overlay/match missing_ok=True
        loglevel.controller: "debug"
   EOF
   ```

   To learn more about the Carvel tool `ytt` and how to write overlays, see the ytt documentation.

2. Update your `tap-values.yaml` file to add the YAML below. This YAML informs the Tanzu Application Platform about the secret name where the overlay is stored and applies the overlay to the `cnrs` package.

   ```
   package_overlays:
   - name: cnrs
     secrets:
     - name: cnrs-patch
   ```

   You can retrieve your `tap-values.yaml` file by running:

   ```
   kubectl get secret tap-tap-install-values -n tap-install -ojsonpath="{.data.tap
   -values\.yaml}" | base64 -d
   ```

3. Update the Tanzu Application Platform installation.

```
tanzu package installed update tap -p tap.tanzu.vmware.com -v ${TAP_VERSION} --
values-file tap-values.yaml -n tap-install
```

4. Confirm your changes were applied to the corresponding ConfigMap.

   To confirm that your changes were applied to the ConfigMap `config-logging` by ensuring `loglevel.controller` is set to `debug`.

```
kubectl get configmap config-logging -n knative-serving -oyaml
```

Configure your external DNS with Cloud Native Runtimes

This topic tells you how to configure your external DNS with Cloud Native Runtimes, commonly known as CNRs.

Overview

Knative uses `svc.cluster.local` as the default domain.

Note

If you are setting up Cloud Native Runtimes for development or testing, you do not have to set up an external DNS. However, to access your workloads over the Internet, you must set up a custom domain and an external DNS.

Configure custom domain

To set up the custom domain and its external DNS record:

1. Configure your custom domain:

   When your workloads are created, Knative automatically creates URLs for each workload based on the configuration in the domain ConfigMap.

   - To set a default custom domain, edit your `cnr-values.yaml` file to contain the following:

```
---
domain_name: "mydomain.com"
```

     This edits the Knative domain ConfigMap to use `domain_name` as the default domain.

     Note

     `domain_name` must be a valid DNS subdomain.

   - **Advanced** To overwrite the domain ConfigMap entirely, edit your `cnr-values.yaml` file to contain the config-domain options that you want, similar to the following:

```
---
domain_config: |
 ---
 mydomain.com: |
```

```
mydomain.org: |
   selector:
      app: nonprofit
```

This replaces the body of the Knative domain ConfigMap with `domain_config`. This allows you to configure multiple custom domains, and configure a custom domain for a service depending on its labels.

See Changing the default domain for more information about the structure of the domain ConfigMap.

Note

`domain_config` must be valid YAML and a valid domain ConfigMap.

Note

You can only use one of `domain_config` or `domain_name` at a time. You can not use both.

2. Get the address of the cluster load balancer:

```
kubectl get service envoy -n EXTERNAL-CONTOUR-NS --output 'jsonpath={.status.lo
adBalancer.ingress}'
```

Where `EXTERNAL-CONTOUR-NS` is the namespace where a Contour serving external traffic is installed. If Cloud Native Runtimes was installed as part of a Tanzu Application Profile, this value is likely `tanzu-system-ingress`.

If this command returns a URL instead of an IP address, `ping` the URL to get the load balancer IP address.

3. Create a wildcard DNS `A` record that assigns the custom domain to the load balancer IP. Follow the instructions provided by your domain name registrar for creating records.

   The following is an example of the record you create:

```
*.DOMAIN IN A TTL LOADBALANCER-IP
```

   Where:

   - `DOMAIN` is the custom domain.
   - `TTL` is the time-to-live.
   - `LOADBALANCER-IP` is the load balancer IP.

   For example:

```
*.mydomain.com IN A 3600 198.51.100.6
```

   If you chose to configure multiple custom domains, you must create a wildcard DNS record for each domain.

Configure Knative service domain template

Knative uses domain template which specifies the golang text template string to use when constructing the Knative service's DNS name. The default value is `{{.Name}}.{{.Namespace}}.`

`{{.Domain}}`. Valid variables defined in the template include Name, Namespace, Domain, Labels, and Annotations.

To configure domain template for the created Knative Services, add the following to your `cnr-values.yaml` file:

```
---
domain_template: "{{.Name}}-{{.Namespace}}.{{.Domain}}"
```

This edits the Knative `domain-template` ConfigMap to use `domain_template` as the default domain template.

Changing this value might be necessary when the extra levels in the domain name generated are problematic for wildcard certificates that only support a single level of domain name added to the certificate's domain. In those cases you might consider using a value of `{{.Name}}-{{.Namespace}}.{{.Domain}}`, or removing the Namespace entirely from the template.

When choosing a new value, be thoughtful of the potential for conflicts, such as when users the use of characters like `-` in their service or namespace names.

You can use `{{.Annotations}}` or `{{.Labels}}` for any customization in the go template if needed.

VMware recommends to keeping namespace in the template to avoid domain name clashes. For example, `{{.Name}}-{{.Namespace}}.{{ index .Annotations "sub"}}.{{.Domain}}` and you have an annotation `{"sub":"foo"}`, the generated template is `{Name}-{Namespace}.foo.{Domain}`.

Use your existing TLS Certificate for Cloud Native Runtimes

This topic tells you how to use your existing TLS Certificate for Cloud Native Runtimes, commonly known as CNRs.

Overview

Configure secure HTTPS connections to enable your web workloads and routes to stop external TLS connections using an existing certificate.

You have the flexibility to provide your own TLS certificate to Cloud Native Runtimes *instead of* relying on the shared ingress issuer for your Knative workloads. To use the feature explained in this topic, you must configure Cloud Native Runtimes to bypass the cert-manager certificate issuer. For example, if you have set `cnrs.contour.default_tls_secret` in your `tap-values.yaml`, set the `cnrs.ingress_issuer` configuration to an empty value. For detailed instructions on how to opt out and deactivate the automatic TLS feature, see Opt out from any ingress issuer and deactivate automatic TLS feature.

Prerequisites

To configure TLS for Cloud Native Runtimes, you must first configure a Service Domain. For more information, see Configuring External DNS with Cloud Native Runtimes.

Configure TLS

To configure your TLS certificate for the created Knative Services, follow the steps:

1. Create a Kubernetes secret to hold your TLS Certificate:

   ```
   kubectl create -n DEVELOPER-NAMESPACE secret tls SECRET_NAME \
     --key key.pem \
     --cert cert.pem
   ```

2. Create a delegation. To do so, create a `tlscertdelegation.yaml` file:

   ```
   apiVersion: projectcontour.io/v1
   kind: TLSCertificateDelegation
   metadata:
     name: default-delegation
     namespace: DEVELOPER-NAMESPACE
   spec:
     delegations:
       - secretName: SECRET-NAME
         targetNamespaces:
           - "DEVELOPER-NAMESPACE"
   ```

   Where `SECRET-NAME` is the name of the Kubernetes secret you created earlier.

3. Apply the YAML file by running:

   ```
   kubectl apply -f tlscertdelegation.yaml
   ```

4. Include the following configuration in your `tap-values.yaml` file under Cloud Native Runtimes section and redeploy:

   ```
   cnrs:
     contour:
       default_tls_secret: "DEVELOPER-NAMESPACE/SECRET-NAME"
   ```

   Where `SECRET-NAME` is the name of the Kubernetes secret you created earlier.

   Where `DEVELOPER-NAMESPACE` is the name of the namespace where the secret was created.

5. Update Tanzu Application Platform.

   To update the Tanzu Application Platform installation with the changes to the values file, run:

   ```
   tanzu package installed update tap -p tap.tanzu.vmware.com -v ${TAP_VERSION} --
   values-file tap-values.yaml -n tap-install
   ```

   This edits the Knative `config-contour` ConfigMap to use `default_tls_secret` as the default TLS certificate.

   Your web workloads' URLs use the scheme `https` by default when this secret is provided.

Configuring observability for Cloud Native Runtimes

This topic tells you how to configure observability for Cloud Native Runtimes, commonly known as CNRs.

Overview

You can set up integrations with third-party observability tools to use logging, metrics, and tracing with Cloud Native Runtimes. These observability integrations allow you to monitor and collect detailed metrics from your clusters on Cloud Native Runtimes. You can collect logs and metrics for all workloads running on a cluster. This includes Cloud Native Runtimes components or any apps running on Cloud Native Runtimes. The integrations in this topic are recommended by VMware, however you can use any Kubernetes-compatible logging, metrics, and tracing platforms to monitor your cluster workload.

Logging

You can collect and forward logs for all workloads on a cluster, including Cloud Native Runtimes components and any apps running on Cloud Native Runtimes. You can use any logging platform that is compatible with Kubernetes to collect and forward logs for Cloud Native Runtimes workloads. VMware recommends using Fluent Bit to collect logs and forward logs to vRealize. The following sections describe configuring logging for Cloud Native Runtimes with Fluent Bit and vRealize as an example.

Configure Logging with Fluent Bit

You can use Fluent Bit to collect logs for all workloads on a cluster, including Cloud Native Runtimes components or any apps running on Cloud Native Runtimes. For more information about using Fluent Bit logs, see Fluent Bit Kubernetes Logging.

Fluent Bit lets you collect logs from Kubernetes containers, add Kubernetes metadata to these logs, and forward logs to third-party log storage services. For more information about collecting logs, see the Knative documentation.

If you are using Tanzu Mission Control (TMC), vSphere 7.0 with Tanzu, or Tanzu Kubernetes Cluster to manage your cloud-native environment, you must set up a role binding that grants required permissions to Fluent Bit containers to configure logging with any integration. Then, follow the instructions in the Fluent Bit documentation to complete the logging configuration. For more information about configuring Fluent Bit logging, see the Fluent Bit documentation.

To configure logging with Fluent Bit for your Cloud Native Runtimes environment:

1. VMware recommends that you add any integrations to the `ConfigMap` in your Knative Serving namespace. Follow the logging configuration steps in the Fluent Bit documentation to create the `Namespace`, `ServiceAccount`, `Role`, `RoleBinding`, and `ConfigMap`. To view these steps, see the Fluent Bit documentation.
2. If you are using TMC, vSphere with Tanzu, or Tanzu Kubernetes Cluster to manage your cloud-native environment, create a role binding in the Kubernetes namespace where your integration is deployed to grant permission for privileged Fluent Bit containers. For information about creating a role binding on a Tanzu platform, see Add a Role Binding. For information about viewing your Kubernetes namespaces, see the Kubernetes documentation.

   Create the following role binding:

   ```
   apiVersion: rbac.authorization.k8s.io/v1
   kind: RoleBinding
   metadata:
     name: fluentbit-psp-rolebinding
     namespace: FLUENTBIT-NAMESPACE
   roleRef:
     apiGroup: rbac.authorization.k8s.io
     kind: ClusterRole
     name:  PRIVILEGED-CLUSTERROLE
   subjects:
   - kind: ServiceAccount
     name: FLUENTBIT-SERVICEACCOUNT
     namespace: FLUENTBIT-NAMESPACE
   ```

   Where:

   - `FLUENTBIT-NAMESPACE` is your Fluent Bit namespace.
   - `PRIVILEGED-CLUSTERROLE` is the name of your privileged cluster role.
   - `FLUENTBIT-SERVICEACCOUNT` is your Fluent Bit service account.

3. To verify that you configured logging successfully, run the following to access logs through your web browser:

   ```
   kubectl port-forward --namespace logging service/log-collector 8080:80
   ```

   For more information about accessing Fluent Bit logs, see the Knative documentation.

Forward Logs to vRealize

After you configure log collection, you can forward logs to log management services. vRealize Log Insight is one service you can use with Cloud Native Runtimes. vRealize Log Insight is a scalable log management solution that provides log management, dashboards, analytics, and third-party extensibility for infrastructure and apps. For more information about vRealize Log Insight, see the VMware vRealize Log Insight Documentation.

To forward logs from your Cloud Native Runtimes environment to vRealize, you can use a new or existing instance of Tanzu Kubernetes Cluster. For information about how to configure log forwarding to vRealize from Tanzu Kubernetes Cluster, see the Configure Log forwarding from VMware Tanzu Kubernetes Cluster to vRealize Log Insight Cloud blog.

Metrics

Cloud Native Runtimes integrates with Prometheus and VMware Aria Operations for Applications (formerly known as Tanzu Observability by Wavefront) to collect metrics on components or apps. For more information about integrating with Prometheus, see the Prometheus documentation and the Wavefront documentation.

You can configure Prometheus endpoints on Cloud Native Runtimes components to collect metrics on your components or apps. For information about configuring this, see the Prometheus documentation.

You can use annotation based discovery with Prometheus to define which Kubernetes objects in your Cloud Native Runtimes environment to add metadata and collect metrics in a more automated way. For more information about using annotation based discovery, see the VMware Aria Operations for Applications documentation in GitHub.

You can then use the Wavefront Collector for Kubernetes collector to dynamically discover and scrape pods with the `prometheus.io/scrape` annotation prefix. For information about the Kubernetes collector, see the VMware Aria Operations for Applications documentation in GitHub.

Note

All Cloud Native Runtimes related metrics have the prefix `tanzu.vmware.com/cloud-native-runtimes.*`.

Tracing

Tracing is a method for understanding the performance of specific code paths in apps as they handle requests. You can configure tracing to collect performance metrics for your apps or Cloud Native Runtimes components. You can trace which aspects of Cloud Native Runtimes and workloads running on Cloud Native Runtimes are performing poorly.

Configuring Tracing

You can configure tracing for your applications on Cloud Native Runtimes. You configure tracing for Knative Serving by editing the ConfigMap `config-tracing` for your Knative namespaces.

VMware recommends that you add any integrations in your Serving namespaces. For information about how to enable request traces in each component, see the Knative documentation.

Forwarding trace data to an observability platform or data visualization tool

You can use the OpenTelemetry integration to forward trace data to a data visualization tool that can ingest data in Zipkin format. For more information about using Zipkin for tracing, see the Zipkin documentation.

VMware recommends integrating with VMware Aria Operations for Applications (formerly known as Tanzu Observability by Wavefront). For information about forwarding trace data, see the VMware Aria Operations for Applications documentation.

Sending trace data to VMware Aria Operations for Applications

You can send trace data to an observability and analytics platform such as VMware Aria Operations for Applications to view and monitor your trace data in dashboards. VMware Aria Operations for Applications offers several deployment options. During development, a single proxy is often sufficient for all data sources. For more information about other deployment options, see the VMware Aria Operations for Applications documentation.

To configure Cloud Native Runtimes to send traces to the Wavefront proxy and then, configure the Wavefront proxy to consume Zipkin spans:

1. Deploy the Wavefront Proxy. For more information about Wavefront proxies, see Install and Manage Wavefront Proxies.
2. Configure the namespace where the Wavefront Proxy was deployed with proper credentials to its container image registry.

   The following example uses the Namespace Provisioner package to automatically configure namespaces labeled with `apps.tanzu.vmware.com/tap-ns`.

   ```
   export WF_NAMESPACE=default
   kubectl label namespace ${WF_NAMESPACE} apps.tanzu.vmware.com/tap-ns=""

   export WF_REGISTRY_HOSTNAME=HOSTNAME
   export WF_REGISTRY_USERNAME=USERNAME
   export WF_REGISTRY_PASSWORD=PASSWORD
   tanzu secret registry add registry-credentials \
    --username ${WF_REGISTRY_USERNAME} --password ${WF_REGISTRY_PASSWORD} \
    --server ${WF_REGISTRY_HOSTNAME} \
    --export-to-all-namespaces --yes --namespace tap-install
   ```

   Where:

   - `WF_NAMESPACE` is the namespace where you deployed the Wavefront Proxy.
   - `HOSTNAME` is the image registry where the Wavefront Proxy image is located.
   - `USERNAME` is your user name to access the image registry to pull the Wavefront Proxy image.
   - `PASSWORD` is your password to access the image registry to pull the Wavefront Proxy image.

   For more information about how to set up developer namespaces, see Provision developer namespaces. Provision developer namespaces.
3. Configure the Wavefront Proxy to allow Zipkin/Istio traces.

You can uncomment the lines indicated in the YAML file for the Wavefront Deployment to enable consumption of Zipkin traces. Edit the Wavefront Deployment to set the `WAVEFRONT_PROXY_ARGS` environment variable to the value `--traceZipkinListenerPorts 9411`. Also, edit the Wavefront Deployment to expose the containerPort `9411`.

4. Confirm that the Wavefront Proxy is running and working.

   Verify that pods are running. For more information about how to test a proxy, see the VMware Aria Operations for Applications documentation.

   ```
   kubectl get pods -n ${WF_NAMESPACE}
   ```

   Where `WF_NAMESPACE` is the namespace where you deployed the Wavefront Proxy.

5. Edit the Serving ConfigMap `config-tracing` to enable the Zipkin tracing integration.

   You can configure Cloud Native Runtimes to send traces to the Wavefront proxy by editing the `zipkin-endpoint` property in the ConfigMap to point to the Wavefront proxy URL. You can configure the Wavefront proxy to consume Zipkin spans by listening to port `9411`.

   Note

   There are two ways of editing a Knative ConfigMap on Cloud Native Runtimes. Depending on your installation, you can edit the ConfigMap directly on the cluster or by using overlays. For information about how to edit ConfigMaps using overlays, see Configuring Cloud Native Runtimes.

   The following example of a Kubernetes secret contains a ytt overlay with the suggested changes to the ConfigMap `config-tracing`:

   ```
   apiVersion: v1
   kind: Secret
   metadata:
    name: cnrs-patch
   stringData:
    patch.yaml: |
      #@ load("@ytt:overlay", "overlay")
      #@overlay/match by=overlay.subset({"kind":"ConfigMap","metadata":{"name":"co
   nfig-tracing","namespace":"knative-serving"}})
      ---
      data:
        #@overlay/match missing_ok=True
        backend: "zipkin"
        #@overlay/match missing_ok=True
        zipkin-endpoint: "http://wavefront-proxy.default.svc.cluster.local:9411/ap
   i/v2/spans"
   ```

   After you follow the steps in Customizing Cloud Native Runtimes to configure your installation to use an overlay, you can examine the ConfigMap on the cluster to confirm that the changes were applied.

   ```
   kubectl get configmap config-tracing --namespace knative-serving --output yaml
   ```

   The ConfigMap looks like this example:

   ```
   apiVersion: v1
   kind: ConfigMap
   metadata:
   name: config-tracing
   data:
   ```

```
_example: |
    ...
backend: "zipkin"
zipkin-endpoint: "http://wavefront-proxy.default.svc.cluster.local:9411/api/v2/
spans"
```

Other resources:

- OpenTelemetry Integration

Configuring Cloud Native Runtimes with Tanzu Service Mesh

This topic tells you how to configure Cloud Native Runtimes, commonly known as CNRs, with Tanzu Service Mesh.

Overview

You cannot install Cloud Native Runtimes on a cluster that has Tanzu Service Mesh attached.

This workaround describes how you can configure Tanzu Service Mesh to ignore the Cloud Native Runtimes. This allows Contour to provide ingress routing for the Knative workloads, while Tanzu Service Mesh continues to satisfy other connectivity concerns.

Note

Cloud Native Runtimes workloads are unable to use Tanzu Service Mesh features like Global Namespace, Mutual Transport Layer Security authentication (mTLS), retries, and timeouts.

For information about Tanzu Service Mesh, see Tanzu Service Mesh Documentation.

Prerequisites

The following prerequisites are required:

- A cluster attached to Tanzu Service Mesh
- You haven't installed Cloud Native Runtimes

Note

If you installed Cloud Native Runtimes on a cluster that has Tanzu Service Mesh attached before doing the following procedure, pods fail to start. To fix this problem, follow the procedure in this topic and then delete all pods in the excluded namespaces.

Run Cloud Native Runtimes on a cluster attached to Tanzu Service Mesh

Configure Tanzu Service Mesh to ignore namespaces related to Cloud Native Runtimes:

1. Navigate to the **Cluster Overview** tab in the Tanzu Service Mesh UI.
2. On the cluster where you want to install Cloud Native Runtimes, click **...**.
3. Click **Edit Cluster...**.
4. Create an Is Exactly rule for each of the following namespaces:
    - CONTOUR-NS
    - knative-serving
    - tap-install
    - rabbitmq-system
    - kapp-controller
    - The namespace or namespaces where you plan to run Knative workloads.

    Where `CONTOUR-NS` is the one or more namespaces where Contour is installed on your cluster. If Cloud Native Runtimes was installed as part of a Tanzu Application Profile, this value is likely `tanzu-system-ingress`.

Next steps

After configuring Tanzu Service Mesh, install Cloud Native Runtimes and verify your installation:

1. Install Cloud Native Runtimes. See Installing Cloud Native Runtimes.
2. Verify your installation. See Verifying Your Installation.

Note

You must create all Knative workloads in the namespace or namespaces where you plan to run these Knative workloads. If you do not, your pods fail to start.

Troubleshooting Cloud Native Runtimes

This topic tells you how to troubleshoot Cloud Native Runtimes, commonly known as CNRs, installation, or configuration.

Installation fails to reconcile app/cloud-native-runtimes

Symptom

When installing Cloud Native Runtimes, you see one of the following errors:

```
11:41:16AM: ongoing: reconcile app/cloud-native-runtimes (kappctrl.k14s.io/v1alpha1) n
amespace: cloud-native-runtime
11:41:16AM:  ^ Waiting for generation 1 to be observed
kapp: Error: Timed out waiting after 15m0s
```

Or,

```
3:15:34PM:  ^ Reconciling
3:16:09PM: fail: reconcile app/cloud-native-runtimes (kappctrl.k14s.io/v1alpha1) names
pace: cloud-native-runtimes
3:16:09PM:  ^ Reconcile failed:  (message: Deploying: Error (see .status.usefulErrorMe
ssage for details))
```

```
kapp: Error: waiting on reconcile app/cloud-native-runtimes (kappctrl.k14s.io/v1alpha
1) namespace: cloud-native-runtimes:
  Finished unsuccessfully (Reconcile failed:  (message: Deploying: Error (see .status.
usefulErrorMessage for details)))
```

Explanation

The `cloud-native-runtimes` deployment app installs the subcomponents of Cloud Native Runtimes. Error messages about reconciling indicate that one or more subcomponents have failed to install.

Solution

Use the following procedure to examine logs:

1. Get the logs from the `cloud-native-runtimes` app by running:

   ```
   kubectl get app/cloud-native-runtimes -n cloud-native-runtimes -o jsonpath="{.s
   tatus.deploy.stdout}"
   ```

   > **Note**
   >
   > If the command does not return log entries, kapp-controller is not installed or is not running correctly.

2. Review the output for sub component deployments that have failed or are still ongoing. See the following examples for suggestions on resolving common problems.

Example 1: The Cloud Provider does not support the creation of Service type LoadBalancer

Follow these steps to identify and resolve the problem of the cloud provider not supporting services of type `LoadBalancer`:

1. Search the log output for `Load balancer`, for example, by running:

   ```
   kubectl -n cloud-native-runtimes get app cloud-native-runtimes -ojsonpath="{.st
   atus.deploy.stdout}" | grep "Load balancer" -C 1
   ```

2. If the output looks similar to the following, ensure that your cloud provider supports services of type `LoadBalancer`. For more information, see Access Tanzu Developer Portal.

   ```
   6:30:22PM: ongoing: reconcile service/envoy (v1) namespace: CONTOUR-NS
   6:30:22PM:  ^ Load balancer ingress is empty
   6:30:29PM: ---- waiting on 1 changes [322/323 done] ----
   ```

   Where `CONTOUR-NS` is the namespace where Contour is installed on your cluster. If Cloud Native Runtimes was installed as part of a Tanzu Application Profile, this value is likely `tanzu-system-ingress`.

Example 2: The webhook deployment failed

Follow these steps to identify and resolve the problem of the `webhook` deployment failing in the `knative-serving` namespace:

1. Review the logs for output similar to the following:

   ```
   10:51:58PM: ok: reconcile customresourcedefinition/httpproxies.projectcontour.i
   o (apiextensions.k8s.io/v1) cluster
   ```

```
10:51:58PM: fail: reconcile deployment/webhook (apps/v1) namespace: knative-ser
ving
10:51:58PM:  ^ Deployment is not progressing: ProgressDeadlineExceeded (messag
e: ReplicaSet "webhook-6f5d979b7d" has timed out progressing.)
```

2. Run `kubectl get pods` to find the name of the pod:

   ```
   kubectl get pods --show-labels -n NAMESPACE
   ```

   Where `NAMESPACE` is the namespace associated with the reconcile error, for example, `knative-serving`.

   For example,

   ```
   $ kubectl get pods --show-labels -n knative-serving
   NAME                       READY   STATUS    RESTARTS   AGE   LABELS
   webhook-6f5d979b7d-cxr9k   0/1     Pending   0          44h   app=webhook,kapp.
   k14s.io/app=1626302357703846007,kapp.k14s.io/association=v1.9621e0a793b4e925077
   dd557acedbcfe,pod-template-hash=6f5d979b7d,role=webhook
   ```

3. Run `kubectl logs` and `kubectl describe`:

   ```
   kubectl logs PODNAME -n NAMESPACE
   kubectl describe pod PODNAME -n NAMESPACE
   ```

   Where:

   - `PODNAME` is found in the output of step 3. For example, `webhook-6f5d979b7d-cxr9k`.
   - `NAMESPACE` is the namespace associated with the reconcile error, for example, `knative-serving`.

   For example:

   ```
   $ kubectl logs webhook-6f5d979b7d-cxr9k -n knative-serving

   $ kubectl describe pod webhook-6f5d979b7d-cxr9k  -n knative-serving
   Events:
   Type     Reason            Age                 From               Message
   ----     ------            ----                ----               -------
   Warning  FailedScheduling  80s (x14 over 14m)  default-scheduler  0/1 nodes are
   available: 1 Insufficient cpu.
   ```

4. Review the output from the `kubectl logs` and `kubectl describe` commands and take further action.

   For this example of the webhook deployment, the output indicates that the scheduler does not have enough CPU to run the pod. In this case, the solution is to add nodes or CPU cores to the cluster. If you are using Tanzu Mission Control (TMC), increase the number of workers in the node pool to three or more through the TMC UI. See Edit a Node Pool, in the TMC documentation.

Knative Service Fails to Come up Due to Invalid HTTPPRoxy

Symptom

When creating a Knative Service, it does not reach ready status. The corresponding Route resource has the status `Ready=Unknown` with `Reason=EndpointsNotReady`. When you inspect the logs for the `net-contour-controller`, you see an error like this:

{"severity":"ERROR","timestamp":"2022-12-08T16:27:08.320604183Z","logger":"net-contour-controller","caller":"ingress/reconciler.go:313","message":"Returned an error","commit":"041f9e3","knative.dev/controller":"knative.dev.net-contour.pkg.reconciler.contour.Reconciler","knative.dev/kind":"networking.internal.knative.dev.Ingress","knative.dev/traceid":"9d615387-f552-449c-a8cd-04c69dd1849e","knative.dev/key":"cody/foo-java","targetMethod":"ReconcileKind","error":"HTTPProxy.projectcontour.io \"foo-java-contour-5f549ae3e6f584a5f33d069a0650c0d8foo-java.cody.\" is invalid: metadata.name: Invalid value: \"foo-java-contour-5f549ae3e6f584a5f33d069a0650c0d8foo-java.cody.\": a lowercase RFC 1123 subdomain must consist of lower case alphanumeric characters, '-' or '.', and must start and end with an alphanumeric character (e.g. 'example.com', regex used for validation is '[a-z0-9]([-a-z0-9]*[a-z0-9])?(\.[a-z0-9]([-a-z0-9]*[a-z0-9])?)*')","stacktrace":"knative.dev/networking/pkg/client/injection/reconciler/networking/v1alpha1/ingress.(*reconcilerImpl).Reconcile\n\tknative.dev/networking@v0.0.0-20221012062251-58f3e6239b4f/pkg/client/injection/reconciler/networking/v1alpha1/ingress/reconciler.go:313\nknative.dev/pkg/controller.(*Impl).processNextWorkItem\n\tknative.dev/pkg@v0.0.0-20221011175852-714b7630a836/controller/controller.go:542\nknative.dev/pkg/controller.(*Impl).RunContext.func3\n\tknative.dev/pkg@v0.0.0-20221011175852-714b7630a836/controller/controller.go:491"}

Solution

Because the `ChildName` function produces invalid resource names, certain combinations of Name, Namespace, and Domain yield invalid names for HTTPProxy resources because of the way the name is hashed and trimmed to fit the size requirement. It can have non-alphanumeric characters at the end of the name.

Resolving this is unique to each Knative service. It is likely to involve renaming your app to be shorter so that after the hash and trim procedure, the name is cut to end on an alphanumeric character.

For example, `foo-java.cody.iterate.tanzu-azure-lab.winterfell.fun` is hashed and trimmed into `foo-java-contour-5f549ae3e6f584a5f33d069a0650c0d8foo-java.cody.`, leaving an invalid `.` at the end.

However, changing the app name to `foo-jav` causes `foo-jav-contour-SOME-DIFFERENT-HASH-foo-jav.cody.it`, which is a valid name.

Cloud Native Runtimes Reference

The following topics give you reference documentation for Cloud Native Runtimes:

- Compatibility Matrix

Integrations you can use with Cloud Native Runtimes

This topic lists integrations you can use with Cloud Native Runtimes.

Cloud Native Runtimes integrations

Cloud Native Runtimes Integration	Version	Documentation
VMware Tanzu Observability	Supported	Configuring Observability for Cloud Native Runtimes
Avi Vantage	Supported	Configuring Cloud Native Runtimes with Avi Vantage
Tanzu Service Mesh	Supported	Configuring Cloud Native Runtimes with Tanzu Service Mesh

For tools and software compatibility, see Prerequisites for installing Tanzu Application Platform.

Overview of Contour

Contour is an ingress controller for Kubernetes that supports dynamic configuration updates and multi-team ingress delegation. It provides the control plane for the Envoy edge and service proxy.

Document organization

The Contour component documentation consists of the following subsections that relate to what you want to achieve:

- How-to guides: To find a set of steps to solve a specific problem acting as a certain user persona.
- Reference: To find specific information such as Contour's APIs.

Overview of Contour

Contour is an ingress controller for Kubernetes that supports dynamic configuration updates and multi-team ingress delegation. It provides the control plane for the Envoy edge and service proxy.

Document organization

The Contour component documentation consists of the following subsections that relate to what you want to achieve:

- How-to guides: To find a set of steps to solve a specific problem acting as a certain user persona.
- Reference: To find specific information such as Contour's APIs.

Install Contour

This topic tells you how to install Contour from the Tanzu Application Platform (commonly known as TAP) package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install Contour. For more information about profiles, see Components and installation profiles.

To install Contour from the Tanzu Application Platform package repository without a profile:

1. Install cert-manager.
2. List version information for the package by running:

   ```
   tanzu package available list contour.tanzu.vmware.com -n tap-install
   ```

   For example:

   ```
   $  tanzu package available list contour.tanzu.vmware.com -n tap-install
     NAME                      VERSION       RELEASED-AT
     contour.tanzu.vmware.com  1.24.4        2023-05-22 19:00:00 -0500 -05
   ```

3. Create a file named `contour-rbac.yaml` by using the following sample and apply the configuration:

   ```
   apiVersion: rbac.authorization.k8s.io/v1
   kind: ClusterRole
   metadata:
   ```

```
  name: contour-tap-install-cluster-admin-role
rules:
- apiGroups:
  - '*'
  resources:
  - '*'
  verbs:
  - '*'
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: contour-tap-install-cluster-admin-role-binding
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: contour-tap-install-cluster-admin-role
subjects:
- kind: ServiceAccount
  name: contour-tap-install-sa
  namespace: tap-install
---
apiVersion: v1
kind: ServiceAccount
metadata:
  name: contour-tap-install-sa
  namespace: tap-install
```

4. Apply the configuration by running:

```
kubectl apply -f contour-rbac.yaml
```

5. Create a file named `contour-install.yaml` by using the following sample and apply the configuration:

Note

The following configuration installs the Contour package with default options. To make changes to the default installation settings, go to the next step.

```
apiVersion: packaging.carvel.dev/v1alpha1
kind: PackageInstall
metadata:
  name: contour
  namespace: tap-install
spec:
  serviceAccountName: contour-tap-install-sa
  packageRef:
    refName: contour.tanzu.vmware.com
    versionSelection:
      constraints: "VERSION-NUMBER"
      prereleases: {}
```

Where `VERSION-NUMBER` is the version of the package listed earlier.

6. (Optional) Make changes to the default installation settings:

    1. Gather values schema by running:

    ```
    tanzu package available get contour.tanzu.vmware.com/1.24.4 --values-sche
    ```

```
ma -n tap-install
```

For example:

```
$ tanzu package available get contour.tanzu.vmware.com/1.24.4 --values-sc
hema -n tap-install

  KEY                                                    DEFAULT
TYPE     DESCRIPTION
  kubernetes_distribution
string   The distribution of Kubernetes, used to determine if distributio
n-specific

configurations need to be applied. Options are empty and openshift. If ru
nning

on an OpenShift cluster, this must be set to openshift. When set to opens
hift,

a Role and RoleBinding are created to associate Contour's controllers wit
h the

appropriate OpenShift Security Context Constraint resource.
  kubernetes_version                                     0.0.0
string   The version of Kubernetes being used, for enabling version-speci
fic behaviors.

Accept any valid major.minor.patch version of Kubernetes. This field is

optional. Currently only has effect when kubernetes_distribution is set t
o

openshift.
  namespace                                              tanzu-system-
ingress      string   The namespace in which to deploy Contour and Envoy.
  registry_secret_names                                  [contour-reg-
creds]       array    The names of the placeholder secrets that will cont
ain registry credentials to

pull the Contour and Envoy images.
  certificates.duration                                  8760h
string   How long the certificates should be valid for.
  certificates.renewBefore                               360h
string   How long before expiration the certificates should be renewed.
  contour.pspNames                                       vmware-system
-restricted  string   Pod security policy names to apply to Contour.
  contour.replicas                                       2
integer  How many Contour pod replicas to have.
  contour.resources.contour.requests.memory
string   Memory request to apply to the contour container.
  contour.resources.contour.requests.cpu
string   CPU request to apply to the contour container.
  contour.resources.contour.limits.cpu
string   CPU limit to apply to the contour container.
  contour.resources.contour.limits.memory
string   Memory limit to apply to the contour container.
  contour.useProxyProtocol                               false
boolean  Whether to enable PROXY protocol for all Envoy listeners.
  contour.configFileContents                             <nil>
<nil>    The YAML contents of the Contour config file. See

https://projectcontour.io/docs/1.24/configuration/#configuration-file for
more

information.
  contour.logLevel                                       info
```

```
string   The Contour log level. Valid options are 'info' and 'debug'.
  envoy.pspNames
string   Pod security policy names to apply to Envoy.
  envoy.service.externalTrafficPolicy
string   The external traffic policy for the Envoy service. If type is 'C
lusterIP', this

field is ignored. Otherwise, defaults to 'Cluster' for vsphere and 'Loca
l' for

others.
  envoy.service.loadBalancerIP
string   The desired load balancer IP. If type is not 'LoadBalancer', thi
s field is

ignored. It is up to the cloud provider whether to honor this request. If
not

specified, then load balancer IP will be assigned by the cloud provider.
  envoy.service.nodePorts.http                                    0
integer  The node port number to expose Envoy's HTTP listener on. If not
specified, a

node port will be auto-assigned by Kubernetes.
  envoy.service.nodePorts.https                                   0
integer  The node port number to expose Envoy's HTTPS listener on. If not
specified, a

node port will be auto-assigned by Kubernetes.
  envoy.service.type
string   The type of Kubernetes service to provision for Envoy. Valid val
ues are

'LoadBalancer', 'NodePort', and 'ClusterIP'. If not specified, will defau
lt to

'NodePort' for vsphere and 'LoadBalancer' for others.
  envoy.service.annotations                                       <nil>
<nil>    Annotations to set on the Envoy service.
  envoy.service.aws.LBType                                        classic
string   The type of AWS load balancer to provision. Options are 'classi
c' and 'nlb'.
  envoy.service.disableWait                                       false
boolean  This setting is no longer supported and is included in the schem
a for backwards

compatibility only.
  envoy.terminationGracePeriodSeconds                             300
integer  The termination grace period, in seconds, for the Envoy pods.
  envoy.workload.replicas                                         2
integer  The number of Envoy replicas to deploy when 'type' is set to 'De
ployment'. If

not specified, it will default to '2'.
  envoy.workload.resources.envoy.limits.cpu
string   CPU limit to apply to the envoy container.
  envoy.workload.resources.envoy.limits.memory
string   Memory limit to apply to the envoy container.
  envoy.workload.resources.envoy.requests.cpu
string   CPU request to apply to the envoy container.
  envoy.workload.resources.envoy.requests.memory
string   Memory request to apply to the envoy container.
  envoy.workload.resources.shutdownManager.limits.cpu
string   CPU limit to apply to the shutdown-manager container.
  envoy.workload.resources.shutdownManager.limits.memory
string   Memory limit to apply to the shutdown-manager container.
```

```
  envoy.workload.resources.shutdownManager.requests.cpu
string   CPU request to apply to the shutdown-manager container.
  envoy.workload.resources.shutdownManager.requests.memory
string   Memory request to apply to the shutdown-manager container.
  envoy.workload.type                                        DaemonSet
string   The type of Kubernetes workload Envoy is deployed as. Options ar
e 'Deployment'

or 'DaemonSet'. If not specified, will default to 'DaemonSet'.
  envoy.hostNetwork                                          false
boolean  Whether to enable host networking for the Envoy pods.
  envoy.hostPorts.https                                      443
integer  If enable == true, the host port number to expose Envoy's HTTPS
listener on.
  envoy.hostPorts.enable                                     true
boolean  Whether to enable host ports. If false, http & https are ignore
d.
  envoy.hostPorts.http                                       80
integer  If enable == true, the host port number to expose Envoy's HTTP l
istener on.
  envoy.logLevel                                             info
string   The Envoy log level.
  infrastructure_provider                                    vsphere
string   The underlying infrastructure provider. Options are vsphere, aw
s, and azure.

This field is not required, but enables better validation and defaulting
if

provided.
```

2. Create a `contour-install.yaml` file by using the following sample as a guide:

Note

This sample is for installation in an AWS public cloud with `LoadBalancer` services.

```
apiVersion: packaging.carvel.dev/v1alpha1
kind: PackageInstall
metadata:
  name: contour
  namespace: tap-install
spec:
  serviceAccountName: contour-tap-install-sa
  packageRef:
    refName: contour.tanzu.vmware.com
    versionSelection:
      constraints: 1.24.4
      prereleases: {}
  values:
  - secretRef:
      name: contour-values
---
apiVersion: v1
kind: Secret
metadata:
  name: contour-values
  namespace: tap-install
stringData:
  values.yaml: |
    envoy:
      service:
```

```
        type: LoadBalancer
    infrastructure_provider: aws
```

The LoadBalancer type is appropriate for most installations, but local clusters such as `kind` can fail to complete the package install if LoadBalancer services are not supported.

For local clusters, you can configure `contour.envoy.service.type` to be `NodePort`. If your local cluster is set up with extra port mappings on the nodes, you might also need configure `envoy.service.nodePorts.http` and `envoy.service.nodePorts.https` to match the port mappings from your local machine into one of the nodes of your local cluster.

Contour provides an Ingress implementation by default. If you have another Ingress implementation in your cluster, you must explicitly specify an IngressClass to select a particular implementation.

Cloud Native Runtimes programs Contour HTTPRoutes are based on the installed namespace. The default installation of Cloud Native Runtimes uses a single Contour to provide internet-visible services. You can install a second Contour instance with service type `ClusterIP` if you want to expose some services to only the local cluster. The second instance must be installed in a separate namespace. You must set the Cloud Native Runtimes value `ingress.internal.namespace` to point to this namespace.

7. Install the package by running:

```
kubectl apply -f contour-install.yaml
```

8. Verify the package install by running:

```
tanzu package installed get contour -n tap-install
```

For example:

```
$ tanzu package installed get contour -n tap-install

NAME:                    contour
PACKAGE-NAME:            contour.tanzu.vmware.com
PACKAGE-VERSION:         1.24.4
STATUS:                  Reconcile succeeded
CONDITIONS:              [{ReconcileSucceeded True  }]
USEFUL-ERROR-MESSAGE:
```

Verify that `STATUS` is `Reconcile succeeded`

9. Verify the installation by running:

```
kubectl get po -n tanzu-system-ingress
```

For example:

```
$  kubectl get po -n tanzu-system-ingress
NAME                       READY   STATUS    RESTARTS   AGE
contour-689789679f-cl8cg   1/1     Running   0          6d16h
contour-689789679f-g2xjn   1/1     Running   0          6d16h
envoy-2blkl                2/2     Running   0          6d16h
envoy-2rjtb                2/2     Running   0          6d16h
envoy-9sljz                2/2     Running   0          6d16h
envoy-cv5fc                2/2     Running   0          6d16h
```

```
envoy-gvtlf                2/2     Running   0          6d16h
envoy-qtrxd                2/2     Running   0          6d16h
```

Ensure that all pods are `Running` with all containers ready.

Contour how-to guides

This section contains the following how-to guides for Contour:

- Configure Cipher Suites and TLS version in Contour
- Configure Contour to propagate header with Domain Mapping
- Configure Contour to support TLS termination at an AWS LoadBalancer
- Troubleshoot Contour

Configure Cipher Suites and TLS version in Contour

This topic tells you how to configure TLS options for Contour in Tanzu Application Platform (commonly known as TAP).

Contour provides configuration options for TLS version and Cipher Suites. Rather than directly exposed through a top level key in the pacakge, they fall into the category of advanced Contour configurations by using the `contour.configFileContents` key. For more information about these configuration options, see Contour documentation.

To configure TLS options for Contour in Tanzu Application Platform, edit the `contour` section of your TAP values file as follows:

```
contour:
  # ... there maybe some configuration already here
  contour:
    configFileContents:
      tls:
        minimum-protocol-version: "1.2"
        cipher-suites:
        - '[ECDHE-ECDSA-AES128-GCM-SHA256|ECDHE-ECDSA-CHACHA20-POLY1305]'
        - '[ECDHE-RSA-AES128-GCM-SHA256|ECDHE-RSA-CHACHA20-POLY1305]'
        - 'ECDHE-ECDSA-AES256-GCM-SHA384'
        - 'ECDHE-RSA-AES256-GCM-SHA384'
```

Expect to see the following Cipher Suites and TLS version data in the Contour configmap:

```
$ kubectl -n tanzu-system-ingress get configmap contour -oyaml
apiVersion: v1
data:
  contour.yaml: |
    tls:
      minimum-protocol-version: "1.2"
      cipher-suites:
      - '[ECDHE-ECDSA-AES128-GCM-SHA256|ECDHE-ECDSA-CHACHA20-POLY1305]'
      - '[ECDHE-RSA-AES128-GCM-SHA256|ECDHE-RSA-CHACHA20-POLY1305]'
      - ECDHE-ECDSA-AES256-GCM-SHA384
      - ECDHE-RSA-AES256-GCM-SHA384
kind: ConfigMap
metadata:
...
```

Important

To update the configmap, you must configure it through Tanzu Application Platform values file. If you change it directly in the configmap, kapp-controller reverts all the changes you made.

Configure Contour to propagate header with Domain Mapping

This topic tells you how to configure Contour for header propagation with Knative Domain Mapping and autoTLS certs.

After `autoTLS` is enabled, a request for a Knative service with Domain Mapping might not maintain the `x-forwaded-proto` header. This can cause issues when the request is forwarded to a system expecting this header to be set to `https`, for example, Spring Security SSO.

You can solve this issue by configuring Contour with `num-trusted-hops: 1`. This allows the header to correctly propagate by using Domain Mapping.

Important

To update the configmap, you must configure it in the Tanzu Application Platform values file. If you change it directly in the configmap, kapp-controller reverts all the changes you made.

Example configuration for Contour by using the Tanzu Application Platform values file (commonly called `tap-values.yaml`):

```
contour:
  contour:
    configFileContents:
      num-trusted-hops: 1
```

Configure Contour to support TLS termination against AWS Elastic Load Balancing

This topic tells you how to configure Contour to accept traffic from an AWS LoadBalancer that stops TLS traffic.

For more information, see the AWS Knowledge Center documentation.

About certificates and domains

This topic focuses on using a wildcard certificate for your domain. For example, if your domain is `bigbiz.com`, the certificate must be for the wildcard domain `*.bigbiz.com`, and everything routed by using Contour must fit that domain pattern.

However, in Tanzu Application Platform, the default URL pattern for Web Workloads, for example, Knative Services, is `{{.Name}}.{{.Namespace}}.{{.Domain}}`.

The wildcard certificate mentioned earlier does not apply to these URLs. To address this, this topic describes how to configure Cloud Native Runtimes so that Web Workload URLs also fit the wildcard domain.

You can keep the default URL pattern if your `DOMAIN` includes the namespace where Web Workloads are deployed.

Prerequisites

The following are required before proceeding with the configuration:

- An EKS cluster.
- The Contour package installed on the cluster, either as part of Tanzu Application Platform or from the standalone component installation. For more information, see Install Contour.
- Access to AWS Certificate Manager.
- A domain registered in Route53 or elsewhere. This topic refers to this domain as `DOMAIN`.

Create a TLS certificate in ACM

Create a public TLS certificate for `*.DOMAIN` by using AWS Certificate Manager (ACM). For more information, see the AWS documentation.

Important

Record the `ARN` of the created certificate, which is required in the following steps.

Configure Tanzu Application Platform

Follow these steps to configure your Tanzu Application Platform:

1. Create the following overlay in `overlay-contour-envoy-secret.yaml`:

```
apiVersion: v1
kind: Secret
metadata:
name: overlay-contour-envoy
namespace: tap-install
stringData:
overlay-contour-envoy.yml: |
  #@ load("@ytt:overlay", "overlay")

  #@overlay/match by=overlay.subset({"kind": "Service", "metadata": {"name": "e
nvoy"}})
  ---
  spec:
    ports:
    #@overlay/match by=overlay.subset({"name":"https"})
    -
      targetPort: 8080
```

2. Apply the overlay to your cluster:

```
kubectl apply -f overlay-contour-envoy-secret.yaml
```

3. Add the following configurations to your Tanzu Application Platform values file:

```
shared:
  ingress_issuer: ""
  ingress_domain: DOMAIN

tap_gui:
  app_config:
    app:
      baseUrl: https://tap-gui.DOMAIN #! note the change in scheme
    backend:
```

```
      baseUrl: https://tap-gui.DOMAIN #! note the change in scheme
      reading:
        allow:
        - host: "*.DOMAIN"

cnrs:
  default_external_scheme: "https"
  ingress_issuer: ""
  domain_template: "{{.Name}}-{{.Namespace}}.{{.Domain}}"

contour:
  infrastructure_provider: aws
  envoy:
    service:
      aws:
        LBType: nlb
      annotations:
        service.beta.kubernetes.io/aws-load-balancer-ssl-cert: ARN
        service.beta.kubernetes.io/aws-load-balancer-backend-protocol: http

package_overlays:
- name: contour
  secrets:
  - name: overlay-contour-envoy
```

Where `ARN` is the ARN recorded in Create a TLS certificate in ACM.

To use the Classic LoadBalancer, remove `contour.envoy.service.aws.LBType: nlb`.

4. Update your Tanzu Application Platform installation:

```
tanzu package installed update tap -n tap-install --values-file tap-values.yaml
-p tap.tanzu.vmware.com -v VERSION
```

Where `VERSION` is the version of Tanzu Application Platform in use, which must be in the form of `X.X.X`.

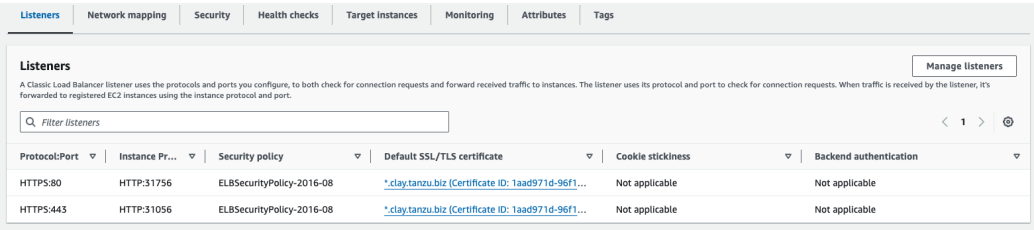
Configure AWS

Follow these steps to configure your AWS:

1. (Optional) Find the load balancer associated with Contour's Envoy LoadBalancer Service and verify the configuration of HTTPS listeners.

   You must have an AWS LoadBalancer pointing to Contour's Envoys.

   There are two listeners, 80 and 443, on your LoadBalancer. Both listeners use the certificate associated with the `ARN` in your tap-values file.



Note

AWS adds SSL or HTTPS listeners for all ports on the Kubernetes service by default. In the context of this topic, it indicates that port 80 is also configured to listen on HTTPS. To leave port 80 open to HTTP traffic, you can add the annotation `service.beta.kubernetes.io/aws-load-balancer-`

`ssl-ports: "https"` to your tap-values file at `contour.envoy.service.annotations`. The annotation adds an SSL or HTTPS listener for the `https` port on the service. For more information about the annotations, see the AWS cloud provider documentation.

2. Configure the domain name system (DNS).
    1. Get the External IP of the Envoy service:

        ```
        kubectl get svc envoy -n NAMESPACE
        ```

        Where `NAMESPACE` is the namespace where Contour is installed. The default value is `tanzu-system-ingress` unless configured otherwise.

        The result resembles the following:

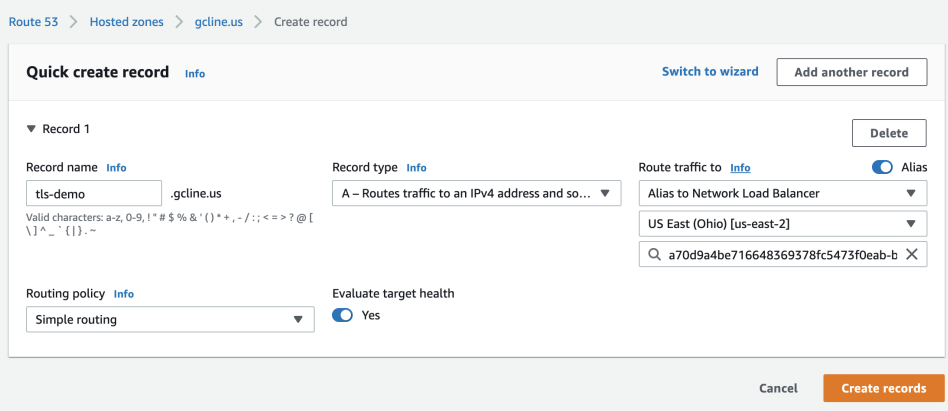
        ```
        NAME     TYPE           CLUSTER-IP      EXTERNAL-IP
        PORT(S)             AGE
         envoy   LoadBalancer   10.100.24.154   a7ea2bbde8a164036a7e4c1ed5700cdf-
        154fb911d990bb1f.elb.us-east-2.amazonaws.com   443:31606/TCP      40d
        ```

    2. Create a DNS record pointing from `DOMAIN` to the NLB Domain, which is the External IP address from the earlier step in this procedure.

        In the **Route traffic to** section, you must set:

        - Alias to Network LoadBalancer.
        - The appropriate region for your NLB.
        - The name of your NLB domain from the previous step.

        It resembles the following:

Important

If not using AWS Route53, you must create a CNAME entry in your DNS provider. Otherwise, with AWS Route53, you can create an “A” record type, and alias it to the Network LoadBalancer.

Verify the configuration

If you have a Web Workload on the cluster, you can verify that it is available at `https://appname-appnamespace.DOMAIN`.

Troubleshoot Contour

This topic tells you how to troubleshoot Contour installation and configuration.

Envoy pods fail with malformed IP address errors

Symptom:

The Contour package fails to reconcile, and the Envoy pods fail with errors like:

```
23-11-23 01:55:11.503][1][warning][config] [source/common/config/grpc_subscription_imp
l.cc:128] gRPC config for type.googleapis.com/envoy.config.listener.v3.Listener reject
ed: Error adding/updating listener(s) ingress_http: malformed IP address: ::
```

Explanation:

By default, the Contour package programs Envoy's listeners to use IPv6 addresses. In most cases, this is OK. However, some clusters, such as TKGI, only support IPv4.

Solution:

Important

This solution only applies to Contour v1.26 or later, which is included in Tanzu Application Platform v1.8.0 and later.

To use IPv4 addresses on the listeners, update the Tanzu Application Platform values file (commonly called `tap-values.yaml`).

The following is an example of the Contour section of the values file:

```
contour:
  envoy:
    listenIPFamily: IPv4
```

Contour reference

This section contains reference documentation for using Contour.

Open source Documentation

The Contour open source documentation contains more detailed Contour-specific reference information for advanced use, including:

- API reference
- Configuration reference
- Compatability matrix

Important

There may be some features or configurations that are not accessible by using the Contour package API in Tanzu Application Platform.

Overview of Crossplane

Crossplane is an open source, Cloud Native Computing Foundation (CNCF) project built on the foundation of Kubernetes. Tanzu Application Platform (commonly known as TAP) uses Crossplane to power a number of capabilities, such as dynamic provisioning of services instances with Services Toolkit and the Bitnami Services.

Note

If installing Tanzu Application Platform to a cluster that already has Crossplane installed, see Use your existing Crossplane installation.

Crossplane with Tanzu Application Platform

Tanzu Application Platform includes a Carvel package named `crossplane.tanzu.vmware.com`, which is included by default in the full, iterate, and run profiles. The package installs Upbound Universal Crossplane (UXP).

In addition, the package includes two pre-configured Crossplane providers: provider-helm and provider-kubernetes. Both of providers provide useful Managed Resources that you can use as part of Composition. These are both used by Tanzu Application Platform's Bitnami Services.

The package installs UXP and the providers to the `crossplane-system` namespace.

Getting started

To learn about working with Crossplane in general, see the Crossplane documentation. To learn about how Tanzu Application Platform integrates with Crossplane, see one of the following tutorials to get started.

For apps teams:

- Tutorial: Working with Bitnami Services

For ops teams:

- Tutorial: Setup Dynamic Provisioning of Service Instances
- How-to guide: Use your existing Crossplane installation
- How-to guide: Delete Crossplane resources when you uninstall Tanzu Application Platform

Alternatively, see the reference material.

Overview of Crossplane

Crossplane is an open source, Cloud Native Computing Foundation (CNCF) project built on the foundation of Kubernetes. Tanzu Application Platform (commonly known as TAP) uses Crossplane to power a number of capabilities, such as dynamic provisioning of services instances with Services Toolkit and the Bitnami Services.

Note

Install Crossplane

This topic tells you how to install Crossplane from the Tanzu Application Platform (commonly known as TAP) package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install Crossplane. For more information about profiles, see Components and installation profiles.

If installing Tanzu Application Platform to a cluster that already has Crossplane installed, see Use your existing Crossplane installation.

Prerequisites

Before installing Crossplane:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.

Install Crossplane

To install Crossplane:

1. See what versions of Crossplane are available to install by running:

   ```
   tanzu package available list -n tap-install crossplane.tanzu.vmware.com
   ```

   For example:

```
$ tanzu package available list -n tap-install crossplane.tanzu.vmware.com
  NAME                              VERSION           RELEASED-AT
  crossplane.tanzu.vmware.com       0.1.1             2023-03-10 14:24:35 +000
0 UTC
```

2. Install Crossplane by running:

   ```
   tanzu package install crossplane \
     --package crossplane.tanzu.vmware.com \
     --version VERSION-NUMBER \
     --namespace tap-install
   ```

   Where `VERSION-NUMBER` is the Crossplane version you want to install. For example, `0.1.1`.

3. Verify that the package installed by running:

   ```
   tanzu package installed get crossplane -n tap-install
   ```

   In the output, confirm that the `STATUS` value is `Reconcile succeeded`.

   For example:

   ```
   $ tanzu package installed get crossplane -n tap-install
   NAMESPACE:          tap-install
   NAME:               crossplane
   PACKAGE-NAME:       crossplane.tanzu.vmware.com
   PACKAGE-VERSION:    0.1.1
   STATUS:             Reconcile succeeded
   CONDITIONS:         - type: ReconcileSucceeded
     status: "True"
     reason: ""
     message: ""
   ```

Crossplane how-to guides

This section contains how-to guides for Crossplane.

In this section:

- Use your existing Crossplane installation
- Delete Crossplane resources when you uninstall Tanzu Application Platform
- Troubleshoot Crossplane

Use your existing Crossplane installation

This topic describes how to install Tanzu Application Platform (commonly known as TAP) to a cluster that already has Crossplane installed. This also applies if you want to install Crossplane without using the Tanzu application Platform package, for example, through Helm install.

About installing the Crossplane package

The `crossplane.tanzu.vmware.com` package is included with the Full, Iterate and Run profiles. By default, any installation of Tanzu Application Platform using one of these profiles installs Crossplane to the cluster through the package. In most cases, this is desirable because Crossplane is necessary to support many of the service related capabilities that Tanzu Application Platform offers.

There are some cases where installing the Crossplane package by default is not desirable. For example, if you plan to install Tanzu Application Platform to a cluster that already has Crossplane

installed on it, or if you want to install Crossplane by some other means.

Exclude the Crossplane package from the installation

If you want to install Crossplane by other means, exclude the Crossplane package from the Tanzu Application Platform installation.

To do so, add the `crossplane.tanzu.vmware.com` package to the `excluded_packages` array in the `tap-values.yaml` file as follows:

```
# tap-values.yaml

excluded_packages:
- crossplane.tanzu.vmware.com
```

Important

Other Tanzu Application Platform components might depend on the Crossplane package, for example, Bitnami Services. If you exclude the Crossplane package, you must also exclude any other Tanzu Application Platform package that depends on it.

Delete Crossplane resources when you uninstall Tanzu Application Platform

This topic describes how to configure the Crossplane package to either retain or delete Crossplane resources when you uninstall Tanzu Application Platform.

About deleting Crossplane resources

By default, the `crossplane.tanzu.vmware.com` package is configured to retain all Crossplane CRDs, providers, and managed resources when the package is uninstalled. This is in the interest of caution in relation to accidental deletion of stateful data.

Consider the following scenario. An organization is using Tanzu Application Platform. They have installed the AWS Provider for Crossplane and are offering development teams self-serve access to AWS RDS databases through Dynamic Provisioning. Development teams have created a number of AWS RDS databases and have bound them to their application workloads. The AWS RDS databases now contain stateful data for the applications. If an operator decides to uninstall Tanzu Application Platform, what happens to the AWS RDS databases?

The answer depends on whether you view the life cycle of external services provisioned through the platform to be tied to the life cycle of the platform itself. By default, Tanzu Application Platform does not tie the life cycle of the platform to the life cycle of external services. This means that you must delete any external resources after deleting Tanzu Application Platform. However, Tanzu Application Platform provides the package value `orphan_resources` to override this default behavior.

Override the default retention behavior

You can configure Tanzu Application Platform to delete Crossplane resources to avoid orphaned resources. To do so, update the `tap-values.yaml` as follows:

```
# tap-values.yaml
```

```
crossplane:
  orphan_resources: false
```

Troubleshoot Crossplane

This topic explains how you troubleshoot issues related to Crossplane on Tanzu Application Platform (commonly known as TAP).

For the limitations of Crossplane, see Crossplane limitations.

Resource already exists error when installing Crossplane

Symptom:

Installation of Crossplane, or a Tanzu Application Platform profile that includes Crossplane, fails with the error:

```
Resource already exists
```

Explanation:

Crossplane is already installed on the cluster. You cannot install the Crossplane package on a cluster that already has Crossplane installed on it by using another method, such as Helm install.

Solution:

Exclude the Crossplane package in the `tap-values.yaml` file. For more information, see Use your existing Crossplane installation.

The `validatingwebhookconfiguration` is not removed when you uninstall the Crossplane Package

Symptom:

The Crossplane Package deploys a `validatingwebhookconfiguration` named `crossplane` during installation. This resource is not deleted when you uninstall the Package.

Solution:

Delete the `validatingwebhookconfiguration` manually by running:

```
kubectl delete validatingwebhookconfiguration crossplane
```

Crossplane reference

This section provides reference documentation for Crossplane.

In this section:

- Package values
- Version matrix
- Crossplane limitations

Package values for Crossplane

This topic lists the keys and values you can use to configure the behavior of the Crossplane package. Configuration is split between configuration specific to Crossplane in Tanzu Application

Platform (commonly known as TAP) and configuration of the Upbound Universal Crossplane (UXP) Helm Chart.

If you are applying configuration to Tanzu Application Platform through the use of profiles and the `tap-values.yaml`, all configuration must exist under the `crossplane` top-level key.

For example:

```
crossplane:
  replicas: 3
```

Tanzu Application Platform configuration

The following table lists configuration specific to Crossplane in Tanzu Application Platform.

KEY	DEFAULT	TYPE	DESCRIPTION
kubernetes_version	`""`	string	Optional: The Kubernetes version. Valid values are `''` or take the form `'1.25.0'`
kubernetes_distribution	`""`	string	Optional: The Kubernetes distribution. Valid values are `''` or `'openshift'`
orphan_resources	`true`	boolean	Optional: Whether to orphan Crossplane CRDs, providers, and managed resources when the package is uninstalled. If `false` the resources are deleted.
adopt_resources	`false`	boolean	Optional: Whether to adopt existing Crossplane CRDs and resources when the package is installed.
ca_cert_data	`""`	string	Optional: PEM-encoded certificate data for Crossplane to trust TLS connections with a custom CA certificate.

Standard Crossplane configuration

The following table lists configuration for the UXP Helm Chart.

KEY	DEFAULT	TYPE	DESCRIPTION
replicas	`1`	integer	
serviceAccount.customAnnotations	`'{}'`	object	
bootstrapper.resources	`'{}'`	object	
bootstrapper.config.args		array	
bootstrapper.config.debugMode	`false`	boolean	
bootstrapper.config.envVars	`'{}'`	object	
bootstrapper.image.pullPolicy	`IfNotPresent`	string	
bootstrapper.image.repository	`xpkg.upbound.io/upbound/uxp-bootstrapper`	string	

KEY	DEFAULT	TYPE	DESCRIPTION
bootstrapper.image.tag	`v1.11.0-up.1`	string	
maxReconcileRate	`""`	string	How frequently Crossplane reconciles its resources in seconds.
metrics.enabled	`false`	boolean	
securityContextCrossplane.allowPrivilegeEscalation	`false`	boolean	
securityContextCrossplane.readOnlyRootFilesystem	`true`	boolean	
securityContextCrossplane.runAsGroup	`65532`	integer	
securityContextCrossplane.runAsUser	`65532`	integer	
xfn.securityContext.allowPrivilegeEscalation	`false`	boolean	
xfn.securityContext.capabilities.add		array	
xfn.securityContext.readOnlyRootFilesystem	`true`	boolean	
xfn.securityContext.runAsGroup	`65532`	integer	
xfn.securityContext.runAsUser	`65532`	integer	
xfn.securityContext.seccompProfile.type	`Unconfined`	string	
xfn.args	`'{}'`	object	
xfn.cache.configMap	`""`	string	
xfn.cache.medium	`""`	string	
xfn.cache.pvc	`""`	string	
xfn.cache.sizeLimit	`1Gi`	string	
xfn.enabled	`false`	boolean	

KEY	DEFAULT	TYPE	DESCRIPTION
xfn.extraEnvVars	`'{}'`	object	
xfn.image.pullPolicy	`IfNotPresent`	string	
xfn.image.repository	`crossplane/xfn`	string	
xfn.image.tag	`v1.11.0-up.1`	string	
xfn.resources.requests.cpu	`1000m`	string	
xfn.resources.requests.memory	`1Gi`	string	
xfn.resources.limits.memory	`2Gi`	string	
xfn.resources.limits.cpu	`2000m`	string	
resourcesCrossplane.limits.cpu	`500m`	string	
resourcesCrossplane.limits.memory	`1Gi`	string	
resourcesCrossplane.requests.cpu	`250m`	string	
resourcesCrossplane.requests.memory	`768Mi`	string	
resourcesRBACManager.limits.memory	`768Mi`	string	
resourcesRBACManager.limits.cpu	`100m`	string	
resourcesRBACManager.requests.cpu	`100m`	string	
resourcesRBACManager.requests.memory	`512Mi`	string	
configuration.packages		array	
deploymentStrategy	`RollingUpdate`	string	
extraEnvVarsCrossplane	`'{}'`	object	List of extra environment variables to set in the Crossplane deployment. For example, `extraEnvironmentVars: sample.key: value1 ANOTHER.KEY: value2` results with `- name: sample_key value: "value1" - name: ANOTHER_KEY value: "value2"`
registryCaBundleConfig	`'{}'`	object	

KEY	DEFAULT	TYPE	DESCRIPTION
billing.awsMarketplace.iamRoleARN	`arn:aws:iam::ACCOUNT-ID>:role/ROLE-NAME`	string	
billing.awsMarketplace.enabled	`false`	boolean	
image.pullPolicy	`IfNotPresent`	string	
image.repository	`upbound/crossplane`	string	
image.tag	`v1.11.0-up.1`	string	
packageCache.configMap	`""`	string	
packageCache.medium	`""`	string	
packageCache.pvc	`""`	string	
packageCache.sizeLimit	`5Mi`	string	
securityContextRBACManager.allowPrivilegeEscalation	`false`	boolean	
securityContextRBACManager.readOnlyRootFilesystem	`true`	boolean	
securityContextRBACManager.runAsGroup	`65532`	integer	
securityContextRBACManager.runAsUser	`65532`	integer	
rbacManager.managementPolicy	`Basic`	string	
rbacManager.nodeSelector	`'{}'`	object	
rbacManager.affinity	`'{}'`	object	
rbacManager.args	`'{}'`	object	
rbacManager.deploy	`true`	boolean	
rbacManager.leaderElection	`true`	boolean	

KEY	DEFAULT	TYPE	DESCRIPTION
rbacManager.replicas	`1`	integer	
rbacManager.skipAggregatedClusterRoles	`true`	boolean	
rbacManager.tolerations		array	
customAnnotations	`'{}'`	object	Custom annotations to add to the Crossplane deployment and pod.
customLabels	`'{}'`	object	Custom labels to add into metadata.
leaderElection	`true`	boolean	
nodeSelector	`'{}'`	object	
podSecurityContextCrossplane	`'{}'`	object	
webhooks.enabled	`false`	boolean	
args	`'{}'`	object	
podSecurityContextRBACManager	`'{}'`	object	
provider.packages		array	
tolerations		array	
upbound.controlPlane.permission	`edit`	string	
affinity	`'{}'`	object	
extraEnvVarsRBACManager	`'{}'`	object	List of extra environment variables to set in the Crossplane RBAC manager deployment. For example, `extraEnvironmentVars: sample.key: value1 ANOTHER.KEY: value2` results with `- name: sample_key value: "value1" - name: ANOTHER_KEY value: "value2"`
nameOverride	`crossplane`	string	
priorityClassName	`""`	string	

Version matrix for Crossplane

This topic provides you with a version matrix for the Crossplane package and its open source components in Tanzu Application Platform v1.9 (commonly known as TAP).

To view this information for another Tanzu Application Platform version, select the version from the drop-down menu at the top of this page.

The following table has the component versions for the Crossplane package.

Component	Version
Crossplane package	0.5.0
UXP	1.15.0-up.1
Upbound Crossplane	1.15.0-up.1
provider-helm	0.15.0
provider-kubernetes	0.12.1

Note

Tanzu Application Platform patch releases are only added to the table when there is a change to one or more of the other versions in the table. Otherwise, the corresponding versions remain the same for each Tanzu Application Platform patch release.

Crossplane limitations

This topic tells you about the limitations related to Crossplane on Tanzu Application Platform (commonly known as TAP).

For troubleshooting guidance, see Troubleshoot Crossplane.

Cluster performance degradation due to large number of CRDs

Take care before installing extra Crossplane Providers into Tanzu Application Platform. Some Providers install hundreds of additional CRDs into the cluster.

This is particularly true of the Providers for AWS, Azure, and GCP. For the number of CRDs installed with these Providers, see:

- provider-aws CRDs
- provider-azure CRDs
- provider-gcp CRDs

You must ensure that your cluster has sufficient resource to support this number of additional CRDs if you choose to install them.

Workaround:

To address this issue, Upbound have released a new feature named Provider Families. For more information, see the Crossplane blog.

Overview of Default roles for Tanzu Application Platform

Tanzu Application Platform (commonly known as TAP) v1.9 includes:

- Documentation for using your existing identity management solution for Kubernetes authentication. For more information, see Set up authentication for your Tanzu Application Platform deployment.
- Six default roles for providing authorization for users and service accounts within a namespace on a cluster that runs one of the Tanzu Application Platform profiles. For more

information about service accounts, see the Kubernetes documentation.

Default roles

Tanzu Application Platform has resources that are namespace scoped, such as workloads, pipelineruns, builds and resources that are cluster scoped, such as clusterbuilders, clustersupplychains, clusterimagetemplates. Tanzu Application Platform provides four roles that include both a namespace scoped role and a cluster scoped role:

Role name	Role description	Namespace scoped role name	Cluster scoped role name
app-editor	View, create, edit, and delete a Tanzu workload or deliverable.	app-editor	app-editor-cluster-access
app-viewer	Read-only for a Tanzu workload or deliverable.	app-viewer	app-view-cluster-access
app-operator	View, create, edit, and delete supply chain resources.	app-operator	app-operator-cluster-access
service-operator	View, create, edit, and delete service instances, service instance classes, and resource claim policies.	service-operator	service-operator-cluster-access

For more information about the different roles and their permissions, see Role descriptions for Tanzu Application Platform.

Additionally, the following two roles are available for service accounts for namespace scoped resources associated with Tanzu Supply Chains:

Role name	Namespace scoped role name
workload	workload
deliverable	deliverable

The default roles provide an opinionated starting point for the most common permissions that users need when using Tanzu Application Platform. However, as described in the Kubernetes documentation about RBAC, you can create customized roles and permissions that better meet your needs. Aggregated cluster roles are used to build VMware Tanzu Application Platform default roles.

Cluster admins must be careful when creating Roles or ClusterRoles. When changing roles or adding new roles that carry one of the labels used by the default roles, the roles are automatically updated to the aggregation state. It can lead to unintentional changes in functions and permissions to all users.

The default roles are installed with every Tanzu Application Platform profile except for `view`.

Assigning with roles using kubectl

For more information about assigning roles to users, see Bind a user or group to a default role.

Disclaimer

Tanzu Developer Portal does not make use of the described roles. Instead, it provides the user with view access for each cluster.

Overview of Default roles for Tanzu Application Platform

Tanzu Application Platform (commonly known as TAP) v1.9 includes:

- Documentation for using your existing identity management solution for Kubernetes authentication. For more information, see Set up authentication for your Tanzu Application Platform deployment.
- Six default roles for providing authorization for users and service accounts within a namespace on a cluster that runs one of the Tanzu Application Platform profiles. For more information about service accounts, see the Kubernetes documentation.

Default roles

Tanzu Application Platform has resources that are namespace scoped, such as workloads, pipelineruns, builds and resources that are cluster scoped, such as clusterbuilders, clustersupplychains, clusterimagetemplates. Tanzu Application Platform provides four roles that include both a namespace scoped role and a cluster scoped role:

Role name	Role description	Namespace scoped role name	Cluster scoped role name
app-editor	View, create, edit, and delete a Tanzu workload or deliverable.	app-editor	app-editor-cluster-access
app-viewer	Read-only for a Tanzu workload or deliverable.	app-viewer	app-view-cluster-access
app-operator	View, create, edit, and delete supply chain resources.	app-operator	app-operator-cluster-access
service-operator	View, create, edit, and delete service instances, service instance classes, and resource claim policies.	service-operator	service-operator-cluster-access

For more information about the different roles and their permissions, see Role descriptions for Tanzu Application Platform.

Additionally, the following two roles are available for service accounts for namespace scoped resources associated with Tanzu Supply Chains:

Role name	Namespace scoped role name
workload	workload
deliverable	deliverable

The default roles provide an opinionated starting point for the most common permissions that users need when using Tanzu Application Platform. However, as described in the Kubernetes documentation about RBAC, you can create customized roles and permissions that better meet your needs. Aggregated cluster roles are used to build VMware Tanzu Application Platform default roles.

Cluster admins must be careful when creating Roles or ClusterRoles. When changing roles or adding new roles that carry one of the labels used by the default roles, the roles are automatically updated to the aggregation state. It can lead to unintentional changes in functions and permissions to all users.

The default roles are installed with every Tanzu Application Platform profile except for `view`.

Assigning with roles using kubectl

For more information about assigning roles to users, see Bind a user or group to a default role.

Disclaimer

Tanzu Developer Portal does not make use of the described roles. Instead, it provides the user with view access for each cluster.

Set up authentication for your Tanzu Application Platform deployment

There are multiple ways to set up authentication for your Tanzu Application Platform (commonly known as TAP) deployment. You can manage authentication at the infrastructure level with your Kubernetes provider, such as Tanzu Kubernetes Grid, EKS, AKS, or GKE.

VMware recommends Pinniped for integrating your identity management into Tanzu Application Platform on multicloud. It provides many supported integrations for widely used identity providers. To use Pinniped, see Installing Pinniped on Tanzu Application Platform and Log in by using Pinniped.

See Integrating Azure Active Directory for Azure Active Directory Integration.

Tanzu Kubernetes Grid

For Tanzu Kubernetes Grid clusters, Pinniped is the default identity solution and is installed as a core package. For more information, see Core Packages and Enable Identity Management in an Existing Deployment in the Tanzu Kubernetes Grid documentation.

Set up authentication for your Tanzu Application Platform deployment

There are multiple ways to set up authentication for your Tanzu Application Platform (commonly known as TAP) deployment. You can manage authentication at the infrastructure level with your Kubernetes provider, such as Tanzu Kubernetes Grid, EKS, AKS, or GKE.

VMware recommends Pinniped for integrating your identity management into Tanzu Application Platform on multicloud. It provides many supported integrations for widely used identity providers. To use Pinniped, see Installing Pinniped on Tanzu Application Platform and Log in by using Pinniped.

See Integrating Azure Active Directory for Azure Active Directory Integration.

Tanzu Kubernetes Grid

For Tanzu Kubernetes Grid clusters, Pinniped is the default identity solution and is installed as a core package. For more information, see Core Packages and Enable Identity Management in an Existing Deployment in the Tanzu Kubernetes Grid documentation.

Install Pinniped on Tanzu Application Platform

Pinniped is used to support authentication on Tanzu Application Platform (commonly known as TAP). This topic tells you how to install Pinniped on a single cluster of Tanzu Application Platform.

Note

This topic only provides an example of one possible installation method for Pinniped on Tanzu Application Platform by using the default Contour ingress controler

included in the platform. See Pinniped documentation for more information about the specific installation method that suits your environment.

Use this topic to learn how to deploy two Pinniped components into the cluster:

- **Pinniped Supervisor:** An OIDC server which allows users to authenticate with an external identity provider (IDP). It hosts an API for the concierge component to fulfill authentication requests.
- **Pinniped Concierge:** A credential exchange API that takes a credential from an identity source, for example, Pinniped Supervisor, proprietary IDP, as input. The Pinniped Concierge authenticates the user by using the credential, and returns another credential that is parsable by the host Kubernetes cluster or by an impersonation proxy that acts on behalf of the user.

Prerequisites

Meet these prerequisites:

- Install the package `certmanager`. This is included in Tanzu Application Platform.
- Install the package `contour`. This is included in Tanzu Application Platform.
- Create a `workspace` directory to function as your workspace.

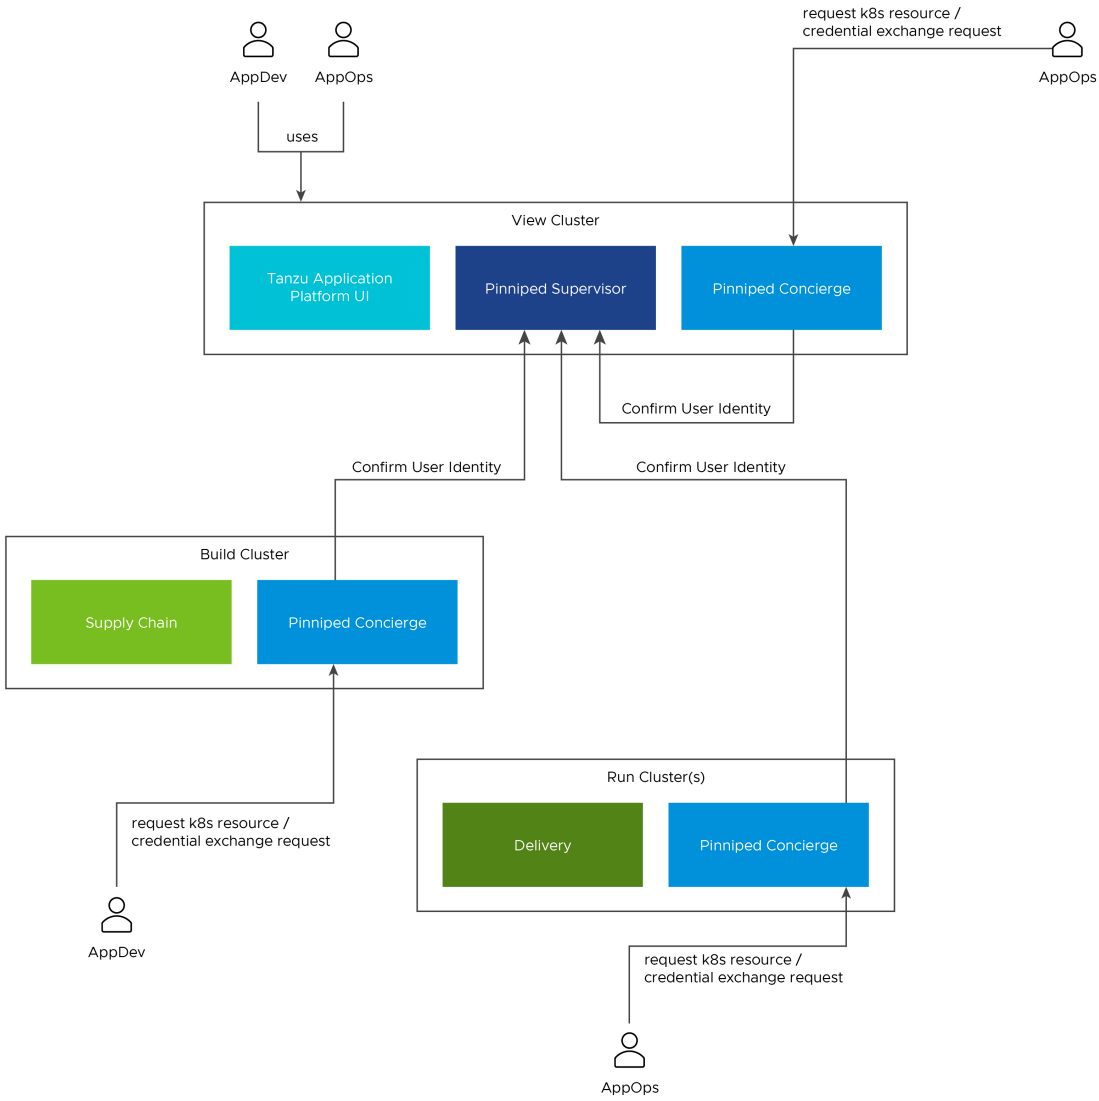
Environment planning

If you run Tanzu Application Platform on a single cluster, both Pinniped Supervisor and Pinniped Concierge are installed to this cluster.

When running a multicluster setup, you must decide which cluster to deploy the Supervisor onto. Furthermore, every cluster must have the Concierge deployed. Pinniped Supervisor runs as a central component that is consumed by multiple Pinniped Concierge instances. As a result, Pinniped Supervisor must be deployed to a single cluster that meets the prerequisites. You can deploy Pinniped Supervisor to the View Cluster of your Tanzu Application Platform, because it is a central single instance cluster. For more information, see Overview of multicluster Tanzu Application Platform.

You must deploy the Pinniped Concierge to every cluster that you want to enable authentication for, including the View Cluster itself.

See the following diagram for a possible deployment model:



For more information about the Pinniped architecture and deployment model, see Pinniped documentation.

Install Pinniped Supervisor by using Let's Encrypt

Follow these steps to install `pinniped-supervisor`:

1. Switch tooling to the desired cluster.
2. Create the necessary certificate files.
3. Create the Ingress resources.
4. Create the `pinniped-supervisor` configuration.
5. Apply these resources to the cluster.

Create Certificates (`letsencrypt` or `cert-manager`)

Choose a fully qualified domain name (FQDN) that can resolve to the Contour instance in the `tanzu-system-ingress` namespace. The FQDN `pinniped-supervisor.example.com` is used in the following sections.

Create a `ClusterIssuer` for `letsencrypt` and a TLS certificate resource for Pinniped Supervisor by creating the following resources and saving them into `workspace/pinniped-`

`supervisor/certificates.yaml`:

```
---
apiVersion: cert-manager.io/v1
kind: ClusterIssuer
metadata:
  name: letsencrypt-staging
  namespace: cert-manager
spec:
  acme:
    email: "EMAIL"
    privateKeySecretRef:
      name: letsencrypt-staging
    server: https://acme-staging-v02.api.letsencrypt.org/directory
    solvers:
    - http01:
        ingress:
          class: contour

---
apiVersion: cert-manager.io/v1
kind: Certificate
metadata:
  name: pinniped-supervisor-cert
  namespace: pinniped-supervisor
spec:
  secretName: pinniped-supervisor-tls-cert
  dnsNames:
  - "DNS-NAME"
  issuerRef:
    name: letsencrypt-staging
    kind: ClusterIssuer
```

Where:

- `EMAIL` is the user email address for `letsencrypt`. For example, `your-mail@example.com`
- `DNS-NAME` is the domain in which the `pinniped-supervisor` is published. For example, `pinniped-supervisor.example.com`

Create Ingress resources

Create a Service and Ingress resource to make the `pinniped-supervisor` accessible from outside the cluster.

To do so, create the following resources and save them into `workspace/pinniped-supervisor/ingress.yaml`:

```
---
apiVersion: v1
kind: Service
metadata:
  name: pinniped-supervisor
  namespace: pinniped-supervisor
spec:
  ports:
  - name: pinniped-supervisor
    port: 8443
    protocol: TCP
    targetPort: 8443
  selector:
    app: pinniped-supervisor

---
apiVersion: projectcontour.io/v1
```

```
kind: HTTPProxy
metadata:
  name: pinniped-supervisor
  namespace: pinniped-supervisor
spec:
  virtualhost:
    fqdn: "DNS-NAME"
    tls:
      passthrough: true
  tcpproxy:
    services:
    - name: pinniped-supervisor
      port: 8443
```

Where:

- `DNS-NAME` is the domain in which the `pinniped-supervisor` is published. For example, `pinniped-supervisor.example.com`
- `tls.passthrough: true` specifies that the TLS connection is forwarded to and terminated in the supervisor pod.

Create the `pinniped-supervisor` configuration

Create a `FederationDomain` to link the concierge to the supervisor instance and configure an `OIDCIdentityProvider` to connect the supervisor to your OIDC Provider. The following example uses `auth0` as the `OIDCIdentityProvider`. For more information about how to configure different identity providers, including OKTA, GitLab, OpenLDAP, Dex, Microsoft AD and more, see Pinniped documentation.

To create the `pinniped-supervisor` configuration, create the following resources and save them into `workspace/pinniped-supervisor/oidc_identity_provider.yaml`:

```
apiVersion: idp.supervisor.pinniped.dev/v1alpha1
kind: OIDCIdentityProvider
metadata:
  namespace: pinniped-supervisor
  name: auth0
spec:
  # Specify the upstream issuer URL associated with your auth0 application.
  issuer: https://"APPLICATION-SUBDOMAIN".auth0.com/

  # Specify how to form authorization requests.
  authorizationConfig:
    additionalScopes: ["openid", "email"]
    allowPasswordGrant: false

  # Specify how claims are mapped to Kubernetes identities. This varies by provider.
  claims:
    username: email
    groups: groups

  # Specify the name of the Kubernetes Secret that contains your
  # application's client credentials (created as follows).
  client:
    secretName: auth0-client-credentials

---
apiVersion: v1
kind: Secret
metadata:
  namespace: pinniped-supervisor
  name: auth0-client-credentials
type: secrets.pinniped.dev/oidc-client
```

```
stringData:
  clientID: "AUTH0-CLIENT-ID"
  clientSecret: "AUTH0-CLIENT-SECRET"

---
apiVersion: config.supervisor.pinniped.dev/v1alpha1
kind: FederationDomain
metadata:
  name: pinniped-supervisor-federation-domain
  namespace: pinniped-supervisor
spec:
  issuer: "DNS-NAME"
  tls:
    secretName: pinniped-supervisor-tls-cert
```

Where:

- `APPLICATION-SUBDOMAIN` is the application specific subdomain that is assigned after the application registration.
- `AUTH0-CLIENT-ID` and `AUTH0-CLIENT-SECRET` are the credentials retrieved from the application registration.
- `DNS-NAME` is the domain in which the `pinniped-supervisor` is published. For example, `pinniped-supervisor.example.com`

Apply the resources

After creating the resource files, you can install them into the cluster. Follow these steps to deploy them as a kapp application:

1. Install the `pinniped-supervisor` by running:

   ```
   kapp deploy -y --app pinniped-supervisor -f pinniped-supervisor -f https://get.
   pinniped.dev/v0.22.0/install-pinniped-supervisor.yaml
   ```

   Note

   To keep the security patches up to date, you must install the most recent version of Pinniped. See Vmware Tanzu Pinniped Releases in GitHub for more information.

2. Get the external IP address of Ingress by running:

   ```
   kubectl -n tanzu-system-ingress get svc/envoy -o jsonpath='{.status.loadBalance
   r.ingress[0].ip}'
   ```

3. If not already covered by the Tanzu Application Platform wildcard DNS entry, add an entry to the DNS system to bind the external IP address with.

Switch to production issuer (`letsencrypt` or `cert-manager`)

Follow these steps to switch to a `letsencrypt` production issuer so the generated TLS certificate is recognized as valid by web browsers and clients:

1. Edit the ClusterIssuer for `letsencrypt` and add TLS certificate resource for `pinniped-supervisor` by creating or updating the following resources and saving them into `workspace/pinniped-supervisor/certificates.yaml`:

```
---
apiVersion: cert-manager.io/v1
kind: ClusterIssuer
metadata:
  name: letsencrypt-prod
  namespace: cert-manager
spec:
  acme:
    server: https://acme-v02.api.letsencrypt.org/directory
    email: "EMAIL"
    privateKeySecretRef:
      name: letsencrypt-prod
    solvers:
    - http01:
        ingress:
          class: contour

---
apiVersion: cert-manager.io/v1
kind: Certificate
metadata:
  name: pinniped-supervisor-cert
  namespace: pinniped-supervisor
spec:
  secretName: pinniped-supervisor-tls-cert
  dnsNames:
  - "DNS-NAME"
  issuerRef:
    name: letsencrypt-prod
    kind: ClusterIssuer
```

Where:

- `EMAIL` is the user email address for `letsencrypt`. For example, `your-mail@example.com`
- `DNS-NAME` is the domain in which the `pinniped-supervisor` is published. For example, `pinniped-supervisor.example.com`

2. Create or update the `pinniped-supervisor` kapp application:

```
kapp deploy -y --app pinniped-supervisor -f pinniped-supervisor -f https://get.
pinniped.dev/v0.22.0/install-pinniped-supervisor.yaml
```

Install Pinniped Supervisor Private CA

Follow these steps to install `pinniped-supervisor`:

1. Switch tooling to the desired cluster.
2. Create the necessary certificate files.
3. Create the Ingress resources.
4. Create the `pinniped-supervisor` configuration.
5. Apply these resources to the cluster.

Create Certificate Secret

Choose a fully qualified domain name (FQDN) that can resolve to the Contour instance in the `tanzu-system-ingress` namespace. Create a certificate by using a CA that the clients trust. This FQDN can be under the `ingress_domain` in the TAP values file, or a dedicated DNS entry. The FQDN `pinniped-supervisor.example.com` is used in the following sections.

After the certificate files are available, they must be encoded to base64 format in a single-line layout. For example, you can encode the certificate file `my.crt` by running:

```
cat my.crt | base64 -w 0
```

Create the following resource and save it into `workspace/pinniped-supervisor/ingress.yaml`:

```
---
apiVersion: v1
kind: Secret
metadata:
  name: pinniped-supervisor-tls-cert
  namespace: pinniped-supervisor
type: kubernetes.io/tls
data:
  tls.crt: PRIVATE-KEY
  tls.key: PUBLIC-KEY
```

Where:

- `PRIVATE-KEY` is the base64 encoded public key.
- `PUBLIC-KEY` is the base64 encoded public key.

Create Ingress resources

Create a Service and Ingress resource to make the `pinniped-supervisor` accessible from outside the cluster.

To do so, create the following resources and save them into `workspace/pinniped-supervisor/ingress.yaml`:

```
---
apiVersion: v1
kind: Service
metadata:
  name: pinniped-supervisor
  namespace: pinniped-supervisor
spec:
  ports:
  - name: pinniped-supervisor
    port: 8443
    protocol: TCP
    targetPort: 8080
  selector:
    app: pinniped-supervisor

---
apiVersion: projectcontour.io/v1
kind: HTTPProxy
metadata:
  name: pinniped-supervisor
  namespace: pinniped-supervisor
spec:
  virtualhost:
    fqdn: "DNS-NAME"
    tls:
      passthrough: true
  tcpproxy:
    services:
    - name: pinniped-supervisor
      port: 8443
```

Where:

- `DNS-NAME` is the domain in which the `pinniped-supervisor` is published. For example, `pinniped-supervisor.example.com`
- `tls.passthrough: true` specifies that the TLS connection is forwarded to and terminated in the supervisor pod.

Create the `pinniped-supervisor` configuration

Create a `FederationDomain` to link the concierge to the supervisor instance and configure an `OIDCIdentityProvider` to connect the supervisor to your OIDC Provider. The following example uses `auth0` as the `OIDCIdentityProvider`. For more information about how to configure different identity providers, including OKTA, GitLab, OpenLDAP, Dex, Microsoft AD and more, see Pinniped documentation.

To create the `pinniped-supervisor` configuration, create the following resources and save them into `workspace/pinniped-supervisor/oidc_identity_provider.yaml`:

```
apiVersion: idp.supervisor.pinniped.dev/v1alpha1
kind: OIDCIdentityProvider
metadata:
  namespace: pinniped-supervisor
  name: auth0
spec:
  # Specify the upstream issuer URL associated with your auth0 application.
  issuer: https://"APPLICATION-SUBDOMAIN".auth0.com/

  # Specify how to form authorization requests.
  authorizationConfig:
    additionalScopes: ["openid", "email"]
    allowPasswordGrant: false

  # Specify how claims are mapped to Kubernetes identities. This varies by provider.
  claims:
    username: email
    groups: groups

  # Specify the name of the Kubernetes Secret that contains your
  # application's client credentials (created as follows).
  client:
    secretName: auth0-client-credentials

---
apiVersion: v1
kind: Secret
metadata:
  namespace: pinniped-supervisor
  name: auth0-client-credentials
type: secrets.pinniped.dev/oidc-client
stringData:
  clientID: "AUTH0-CLIENT-ID"
  clientSecret: "AUTH0-CLIENT-SECRET"

---
apiVersion: config.supervisor.pinniped.dev/v1alpha1
kind: FederationDomain
metadata:
  name: pinniped-supervisor-federation-domain
  namespace: pinniped-supervisor
spec:
  issuer: "DNS-NAME"
  tls:
    secretName: pinniped-supervisor-tls-cert
```

Where:

- `APPLICATION-SUBDOMAIN` is the application specific subdomain that is assigned after the application registration.
- `AUTH0-CLIENT-ID` and `AUTH0-CLIENT-SECRET` are the credentials retrieved from the application registration.
- `DNS-NAME` is the domain in which the pinniped-supervisor is published. For example, `pinniped-supervisor.example.com`

Apply the resources

After creating the resource files, you can install them into the cluster. Follow these steps to deploy them as a kapp application:

1. Install the supervisor by running:

```
kapp deploy -y --app pinniped-supervisor -f pinniped-supervisor -f https://get.
pinniped.dev/v0.22.0/install-pinniped-supervisor.yaml
```

> **Note**
>
> To keep the security patches up to date, you must install the most recent version of Pinniped. See Vmware Tanzu Pinniped Releases in GitHub for more information.

2. Get the external IP address of Ingress by running:

```
kubectl -n tanzu-system-ingress get svc/envoy -o jsonpath='{.status.loadBalance
r.ingress[0].ip}'
```

3. If not already covered by a Tanzu Application Platform wildcard DNS entry, add an entry to the DNS system to bind the external IP address with.

Install Pinniped Concierge

To install Pinniped Concierge:

1. Switch tooling to the desired cluster.
2. Deploy the Pinniped Concierge by running:

```
kapp deploy -y --app pinniped-concierge \
  -f https://get.pinniped.dev/v0.22.0/install-pinniped-concierge.yaml
```

3. Get the CA certificate of the supervisor by running the following command against the cluster running the `pinniped-supervisor`:

```
kubectl get secret pinniped-supervisor-tls-cert -n pinniped-supervisor -o 'go-t
emplate={{index .data "tls.crt"}}'
```

> **Note**
>
> The `tls.crt` contains the entire certificate chain including the CA certificate for `letsencrypt` generated certificates.

4. Create the following resource to `workspace/pinniped-concierge/jwt_authenticator.yaml`:

```
---
apiVersion: authentication.concierge.pinniped.dev/v1alpha1
kind: JWTAuthenticator
metadata:
  name: pinniped-jwt-authenticator
spec:
  issuer: "DNS-NAME"
  audience: concierge
  tls:
    certificateAuthorityData: "CA-DATA"
```

If you use the `letsencrypt` production issuer, you can omit the `tls` section:

```
---
apiVersion: authentication.concierge.pinniped.dev/v1alpha1
kind: JWTAuthenticator
metadata:
  name: pinniped-jwt-authenticator
spec:
  issuer: "DNS-NAME"
  audience: concierge
```

Where:

- `DNS-NAME` is the domain in which the `pinniped-supervisor` is published. For example, `pinniped-supervisor.example.com`
- `CA-DATA` is the public key of the signing CA or the public key of the Pinniped httpproxy certificate.

5. Deploy the resource by running:

```
kapp deploy -y --app pinniped-concierge-jwt --into-ns pinniped-concierge -f pin
niped-concierge/jwt_authenticator.yaml
```

Log in to the cluster

See Log in by using Pinniped.

Integrate your Azure Active Directory

This topic tells you how to integrate your Azure Active Directory (commonly known as AD).

Integrate Azure AD with a new or existing AKS without Pinniped

Perform the following procedures to integrate Azure AD with a new or existing AKS without Pinniped.

Prerequisites

Download and install the Azure CLI.

Set up a platform operator

To set up a platform operator:

1. Navigate to the **Azure Active Directory Overview** page.
2. Select **Groups** under the **Manage** side menu.

3. Identify or create an admin group for the AKS cluster.
4. Retrieve the object ID of the admin group.
5. Take one of the following actions.
    - Create an AKS Cluster with Azure AD enabled by running:

      ```
      az group create --name RESOURCE-GROUP --location LOCATION
      az aks create -g RESOURCE-GROUP -n MANAGED-CLUSTER --enable-aad --aad-adm
      in-group-object-ids OBJECT-ID
      ```

      Where:

        - `RESOURCE-GROUP` is your resource group
        - `LOCATION` is your location
        - `MANAGED-CLUSTER` is your managed cluster
        - `OBJECT-ID` is the object ID
    - Enable Azure AD integration on the existing cluster by running:

      ```
      az aks update -g RESOURCE-GROUP -n MANAGED-CLUSTER --enable-aad --aad-adm
      in-group-object-ids OBJECT-ID
      ```

      Where:

        - `RESOURCE-GROUP` is your resource group
        - `MANAGED-CLUSTER` is your managed cluster
        - `OBJECT-ID` is the object ID
6. Add **Platform Operators** to the admin group.
7. Log in to the AKS cluster by running:

   ```
   az aks get-credentials --resource-group RESOURCE-GROUP --name MANAGED-CLUSTER -
   -admin
   ```

   Where:

    - `RESOURCE-GROUP` is your resource group
    - `MANAGED-CLUSTER` is your managed cluster

Set up a Tanzu Application Platform default role group

To set up a Tanzu Application Platform default role group:

1. Navigate to the **Azure Active Directory Overview** page.
2. Select **Groups** under the **Manage** side menu.
3. Identify or create a list of groups in the Azure AD for each of the Tanzu Application Platform default roles (`app-operator`, `app-viewer`, and `app-editor`).
4. Retrieve the corresponding object IDs for each group.
5. Add users to the groups accordingly.
6. For each object ID retrieved earlier, use the Tanzu CLI RBAC plug-in to bind the `object id` group to a role by running:

   ```
   tanzu rbac binding add -g OBJECT-ID -r TAP-ROLE -n NAMESPACE
   ```

Where:

- `OBJECT-ID` is the object ID
- `TAP-ROLE` is the Tanzu Application Platform role
- `NAMESPACE` is the namespace

Set up kubeconfig

To set up kubeconfig:

1. Set up the `kubeconfig` to point to the AKS cluster by running:

   ```
   az aks get-credentials --resource-group RESOURCE-GROUP --name MANAGED-CLUSTER
   ```

   Where:

   - `RESOURCE-GROUP` is your resource group
   - `MANAGED-CLUSTER` is your managed cluster

2. Run any kubectl command to trigger a browser login. For example:

   ```
   kubectl get pods
   ```

Integrate Azure AD with Pinniped

Perform the following procedures to set up Azure AD with Pinniped.

Prerequisites

Install Pinniped supervisor and concierge on the cluster without setting up the OIDCIdentityProvider and secret.

Set up the Azure AD app

To set up the Azure AD app:

1. Navigate to the **Azure Active Directory Overview** page.
2. Select **App registrations** under the **Manage** side menu.
3. Select **New Registration**.
4. Enter the name of the application. For example, `gke-pinniped-supervisor-app`.
5. Under **Supported account types**, select **Accounts in this organisational directory only (VMware, Inc. only - Single tenant)**.
6. Under **Redirect URI**, select **Web** as the platform.
7. Enter the call URI to the supervisor. For example, `https://pinniped-supervisor.example.com/callback`.
8. Select **Register** to create the app.
9. If not already redirected, navigate to the app settings page.
10. Select **Token configuration** under the **Manage** menu.
11. Select **Add groups claim** > **All groups (includes distribution lists but not groups assigned to the application)**.
12. Select **Add** to create the group claim.

13. Select the app name in the breadcrumb navigation to return to the app settings page.
14. Select the **Endpoints** tab and record the value in the **OpenID Connect metadata document** field.
15. Return to the app settings page.
16. Record the **Application (client) ID**.
17. Select **Certificates & secrets** under the **Manage** menu.
18. Create a new client secret and record this value.
19. Add the following YAML to `oidc_identity_provider.yaml`.

    ```
    ---
    apiVersion: idp.supervisor.pinniped.dev/v1alpha1
    kind: OIDCIdentityProvider
    metadata:
      namespace: pinniped-supervisor
      name: azure-ad
    spec:
      # Specify the upstream issuer URL.
      issuer: ISSUER-URL

      authorizationConfig:
        additionalScopes: ["openid", "email", "profile"]
        allowPasswordGrant: false

      # Specify how claims are mapped to Kubernetes identities.
      claims:
        username: preferred_username
        groups: groups

      # Specify the name of the Kubernetes Secret that contains your
      # application's client credentials (created below).
      client:
        secretName: azure-ad-client-credentials
    ---
    apiVersion: v1
    kind: Secret
    metadata:
      namespace: pinniped-supervisor
      name: azure-ad-client-credentials
    type: secrets.pinniped.dev/oidc-client
    stringData:
      clientID: "AZURE-AD-CLIENT-ID"
      clientSecret: "AZURE-AD-CLIENT-SECRET"
    ```

    Where:

    - `ISSUER-URL` is the OpenID Connect metadata document URL you recorded earlier, but without the trailing `/.well-known/openid-configuration`
    - `AZURE-AD-CLIENT-ID` is the Azure AD client ID you recorded earlier
    - `AZURE-AD-CLIENT-SECRET` is the Azure AD client secret you recorded earlier

20. Apply your changes from the kubectl CLI by running:

    ```
    kubectl apply workspace/pinniped-supervisor/oidc_identity_provider.yaml
    ```

Set up the Tanzu Application Platform default role group

To set up a Tanzu Application Platform default role group:

1. Navigate to the **Azure Active Directory Overview** page.
2. Select **Groups** under the **Manage** side menu.
3. Identify or create a list of groups in the Azure AD for each of the Tanzu Application Platform default roles (`app-operator`, `app-viewer`, and `app-editor`).
4. Retrieve the corresponding object IDs for each group.
5. Add users to the groups accordingly.
6. For each object ID retrieved earlier, use kubectl to bind the `object id` group to a role by running:

   ```
   kubectl apply -n DEVELOPER_NAMESPACE -f - << EOF
   ---
   apiVersion: rbac.authorization.k8s.io/v1
   kind: RoleBinding
   metadata:
     name: TAP-ROLE
     namespace: $DEVELOPER_NAMSPACE
   roleRef:
     apiGroup: rbac.authorization.k8s.io
     kind: ClusterRole
     name: TAP-ROLE
   subjects:
   - apiGroup: rbac.authorization.k8s.io
     kind: Group
     name: OBJECT-ID
   EOF
   ---
   apiVersion: rbac.authorization.k8s.io/v1
   kind: ClusterRoleBinding
   metadata:
     name: TAP-ROLE-cluster-access
   roleRef:
     apiGroup: rbac.authorization.k8s.io
     kind: ClusterRole
     name: TAP-ROLE
   subjects:
   - apiGroup: rbac.authorization.k8s.io
     kind: Group
     name: OBJECT-ID
   ```

   Where:

   - `OBJECT-ID` is the object ID.
   - `TAP-ROLE` is the Tanzu Application Platform role.
   - `DEVELOPER-NAMESPACE` is the namespace for scoping the group.

For more information about binding users or groups to roles, see Bind a user or group to a default role.

Set up kubeconfig

Follow these steps to set up kubeconfig:

1. Set up `kubeconfig` using the Pinniped CLI by running:

   ```
   pinniped get kubeconfig --kubeconfig-context YOUR-KUBECONFIG-CONTEXT > /tmp/con
   cierge-kubeconfig
   ```

   Where `YOUR-KUBECONFIG-CONTEXT` is your your kubeconfig context.

2. Run any kubectl command to trigger a browser login. For example:

```
export KUBECONFIG="/tmp/concierge-kubeconfig"
kubectl get pods
```

Role descriptions for Tanzu Application Platform

This topic is a high level overview of each default role. For more information about the specific permissions of each role for every Tanzu Application Platform (commonly known as TAP) component, see Detailed role permissions for Tanzu Application Platform.

app-editor

The app-editor role can create, edit, and delete a Tanzu workload or deliverable.

Assign this role to a user, for example an app developer, to give permissions to create running workloads on the cluster. This allows them to deploy their applications. This role allows the user to:

- View, create, update, or delete a Tanzu workload or deliverable. This includes viewing the logs of the pods spun up through the Tanzu workload and tracing a commit through the build process.
- Download the images associated with their Tanzu workload so they can test images locally, or create a Tanzu workload from it instead of starting from source code in a repository.
- View and use Application Accelerator templates.
- View, create, update, or delete a Tanzu workload binding with an existing service.

app-viewer

The app-viewer role cannot create, edit, or delete a Tanzu workload or deliverable.

This role has a subset of the permissions of the app-editor role. Use it if you do not want a user to create, edit, or delete a Tanzu workload or deliverable, but they need to view its status. For example, give these permissions to an application developer that requires visibility into the state of their Tanzu workload or micro-service, but does not have the permissions to deploy it, such as to production or staging environments. This role cannot bind services with a Tanzu workload.

app-operator

The app-operator role can create, edit, and delete supply chain resources.

Assign this role to a user who defines the activities within a supply chain or the path to production. For example, building, testing, or scanning. This role can view, create, update, or delete Tanzu supply chain resources, including Tanzu Build Service control plane resources such as:

- kpack's builder, stack, and store
- Scanning resources
- Grype
- The metadata store

If this person must create Tanzu workloads, you can bind the user with the app-editor role as well.

service-operator

The service-operator role can create, edit, and delete service instances, service instance classes, and resource claim policies to permit the claimability of service instances across one or more namespaces.

Assign this role to a user who is responsible for the life cycle (create, edit and delete) of service instances. This role can also view resource claims across all namespaces as well as query for the list of claimable service instances in a given namespace.

workload

This role provides the service account associated with the Tanzu workload the permissions needed to execute the activities in the supply chain. This role is for a "robot" versus a user.

deliverable

This role gives the delivery “robot” service account the permissions needed to create running workloads. This role is not for a user.

Role descriptions for Tanzu Application Platform

This topic is a high level overview of each default role. For more information about the specific permissions of each role for every Tanzu Application Platform (commonly known as TAP) component, see Detailed role permissions for Tanzu Application Platform.

app-editor

The app-editor role can create, edit, and delete a Tanzu workload or deliverable.

Assign this role to a user, for example an app developer, to give permissions to create running workloads on the cluster. This allows them to deploy their applications. This role allows the user to:

- View, create, update, or delete a Tanzu workload or deliverable. This includes viewing the logs of the pods spun up through the Tanzu workload and tracing a commit through the build process.
- Download the images associated with their Tanzu workload so they can test images locally, or create a Tanzu workload from it instead of starting from source code in a repository.

```

Bind a user or group to a default role

This topic tells you how to use Kubernetes manifests to create the binding between users or groups and roles. Using a manifest allows you to add or remove users or groups after the initial creation. You can update the manifest and re-apply it by using kubectl.

After configuring your identity provider for Kubernetes, users can be authenticated to Kubernetes. However, they must be authorized to perform actions on resources. You can use kubectl to create role bindings that binds a user to the roles. For more information, see Role descriptions for Tanzu Application Platform.

Prerequisites

Meet these prerequisites:

1. Configure kubectl and have admin access to the cluster.
2. Configure an authentication solution for the cluster. You can use Pinniped or the authentication service native to your Kubernetes distribution.

Manage a user or groups mapping to a role

A Kubernetes RoleBinding or ClusterRoleBinding grants a user or group mapping to a role. A RoleBinding grants a role or ClusterRole to a specific namespace. Alternatively, a ClusterBinding maps a clusterrole to all namespaces. For more information, see the Kubernetes documentation.

Each of the four roles for users have both a role for namespace scoped resources and a role for cluster scoped resources. To ensure that the roles have access to the resources at the correct scoping, you must create bindings for both the namespace scoped resources and the cluster scoped resources. For a listing of the roles and cluster roles for each out-of-the-box Tanzu Application Platform role, see Default roles.

The following is an example of mapping the user `developer-1` to the `app-editor` role:

```
kubectl apply -n DEVELOPER_NAMESPACE -f - << EOF
---
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: app-editor
  namespace: $DEVELOPER_NAMSPACE
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: app-editor
subjects:
- apiGroup: rbac.authorization.k8s.io
  kind: User
  name: developer-1
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: app-editor-cluster-access
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: app-editor-cluster-access
subjects:
- apiGroup: rbac.authorization.k8s.io
  kind: User
  name: developer-1
EOF
```

Where `DEVELOPER-NAMESPACE` is the namespace for scoping the developers access.

To simplify the management of user to role membership, you can bind a group to a role in Kubernetes and manage a users group membership with an enteprise identity provider. For an example of Azure AD, see Integrate your Azure Active Directory.

The following example demonstrates how to add the group `developers` to the `app-editor` role:

```
kubectl apply -n DEVELOPER_NAMESPACE -f - << EOF
---
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: app-editor
```

```
  namespace: $DEVELOPER_NAMSPACE
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: app-editor
subjects:
- apiGroup: rbac.authorization.k8s.io
  kind: Group
  name: developers
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: app-editor-cluster-access
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: app-editor-cluster-access
subjects:
- apiGroup: rbac.authorization.k8s.io
  kind: Group
  name: developers
EOF
```

Where `DEVELOPER-NAMESPACE` is the namespace for scoping the developers access.

To add additional users or groups to the role, you can add another subject to the list. For example, to add the user `developer-2`, the `subjects` key looks like the following:

```
subjects:
- apiGroup: rbac.authorization.k8s.io
  kind: User
  name: developer-1
- apiGroup: rbac.authorization.k8s.io
  kind: User
  name: developer-2
```

Additionally, you can use a combination of users and groups in the `subject` key as follows:

```
subjects:
- apiGroup: rbac.authorization.k8s.io
  kind: Group
  name: developers
- apiGroup: rbac.authorization.k8s.io
  kind: User
  name: developer-1
```

Log in to Tanzu Application Platform by using Pinniped

This topic tells you how to log in to your Tanzu Application Platform (commonly known as TAP) by using Pinniped.

As a prerequisite, the administrator must provide authorization for users to resources by using `rolebindings`. For more information, see Bind a user or group to a default role.

To log in to your cluster by using Pinniped, follow these steps:

1. Install the Pinniped CLI.

   For more information, see Pinniped documentation.

   Important

> The latest compatible version of Pinniped CLI is required not only for the administrator to generate the `kubeconfig`, but also for the user to log in with the provided configuration.

2. Generate and distribute `kubeconfig` to users.
3. Login with the provided `kubeconfig`.

Download the Pinniped CLI

You must use a Pinniped CLI version that matches the installed Concierge or Supervisor. Use one of the following links to download the Pinniped CLI version `0.22.0`:

- Mac OS with AMD64
- Linux with AMD64
- Windows with AMD64

You must install the command-line tool on your `$PATH`, such as `/usr/local/bin` on macOS or Linux. You must also mark the file as executable.

Generate and distribute kubeconfig to users

As an administrator, you can generate the kubeconfig by using the following command:

```
pinniped get kubeconfig --kubeconfig-context <your-kubeconfig-context>  > /tmp/concier
ge-kubeconfig
```

Distribute this `kubeconfig` to your users so they can login by using `pinniped`.

Login with the provided kubeconfig

As a user of the cluster, you need the `kubeconfig` provided by your admin and the Pinniped CLI installed on your local machine to log in. Logging in is required to request information from the cluster. You can execute any resource request with kubectl to enter the authentication flow. For example:

```
kubectl --kubeconfig /tmp/concierge-kubeconfig get pods
```

If you do not want to explicitly use `--kubeconfig` in every command, you can also export an environment variable to set the `kubeconfig` path in your shell session.

```
export KUBECONFIG="/tmp/concierge-kubeconfig"
kubectl get pods
```

This command enables `pinniped` to print a URL for you to visit in the browser. You can then log in, copy the authentication code and paste it back to the terminal. After the login succeeds, you either see the resources or a message indicating that you have no permission to access the resources.

If you use a Windows machine, the command referenced in the generated `kubeconfig` might not work. In this case, you must change the path under `user.exec.command` in the `kubeconfig` to point to the install path of the Pinniped CLI.

Additional resources about Tanzu Application Platform authentication and authorization

Use this topic to learn additional information about authentication and authorization for Tanzu Application Platform (commonly known as TAP).

See Default roles for Tanzu Application Platform overview to get started.

Install

Default roles are released as part of Tanzu Application Platform. Alternatively, you can also install default roles independently. See Install default roles independently for more information.

Additional resources about Tanzu Application Platform authentication and authorization

Use this topic to learn additional information about authentication and authorization for Tanzu Application Platform (commonly known as TAP).

See Default roles for Tanzu Application Platform overview to get started.

Install

Default roles are released as part of Tanzu Application Platform. Alternatively, you can also install default roles independently. See Install default roles independently for more information.

Install default roles independently for your Tanzu Application Platform

This topic tells you how to install default roles for Tanzu Application Platform (commonly known as TAP) without deploying a TAP profile.

Note

Follow the steps in this topic if you do not want to use a profile to install default roles. For more information about profiles, see Components and installation profiles.

Prerequisites

Before installing default roles, complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.

Install

To install default roles:

1. List version information for the package by running:

   ```
   tanzu package available list tap-auth.tanzu.vmware.com --namespace tap-install
   ```

   For example:

   ```
   $ tanzu package available list tap-auth.tanzu.vmware.com --namespace tap-instal
   l
   - Retrieving package versions for tap-auth.tanzu.vmware.com...
     NAME                          VERSION       RELEASED-AT
     tap-auth.tanzu.vmware.com     1.0.1
   ```

2. Install the package by running:

```
tanzu package install tap-auth \
  --package tap-auth.tanzu.vmware.com \
  --version VERSION \
  --namespace tap-install
```

Where:

- `VERSION` is the package version number. For example, `1.0.1`.

For example:

```
$ tanzu package install tap-auth \
  --package tap-auth.tanzu.vmware.com \
  --version 1.0.1 \
  --namespace tap-install
```

Overview of Developer Conventions

Developer Conventions is a set of conventions that enable your workloads to support live-update and debug operations in Tanzu Application Platform (commonly known as TAP).

Prerequisites

- Tanzu CLI Apps plug-in
- Tanzu Dev Tools for VSCode IDE extension.

Features

Enabling Live Updates

Developer Conventions modifies your workload to enable live updates in either of the following situations:

- You deploy a workload by using the Tanzu CLI Apps plug-in and include the flag `--live-update=true`. For more information about how to deploy a workload with the CLI, see Create or update a workload.
- You deploy a workload by using the `Tanzu: Live Update Start` option through the Tanzu Developer Tools for VS Code extension. For more information about live updating with the extension, see Overview of Tanzu Developer Tools for Visual Studio Code.

When either of the preceding actions take place, the convention behaves as follows:

1. Looks for the `apps.tanzu.vmware.com/live-update=true` annotation on a PodTemplateSpec associated with a workload.
2. Verifies that the image to which conventions are applied contains a process that can be live updated.
3. Adds annotations to the PodTemplateSpec to modify the Knative properties `minScale` & `maxScale` such that the minimum and maximum number of pods is 1. This ensures the eventual running pod is not scaled down to 0 during a live update session.

After these changes are made, you can use the Tanzu Dev Tools extension or the Tilt CLI to make live update changes to source code directly on the cluster.

Enabling debugging

Developer Conventions modifies your workload to enable debugging in either of the following situations:

- You deploy a workload by using the Tanzu CLI Apps plug-in and include the flag `--debug=true`. For more information about how to deploy a workload with the CLI, see Create or update a workload.
- You deploy a workload by using the `Tanzu Java Debug Start` option through the Tanzu Developer Tools for VS Code extension. For more information about debugging with the extension, see Overview of Tanzu Developer Tools for Visual Studio Code.

When either of the preceding actions take place, the convention behaves as follows:

1. It looks for the `apps.tanzu.vmware.com/debug=true` annotation on a PodTemplateSpec associated with a workload.
2. It checks for the `debug-8` or `debug-9` labels on the image configuration's bill of materials (BOM).
3. It sets the TimeoutSeconds of the Liveness, Readiness, and Startup probes to 600 if currently set to a lower number.
4. It adds annotations to the PodTemplateSpec to modify the Knative properties `minScale` & `maxScale` such that the minimum and maximum number of pods is 1. This ensures the eventual running pod won't be scaled down to 0 during a debug session.

After these changes are made, you can use the Tanzu Dev Tools extension or other CLI-based debuggers to debug your workload directly on the cluster.

Note

Currently, Developer Conventions only supports debug operations for Java applications.

Next steps

- Install Developer Conventions

Overview of Developer Conventions

Developer Conventions is a set of conventions that enable your workloads to support live-update and debug operations in Tanzu Application Platform (commonly known as TAP).

Prerequisites

- Tanzu CLI Apps plug-in
- Tanzu Dev Tools for VSCode IDE extension.

Features

Enabling Live Updates

Developer Conventions modifies your workload to enable live updates in either of the following situations:

- You deploy a workload by using the Tanzu CLI Apps plug-in and include the flag `--live-update=true`. For more information about how to deploy a workload with the CLI, see

Create or update a workload.

- You deploy a workload by using the `Tanzu: Live Update Start` option through the Tanzu Developer Tools for VS Code extension. For more information about live updating with the extension, see Overview of Tanzu Developer Tools for Visual Studio Code.

When either of the preceding actions take place, the convention behaves as follows:

1. Looks for the `apps.tanzu.vmware.com/live-update=true` annotation on a PodTemplateSpec associated with a workload.
2. Verifies that the image to which conventions are applied contains a process that can be live updated.
3. Adds annotations to the PodTemplateSpec to modify the Knative properties `minScale` & `maxScale` such that the minimum and maximum number of pods is 1. This ensures the eventual running pod is not scaled down to 0 during a live update session.

After these changes are made, you can use the Tanzu Dev Tools extension or the Tilt CLI to make live update changes to source code directly on the cluster.

Enabling debugging

Developer Conventions modifies your workload to enable debugging in either of the following situations:

- You deploy a workload by using the Tanzu CLI Apps plug-in and include the flag `--debug=true`. For more information about how to deploy a workload with the CLI, see Create or update a workload.
- You deploy a workload by using the `Tanzu Java Debug Start` option through the Tanzu Developer Tools for VS Code extension. For more information about debugging with the extension, see Overview of Tanzu Developer Tools for Visual Studio Code.

When either of the preceding actions take place, the convention behaves as follows:

1. It looks for the `apps.tanzu.vmware.com/debug=true` annotation on a PodTemplateSpec associated with a workload.
2. It checks for the `debug-8` or `debug-9` labels on the image configuration's bill of materials (BOM).
3. It sets the TimeoutSeconds of the Liveness, Readiness, and Startup probes to 600 if currently set to a lower number.
4. It adds annotations to the PodTemplateSpec to modify the Knative properties `minScale` & `maxScale` such that the minimum and maximum number of pods is 1. This ensures the eventual running pod won't be scaled down to 0 during a debug session.

After these changes are made, you can use the Tanzu Dev Tools extension or other CLI-based debuggers to debug your workload directly on the cluster.

Note

Currently, Developer Conventions only supports debug operations for Java applications.

Next steps

- Install Developer Conventions

Install Developer Conventions

This document tells you how to install Developer Conventions from the Tanzu Application Platform (commonly known as TAP) package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install Developer Conventions. For more information about profiles, see About Tanzu Application Platform components and profiles.

Prerequisites

Before installing Developer Conventions:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- Install Supply Chain Choreographer.
- Create conventions with Cartographer Conventions.

Install

To install Developer Conventions:

1. Get the exact name and version information for the Developer Conventions package to be installed by running:

   ```
   tanzu package available list developer-conventions.tanzu.vmware.com --namespace
   tap-install
   ```

   For example:

   ```
   $ tanzu package available list developer-conventions.tanzu.vmware.com --namespa
   ce tap-install
   - Retrieving package versions for developer-conventions.tanzu.vmware.com
     NAME                                    VERSION        RELEASED-AT
     developer-conventions.tanzu.vmware.com  0.3.0          2021-10-19T00:00:00Z
   ```

2. Install the package by running:

   ```
   tanzu package install developer-conventions \
     --package developer-conventions.tanzu.vmware.com \
     --version 0.3.0 \
     --namespace tap-install
   ```

3. Verify the package install by running:

   ```
   tanzu package installed get developer-conventions --namespace tap-install
   ```

   For example:

   ```
   tanzu package installed get developer-conventions -n tap-install
   | Retrieving installation details for developer-conventions...
   NAME:                    developer-conventions
   PACKAGE-NAME:            developer-conventions.tanzu.vmware.com
   PACKAGE-VERSION:         0.3.0
   STATUS:                  Reconcile succeeded
   ```

```
CONDITIONS:              [{ReconcileSucceeded True  }]
USEFUL-ERROR-MESSAGE:
```

Verify that `STATUS` is `Reconcile succeeded`

Resource limits

The following resource limits are set on the Developer Conventions service:

```
resources:
  limits:
  cpu: 100m
  memory: 256Mi
  requests:
  cpu: 100m
  memory: 20Mi
```

Uninstall

To uninstall Developer Conventions, follow the guide for Uninstall Tanzu Application Platform packages. The package name for developer conventions is `developer-conventions`.

Run Developer Conventions on an OpenShift cluster

This topic tells you about considerations for running Developer Conventions on OpenShift.

On OpenShift clusters, Developer Conventions must run with a custom SecurityContextConstraint (SCC) to enable compliance with restricted Kubernetes pod security standards. Tanzu Application Platform configures the following SCC for the Developer Convention's webhook when you configure the `kubernetes_distribution: openshift` key in the `tap-values.yaml` file.

Specification follows:

```
---
apiVersion: security.openshift.io/v1
kind: SecurityContextConstraints
metadata:
  name: developer-conventions-scc
allowHostDirVolumePlugin: false
allowHostIPC: false
allowHostNetwork: false
allowHostPID: false
allowHostPorts: false
allowPrivilegeEscalation: false
allowPrivilegedContainer: false
defaultAddCapabilities: null
fsGroup:
  type: RunAsAny
priority: null
readOnlyRootFilesystem: false
requiredDropCapabilities: null
runAsUser:
  type: MustRunAsNonRoot
seLinuxContext:
  type: MustRunAs
supplementalGroups:
  type: RunAsAny
volumes:
  - secret
seccompProfiles: []
```

```
groups:
  - system:serviceaccounts:developer-conventions
```

Use External Secrets Operator in Tanzu Application Platform

The External Secrets Operator is a Kubernetes operator that integrates with external secret management systems, for example, Google Secrets Manager and Hashicorp Vault. It reads information from external APIs and automatically injects the values into a Kubernetes secret.

Tanzu Application Platform (commonly known as TAP) uses the External Secrets Operator to simplify Kubernetes secret life cycle management. The `external-secrets` plug-in, which is available in the Tanzu CLI, interacts with the External Secrets Operator API. Users can use this CLI plug-in to create and view External Secrets Operator resources on a Kubernetes cluster.

External Secrets Operator is available in Tanzu Application Platform packages with a Carvel Package named `external-secrets.apps.tanzu.vmware.com`. It is not part of any installation profile.

Where to start

To learn more about managing secrets with External Secrets in general, see the official External Secrets Operator documentation. For installing the External Secrets Operator and the CLI plug-in see the following documentation. Also, see the example integration of External-Secrets with Hashicorp Vault.

- Installing External Secrets Operator in TAP
- Installing Tanzu CLI
- External-Secrets with Hashicorp Vault
- Tanzu External Secrets CLI plug-in Reference

Use External Secrets Operator in Tanzu Application Platform

The External Secrets Operator is a Kubernetes operator that integrates with external secret management systems, for example, Google Secrets Manager and Hashicorp Vault. It reads information from external APIs and automatically injects the values into a Kubernetes secret.

Tanzu Application Platform (commonly known as TAP) uses the External Secrets Operator to simplify Kubernetes secret life cycle management. The `external-secrets` plug-in, which is available in the Tanzu CLI, interacts with the External Secrets Operator API. Users can use this CLI plug-in to create and view External Secrets Operator resources on a Kubernetes cluster.

External Secrets Operator is available in Tanzu Application Platform packages with a Carvel Package named `external-secrets.apps.tanzu.vmware.com`. It is not part of any installation profile.

Where to start

To learn more about managing secrets with External Secrets in general, see the official External Secrets Operator documentation. For installing the External Secrets Operator and the CLI plug-in see the following documentation. Also, see the example integration of External-Secrets with Hashicorp Vault.

- Installing External Secrets Operator in TAP
- Installing Tanzu CLI

- External-Secrets with Hashicorp Vault
- Tanzu External Secrets CLI plug-in Reference

Install External Secrets Operator in Tanzu Application Platform

This topic tells you how to install the External Secrets Operator from the Tanzu Application Platform (commonly known as TAP) package repository.

Important

External Secrets Operator is not included or installed with any Tanzu Application Platform profile.

Prerequisites

Before installing External Secrets Operator:

- Complete all prerequisites to install the Tanzu Application Platform. For more information, see Prerequisites.

Install

To install External Secrets Operator:

1. List version information for the package by running:

   ```
   tanzu package available list external-secrets.apps.tanzu.vmware.com -n tap-inst
   all
   ```

   For example:

   ```
   NAME                                     VERSION         RELEASED-AT
   external-secrets.apps.tanzu.vmware.com   0.9.4+tanzu.2   2023-11-10 00:00:00 -050
   0 EST
   ```

2. (Optional) For Tanzu Application Platform v1.7.1 and later, you can create a YAML values file to specify optional configuration for the External Secrets Operator. In this release, there is only one setting: `kubernetes_distribution`, which you can set to `"openshift"` or `""`.
   - To run External Secrets Operator on an OpenShift cluster, set the `kubernetes_distribution` value to `openshift`. This setting removes some of the default security settings in External Secrets Operator so that OpenShift can replace the security settings with its own.
   - If you are running the External Secrets Operator on any other platform, leave `kubernetes_distribution` as an empty string or omit the value entirely.

   Note

   The `kubernetes_distribution` setting is available as of External Secrets Operator v0.9.4+tanzu.2, which is available in Tanzu Application Platform v1.7.1. External Secrets Operator v0.9.4+tanzu.1 and earlier might not be able to run on OpenShift clusters.

3. Install the package by running:

```
tanzu package install external-secrets \
 --package external-secrets.apps.tanzu.vmware.com \
 --version VERSION-NUMBER \
 --values-file VALUES-FILE.yaml \ # The use of this file is optional
 --namespace tap-install
```

Where:

- `VERSION-NUMBER` is the package version you retrieved earlier.
- (Optional) `VALUES-FILE` is the YAML file you created earlier containing the values used to configure External Secrets Operator.

For example:

```
$ tanzu package install external-secrets \
   --package external-secrets.apps.tanzu.vmware.com \
   --version 0.6.1+tap.6 \
   --values-file external-secrets-values.yaml \
   --namespace tap-install

\ Installing package 'external-secrets.apps.tanzu.vmware.com'
| Getting package metadata for 'external-secrets.apps.tanzu.vmware.com'
| Creating service account 'external-secrets-tap-install-sa'
/ Creating cluster admin role 'external-secrets-tap-install-cluster-role'
| Creating cluster role binding 'external-secrets-tap-install-cluster-rolebindi
n
/ Creating cluster role binding 'external-secrets-tap-install-cluster-rolebindi
n
\ Creating cluster role binding 'external-secrets-tap-install-cluster-rolebindi
n
| Creating cluster role binding 'external-secrets-tap-install-cluster-rolebindi
ng'
\ Creating package resource
Waiting for 'PackageInstall' reconciliation for 'external-secrets'
'PackageInstall' resource install status: Reconciling
'PackageInstall' resource install status: ReconcileSucceeded

Added installed package 'external-secrets'
```

4. Verify the package installation by running:

```
tanzu package installed get external-secrets --namespace tap-install
```

For example:

```
tanzu package installed get external-secrets -n tap-install

NAME:                    external-secrets
PACKAGE-NAME:            external-secrets.apps.tanzu.vmware.com
PACKAGE-VERSION:         0.9.4+tanzu.2
STATUS:                  Reconcile succeeded
CONDITIONS:              [{ReconcileSucceeded True  }]
USEFUL-ERROR-MESSAGE:
```

Integrate External Secrets Operator with HashiCorp Vault in Tanzu Application Platform

This topic shows you how to integrate External Secrets Operator with HashiCorp Vault in Tanzu Application Platform.

The operator synchronizes secret data from external APIs to a Kubernetes secret resource. For more information about Kubernetes secret resources, see the Kubernetes documentation.

Important

This example integration is constructed to showcase the features available and must not be considered in a production environment.

Prerequisites

Before proceeding with this example, you must:

- Install External Secrets Operator. For more information, see Install External Secrets Operator.
- Install the Tanzu CLI. The Tanzu CLI includes the plug-in `external-secrets`. For Tanzu CLI installation, see Tanzu CLI.
- Have a running instance of HashiCorp Vault. In this instance, there is a secret defined with the key `eso-demo/reg-cred`.

Set up the integration

To set up the External Secrets Operator integration with HashiCorp Vault:

1. Create a `Secret` with the vault token. For example:

```
VAULT_TOKEN="vault-token-value"

cat <<EOF | kubectl apply -f -
apiVersion: v1
kind: Secret
metadata:
name: vault-token
stringData:
token: $VAULT_TOKEN
EOF
```

2. Create a `SecretStore` resource referencing the `vault-token` secret. For example:

Caution

When creating the `SecretStore`, ensure that you match the Vault KV secret engine version. This is either `v1` or `v2`. The default is `v2`. For more information, see Vault KV Secrets Engine documentation.

```
VAULT_SERVER="http://my.vault.server:8200"
VAULT_PATH="eso-demo"

cat <<EOF | tanzu external-secrets store create -y -f -
---
apiVersion: external-secrets.io/v1beta1
kind: SecretStore
metadata:
  name: vault-secret-store
spec:
  provider:
    vault:
```

```
      server: $VAULT_SERVER
      path: $VAULT_PATH
      version: v2
      auth:
        tokenSecretRef:
          name: "vault-token" # vault-token created in the previous step
          key: "token"
EOF
```

Important

If you are using a secret store service with a custom CA certificate then you must provide this certificate to External Secret Operator directly by including the CA `SecretStore` or `ClusterSecretStore` resource.

The Tanzu Application Platform distribution of External Secret Operator does not support the Tanzu Application Platform field `shared.ca_cert_data`. For more information about setting the CA in the ESO configuration, see the ESO documentation.

3. Verify that the status of the `SecretStore` resource is `Valid` by running:

```
tanzu external-secrets store list
```

Example output:

```
NAMESPACE  NAME                PROVIDER         STATUS
default    vault-secret-store  Hashicorp Vault  Valid
```

4. Create an `ExternalSecret` resource that uses the `SecretStore` you just created by running:

```
cat <<EOF | tanzu external-secrets secret create -y -f -
---
apiVersion: external-secrets.io/v1beta1
kind: ExternalSecret
metadata:
  name: vault-secret-example
spec:
  refreshInterval: 15m
  secretStoreRef:
    name: vault-secret-store
    kind: SecretStore
  target:
    name: registry-secret
    template:
      type: kubernetes.io/dockerconfigjson
      data:
        .dockerconfigjson: "{{ .registryCred | toString }}"
    creationPolicy: Owner
  data:
  - secretKey: registryCred
    remoteRef:
      key: $VAULT_PATH/eso-demo
      property: reg-cred
EOF
```

5. Verify that the status of the `ExternalSecret` resource is `Valid` by running:

```
tanzu external-secrets secret list
```

Example output:

```
NAMESPACE  NAME                  SECRET NAME      STORE               REFRESH I
NTERVAL  STATUS             LAST UPDATED  LAST REFRESH
default    vault-secret-example  registry-secret  vault-secret-store  15m
SecretSynced  21s           10m
```

6. After the resource has reconciled, a Kubernetes `secret` resource is created. Look for a secret named `registry-secret` created by the referenced `ExternalSecret`. For example:

```
kubectl get secrets registry-secret -o="jsonpath={.data.\.dockerconfigjson}" |
base64 -D
{"auths":{"my-registry.example:8200":{"username":"foo","password":"bar4","emai
l":"foo@bar.example","auth":"Zm9vOmJhcjQ="}}}
```

Tanzu External Secrets CLI plug-in command reference

The Tanzu External Secrets CLI plug-in command reference has moved to the Tanzu CLI Command Reference documentation.

Overview of Flux CD Source Controller

Flux CD Source Controller provides you with APIs for acquiring resources such as Git, Helm repositories and S3 buckets on the cluster. For more information, see Flux CD Source Controller documentation.

The source-controller implements the source.toolkit.fluxcd.io API in GitHub and is a core component of the GitOps toolkit.

Overview of Flux CD Source Controller

Flux CD Source Controller provides you with APIs for acquiring resources such as Git, Helm repositories and S3 buckets on the cluster. For more information, see Flux CD Source Controller documentation.

The source-controller implements the source.toolkit.fluxcd.io API in GitHub and is a core component of the GitOps toolkit.

Install Flux CD Source Controller

This topic tells you how to install Flux CD Source Controller from the Tanzu Application Platform (commonly known as TAP) package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install Flux CD Source Controller. For more information about profiles, see Components and installation profiles.

Prerequisites

Before installing Flux CD Source Controller:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- Install cert-manager on the cluster. For more information, see Install cert-manager.

Configuration

The Flux CD Source Controller package has no configuration values.

Installation

To install Flux CD Source Controller from the Tanzu Application Platform package repository:

1. List version information for the package by running:

   ```
   tanzu package available list fluxcd.source.controller.tanzu.vmware.com -n tap-i
   nstall
   ```

   For example:

   ```
   $ tanzu package available list fluxcd.source.controller.tanzu.vmware.com -n tap
   -install
       \ Retrieving package versions for fluxcd.source.controller.tanzu.vmware.co
   m...
         NAME                                          VERSION  RELEASED-AT
         fluxcd.source.controller.tanzu.vmware.com  1.1.2    2024-03-11 00:00:00 -
   0500 -05
   ```

2. Install the package by running:

   ```
   tanzu package install fluxcd-source-controller -p fluxcd.source.controller.tanz
   u.vmware.com -v VERSION-NUMBER -n tap-install
   ```

   Where:

   - `VERSION-NUMBER` is the version of the package listed in step 1.

   For example:

   ```
   tanzu package install fluxcd-source-controller -p fluxcd.source.controller.tanz
   u.vmware.com -v 1.1.2 -n tap-install
   \ Installing package 'fluxcd.source.controller.tanzu.vmware.com'
   | Getting package metadata for 'fluxcd.source.controller.tanzu.vmware.com'
   | Creating service account 'fluxcd-source-controller-tap-install-sa'
   | Creating cluster admin role 'fluxcd-source-controller-tap-install-cluster-rol
   e'
   | Creating cluster role binding 'fluxcd-source-controller-tap-install-cluster-r
   olebinding'
   | Creating package resource
   - Waiting for 'PackageInstall' reconciliation for 'fluxcd-source-controller'
   | 'PackageInstall' resource install status: Reconciling

     Added installed package 'fluxcd-source-controller'
   ```

   This package creates a new namespace called `flux-system`. This namespace hosts all the elements of fluxcd.

3. Verify the package install by running:

   ```
   tanzu package installed get fluxcd-source-controller -n tap-install
   ```

   For example:

   ```
   tanzu package installed get fluxcd-source-controller -n tap-install
   \ Retrieving installation details for fluxcd-source-controller...
   NAME:                    fluxcd-source-controller
   PACKAGE-NAME:            fluxcd.source.controller.tanzu.vmware.com
   ```

```
PACKAGE-VERSION:          0.16.0
STATUS:                   Reconcile succeeded
CONDITIONS:               [{ReconcileSucceeded True  }]
USEFUL-ERROR-MESSAGE:
```

Verify that `STATUS` is `Reconcile succeeded`.

```
kubectl get pods -n flux-system
```

For example:

```
$ kubectl get pods -n flux-system
NAME                                READY   STATUS    RESTARTS   AGE
source-controller-69859f545d-ll8fj   1/1     Running   0          3m38s
```

Verify that `STATUS` is `Running`.

Try fluxcd-source-controller

1. Verify the main components of `fluxcd-source-controller` were installed by running:

   ```
   kubectl get all -n flux-system
   ```

   Expect to see the following outputs or similar:

   ```
   NAME                                      READY   STATUS    RESTARTS   AGE
   pod/source-controller-7684c85659-2zfxb    1/1     Running   0          40m

   NAME                          TYPE        CLUSTER-IP      EXTERNAL-IP   PORT(S)
   AGE
   service/source-controller     ClusterIP   10.108.138.74   <none>        80/TCP
   40m

   NAME                                  READY   UP-TO-DATE   AVAILABLE   AGE
   deployment.apps/source-controller     1/1     1            1           40m

   NAME                                             DESIRED   CURRENT   READY   AGE
   replicaset.apps/source-controller-7684c85659     1         1         1       40m
   ```

2. Verify all the CRD were installedby running:

   ```
   kubectl get crds -n flux-system | grep ".fluxcd.io"
   buckets.source.toolkit.fluxcd.io                          2022-03-07T19:20:14Z
   gitrepositories.source.toolkit.fluxcd.io                  2022-03-07T19:20:14Z
   helmcharts.source.toolkit.fluxcd.io                       2022-03-07T19:20:14Z
   helmrepositories.source.toolkit.fluxcd.io                 2022-03-07T19:20:14Z
   ```

   Note

   You will communicate with `fluxcd-source-controller` through its CRDs.

3. If you are using a Git repository with a custom CA certificate, provide this certificate to the Flux CD Source Controller directly by including the CA in the service account used by the supply chain.

   The Tanzu Application Platform distribution of Flux CD Source Controller does not support the Tanzu Application Platform `shared.ca_cert_data` field. For more information about setting the CA in the service account, see Use Git authentication with Supply Chain Choreographer.

4. Follow these steps to consume a `GitRepository` object:

    1. Create the following `gitrepository-sample.yaml` file:

        ```
        apiVersion: source.toolkit.fluxcd.io/v1
        kind: GitRepository
        metadata:
          name: gitrepository-sample
        spec:
          interval: 1m
          url: https://github.com/vmware-tanzu/application-accelerator-samples
          ref:
            branch: main
        ```

    2. Apply the created conf:

        ```
        kubectl apply -f gitrepository-sample.yaml
        gitrepository.source.toolkit.fluxcd.io/gitrepository-sample created
        ```

    3. Verify the git-repository was fetched correctly:

        ```
        kubectl get GitRepository
        NAME                    URL
        READY   STATUS
        AGE
        gitrepository-sample   https://github.com/vmware-tanzu/application-accele
        rator-samples   True    Fetched revision: main/132f4e719209eb10b9485302f8
        593fc0e680f4fc   4s
        ```

    For more examples, see the samples directory on fluxcd/source-controller/samples in GitHub.

Configure resource limits

Each system has its unique resource requirements, and the default resources provided by Flux Source Controller might not meet the needs of your specific use case.

Flux Source Controller uses the following resource limits by default:

```
resources:
  limits:
    cpu: 1000m
    memory: 1Gi
  requests:
    cpu: 50m
    memory: 64Mi
```

You can configure the resource limits by following these steps:

1. Create a `Secret` with the following `ytt` overlay:

    ```
    apiVersion: v1
    kind: Secret
    metadata:
      name: fluxcd-source-overlay-secret
      namespace: tap-install
    stringData:
      fluxcd-source-overlay.yaml: |
          #@ load("@ytt:data", "data")
          #@ load("@ytt:overlay", "overlay")
          #@overlay/match by=overlay.subset({"kind":"Deployment", "metadata":{"nam
    e":"fluxcd-source-controller", "namespace": "flux-system"}}), expects="1+"
          ---
    ```

```
      spec:
        template:
          spec:
            containers:
            #@overlay/match by="name"
            - name: manager
              resources:
                limits:
                  cpu: "4"
                  memory: "4Gi"
                requests:
                  cpu: "2"
                  memory: "2Gi"
```

2. Update the Tanzu Application Platform values file by including a `package_overlays` field:

```
package_overlays:
- name: fluxcd-source-controller
  secrets:
  - name: fluxcd-source-overlay-secret
```

3. Update Tanzu Application Platform by running:

```
tanzu package installed update tap -p tap.tanzu.vmware.com -v 1.9.0 --values-fi
le tap-values.yaml -n tap-install
```

For more information about the package customization, see Customize your package installation.

Documentation

For documentation specific to fluxcd-source-controller, see the main repository fluxcd/source-controller in GitHub.

Use Flux CD Source Controller

To build workload by using the `GitRepository` API of Flux CD Source Controller, see Building from source with Supply Chain Choreographer.

For authenticating to Git repositories by using Flux CD Source Controller in Supply Chain Choreographer, see Git authentication with Supply Chain Choreographer.

Overview of Learning Center for Tanzu Application Platform

Learning Center is no longer part of Tanzu Application Platform. Use Tanzu Academy instead for all Tanzu Application Platform learning and education needs.

Overview of Local Source Proxy

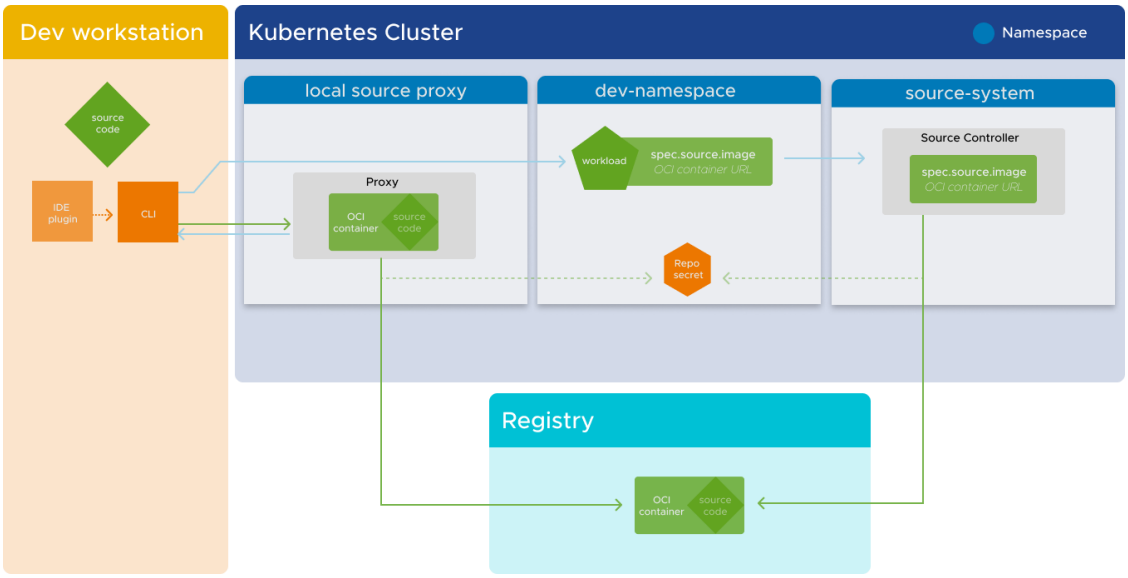
Local Source Proxy (LSP) offers developers a secure and user-friendly approach to seamlessly upload their local source code to a Tanzu Application Platform cluster. This enables developers to navigate their code smoothly through a predefined production pathway using supply chains.

With Local Source Proxy, developers can:

- Interact with external registries without needing to know registry specifics, such as endpoints, credentials, and certificates. This eliminates the burden of platform and app operators having to distribute registry credentials to developer workstations.

- Deploy their workloads from a local source through any mechanism, including IDE extensions, without providing the source image location. Developers can seamlessly deploy their applications without managing registry credentials on their local machines or keeping track of where their local source is uploaded.

Consequently, the `--source-image` flag in the Apps CLI plug-in becomes optional, and there is no longer a need for Docker registry credentials on the developer's local machine. Local Source Proxy abstracts these details, making deployment more streamlined and user-friendly for developers.



By removing the necessity for specific registry information and credentials, Local Source Proxy simplifies the developer experience. This enables developers to focus on developing their applications instead of managing registry-related complexities.

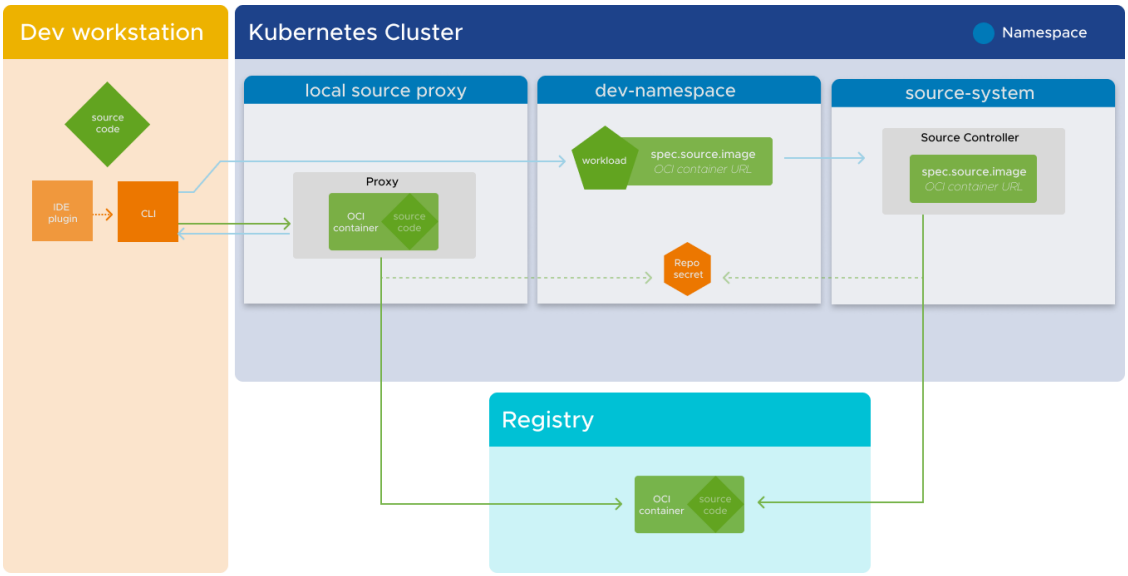
Overview of Local Source Proxy

Local Source Proxy (LSP) offers developers a secure and user-friendly approach to seamlessly upload their local source code to a Tanzu Application Platform cluster. This enables developers to navigate their code smoothly through a predefined production pathway using supply chains.

With Local Source Proxy, developers can:

- Interact with external registries without needing to know registry specifics, such as endpoints, credentials, and certificates. This eliminates the burden of platform and app operators having to distribute registry credentials to developer workstations.
- Deploy their workloads from a local source through any mechanism, including IDE extensions, without providing the source image location. Developers can seamlessly deploy their applications without managing registry credentials on their local machines or keeping track of where their local source is uploaded.

Consequently, the `--source-image` flag in the Apps CLI plug-in becomes optional, and there is no longer a need for Docker registry credentials on the developer's local machine. Local Source Proxy abstracts these details, making deployment more streamlined and user-friendly for developers.



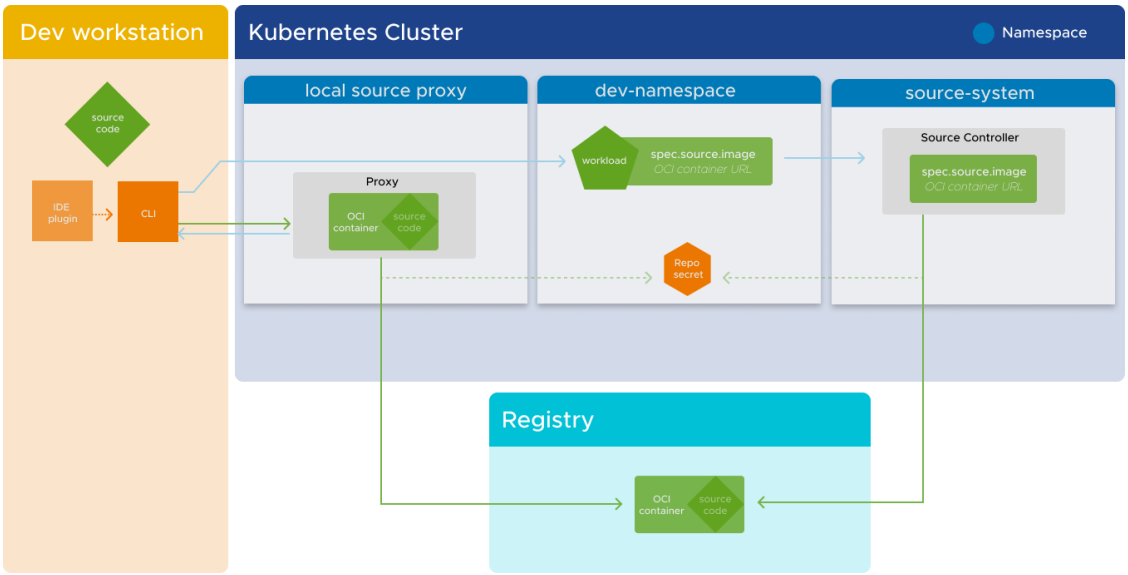
By removing the necessity for specific registry information and credentials, Local Source Proxy simplifies the developer experience. This enables developers to focus on developing their applications instead of managing registry-related complexities.

Design of Local Source Proxy

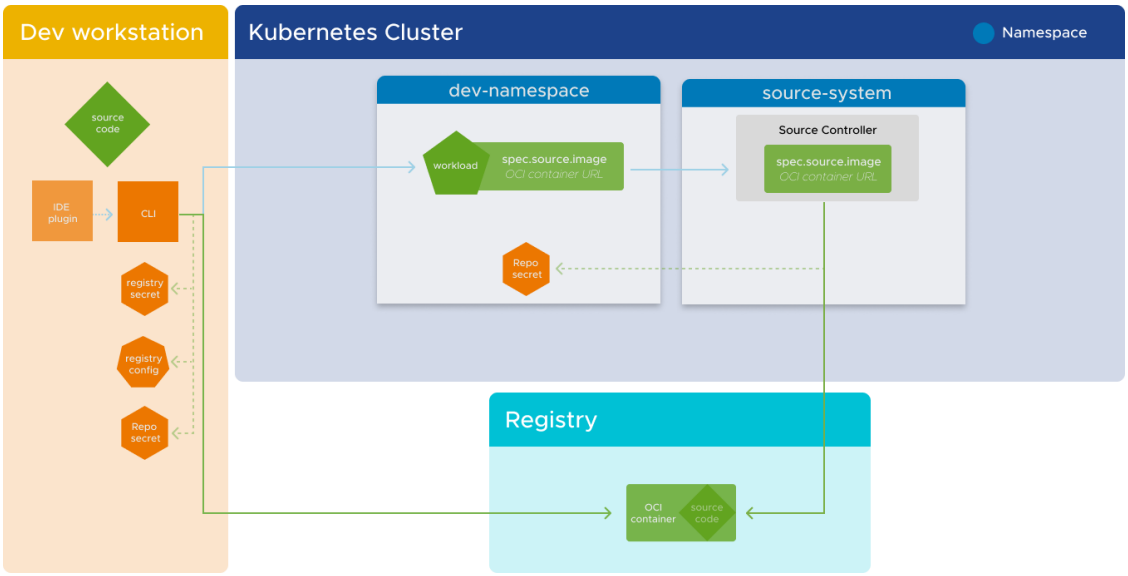
Local Source Proxy (LSP) serves as a proxy registry server with OCI (Open Container Initiative) compatibility. Its main purpose is to handle image push requests by forwarding them to an external registry server, which is configured through the `tap-values.yaml` file.

Local Source Proxy takes care of authentication and authorization against the external registry provider internally. This ensures that the external registry remains transparent to the user.

By functioning as a proxy registry server, Local Source Proxy simplifies the process of interacting with external registry servers. Local Source Proxy provides a centralized and transparent approach for image push requests, handling authentication and authorization seamlessly.



If you don't use Local Source Proxy, your developer workstation requires more configuration, and the process of interacting with external registry servers is more complicated.



The Apps CLI plug-in generates requests that adhere to the OCI distribution standard to push artifacts to Local Source Proxy instances. The Kubernetes API server handles user authentication and authorization.

Consequently this default mechanism becomes the primary way to push a developer's local source code to the Tanzu Application Platform cluster. This renders the `--source-image` flag optional. By leveraging Local Source Proxy, developers can seamlessly deploy their code without explicitly specifying the source image.

However, the system remains backward-compatible to accommodate different scenarios.

The `local-source-proxy` mechanism is completely bypassed if either of the following is true:

- The `--source-image` flag is provided
- The workload has a defined source image that Local Source Proxy didn't set

This ensures compatibility with existing workflows and allows developers to continue using their preferred methods for deployment.

By default, the `iterate` and `full` profiles include the installation of this package. To suppress this behavior, exclude the package by adding `local-source-proxy.apps.tanzu.vmware.com` to the list of excluded packages. For how to do so, see Exclude packages from a Tanzu Application Platform profile.

Prerequisites for Local Source Proxy

You need the following prerequisites before you can install Local Source Proxy (LSP):

- The Tanzu Application Platform profile `full` or `iterate`. For more information, see Components and installation profiles for Tanzu Application Platform.
- A registry server with a repository capable of accepting and hosting OCI artifacts, such as Google Artifact Registry, JFrog Artifactory, Harbor, Elastic Container Registry, and so on.
- Either IaaS-specific trust for Kubernetes service accounts to access the registry, or a secret with sufficient privileges to push and pull artifacts from that repository.
- If you install Local Source Proxy on a Kubernetes cluster that a cloud provider manages (such as EKS, AKS, or GKE), ensure that TCP port 5002 is open between control plane nodes and your worker nodes.

The rest of this topic tells you how to obtain these prerequisites.

Using Tanzu CLI

All registries except ECR can use the following code:

```
tanzu secret registry add lsp-push-credentials \
--username USERNAME-VALUE --password PASSWORD-VALUE \
--server REGISTRY-SERVER \
--namespace tap-install --yes
```

Declarative syntax

For declarative syntax:

```
---
apiVersion: v1
kind: Secret
metadata:
  name: lsp-push-credentials
  namespace: tap-install
type: kubernetes.io/dockerconfigjson
stringData:
  .dockerconfigjson: BASE64-ENCODED-DOCKER-CONFIG-JSON
```

The `dockerconfigjson` structure is as follows:

```
{"auths":{"REGISTRY-SERVER":{"username":"USERNAME-VALUE","password": "PASSWORD-VALU
E"}}}
```

If you're using the Tanzu Application Platform GitOps installer using Secrets OPerationS (SOPS), after using SOPS to encrypt the secret put the secret in the `clusters/CLUSTER-NAME/cluster-config/config/lsp` directory in your GitOps repository.

If you're using the Tanzu Application Platform GitOps installer using ESO, create a secret as follows:

```
#@ load("@ytt:data", "data")
#@ load("@ytt:json", "json")

#@ def config():
#@  return {
#@    "auths": {
#@      data.values.tap_value.{path-to-registry-host}: {
#@       "username": data.values.tap_values.{path-to-registry-username},
#@       "password": data.values.tap_values.{path-to-registry-password}
#@      }
#@    }
#@  }
#@ end
---
apiVersion: v1
kind: Secret
metadata:
  name: lsp-push-credentials
  namespace: tap-install
type: kubernetes.io/dockerconfigjson
stringData:
  .dockerconfigjson: #@ json.encode(config())
```

The procedure you use to obtain a secret with sufficient privileges depends on whether your registry is Elastic Container Registry (ECR) or something else.

Using AWS

If you're using Elastic Container Registry as your registry, you must create the container repository ahead of time. Additionally you require an AWS Identity Access and Management (IAM) role Amazon Resource Name (ARN) that possesses the necessary privileges to push and pull artifacts to the ECR repository. This is limited in scope to the service account for Local Source Proxy.

1. Export the variables by running:

```
export AWS_ACCOUNT_ID=012345678901  # Your AWS account ID
export AWS_REGION=us-west-2         # The AWS region you are going to deploy
to
export EKS_CLUSTER_NAME=tap-on-aws  # The name of your Elastic Kubernetes Ser
vice Cluster
```

2. Create the repository by running:

```
aws ecr create-repository --repository-name tap-lsp --region $AWS_REGION
```

3. Output the files, and then use the policy documents to create the IAM roles, by running:

```
export OIDCPROVIDER=$(aws eks describe-cluster --name $EKS_CLUSTER_NAME --reg
ion $AWS_REGION \
--output json | jq '.cluster.identity.oidc.issuer' | tr -d '"' | sed 's/http
s:\/\///')

cat << EOF > local-source-proxy-trust-policy.json
{
  "Version": "2012-10-17",
  "Statement": [
      {
          "Effect": "Allow",
          "Principal": {
              "Federated": "arn:aws:iam::${AWS_ACCOUNT_ID}:oidc-provider/${OI
DCPROVIDER}"
          },
          "Action": "sts:AssumeRoleWithWebIdentity",
          "Condition": {
              "StringEquals": {
                  "${OIDCPROVIDER}:aud": "sts.amazonaws.com"
              },
              "StringLike": {
                  "${OIDCPROVIDER}:sub": [
                      "system:serviceaccount:tap-local-source-system:proxy-ma
nager"
                  ]
              }
          }
      }
  ]
}
EOF

cat << EOF > local-source-proxy-policy.json
{
  "Version": "2012-10-17",
  "Statement": [
      {
          "Action": [
              "ecr:GetAuthorizationToken"
          ],
          "Resource": "*",
          "Effect": "Allow",
          "Sid": "TAPLSPGlobal"
      },
```

```
      {
          "Effect": "Allow",
          "Action": [
              "ecr:BatchCheckLayerAvailability",
              "ecr:GetDownloadUrlForLayer",
              "ecr:GetRepositoryPolicy",
              "ecr:DescribeRepositories",
              "ecr:ListImages",
              "ecr:DescribeImages",
              "ecr:BatchGetImage",
              "ecr:GetLifecyclePolicy",
              "ecr:GetLifecyclePolicyPreview",
              "ecr:ListTagsForResource",
              "ecr:DescribeImageScanFindings",
              "ecr:InitiateLayerUpload",
              "ecr:UploadLayerPart",
              "ecr:CompleteLayerUpload",
              "ecr:PutImage"
          ],
          "Resource": [
              "arn:aws:ecr:${AWS_REGION}:${AWS_ACCOUNT_ID}:repository/tap-ls
p"
          ],
          "Sid": "TAPLSPScoped"
      }
  ]
}
EOF

# Create the TAP Local Source Proxy Role
aws iam create-role --role-name tap-local-source-proxy --assume-role-policy-d
ocument \
file://local-source-proxy-trust-policy.json
# Attach the Policy to the tap-local-source-proxy Role created above
aws iam put-role-policy --role-name tap-local-source-proxy --policy-name tapL
ocalSourcePolicy \
--policy-document file://local-source-proxy-policy.json
```

Using a secret with pull privileges only

You can use a secret with only pull privileges if you prefer to have a dedicated credential with a least-privilege policy, specifically for downloading artifacts instead of reusing credentials with higher privileges.

The secret containing this credential is distributed across developer namespaces by using the Secretgen `SecretExport` resource. Namespace Provisioner automatically imports it to the developer namespace. However, for development purposes, you can skip this step and use the same secret for both pushing and pulling artifacts.

To use a secret with pull privileges only, run:

```
# For all registries except ECR
tanzu secret registry add lsp-pull-credentials \
--username USERNAME-VALUE --password 'PASSWORD-VALUE' \
--server REGISTRY-SERVER \
--namespace tap-install --yes
```

Install Local Source Proxy

This topic tells you how to install and customize Local Source Proxy (LSP).

Prerequisites

Meet the prerequisites before attempting to install Local Source Proxy.

Install

Install Local Source Proxy by updating `tap-values.yaml` with the following details:

```
local_source_proxy:
  repository: REGISTRY-SERVER/REPOSITORY-PATH

  push_secret:
   name: lsp-push-credentials
   namespace: tap-install
   create_export: true

  pull_secret:
   name: lsp-pull-credentials
   namespace: tap-install
   create_export: true
```

Where:

- `local_source_proxy.repository` is required. This is the repository where all your source code will be uploaded. Examples of commonly used repositories include:
    - Harbor, which has the form `my-harbor.io/my-project/local-source`.
    - Docker Hub, which has the form `my-dockerhub-user/local-source` or `index.docker.io/my-user/local-source`.
    - Google Artifact Registry, which has the form `MY-REGISTRY-REGION-docker.pkg.dev/my-project/local-source/image`.
    - Google Cloud Registry, which has the form `gcr.io/my-project/local-source`.

  You are not restricted to using a repository from this list.
- `local_source_proxy.push_secret` is required. This is the push secret reference that has the permission to push artifacts to the repository mentioned in `local_source_proxy.repository`.
- `local_source_proxy.push_secret.create_export` is `false` by default. Set it as `true` to tell Local Source Proxy to create a `SecretExport` for the referenced secret and own it. Do one of the following if you're reusing the secret that already existed in your cluster:
    - Ensure that it's not exported by any other process
    - Set this flag to `false` and ensure that it is exportable to the `tap-local-source-system` namespace by using a `SecretExport` resource
- `local_source_proxy.pull_secret` is optional, but recommended for production. Use the credential that has pull permissions. You can re-use `lsp-push-credentials` that have pull access if you chose not to create a separate request for pulling.
- `local_source_proxy.pull_secret.create_export` is `false` by default. Set it as `true` to tell Local Source Proxy to create a SecretExport for the referenced secret and own it.

In a production installation of Tanzu Application Platform, do not share the registry secret that has write access across developer namespaces. Instead, distribute a separate registry secret that only has read access.

In such cases, `pull_secret` can be specified, and `source-controller` uses the `pull_secret` to pull source artifacts for deployment.

The `pull_secret` uses a Docker registry credentials secret referenced by its `name` and `namespace`.

To enable the Tanzu Application Platform installer to automatically create a `SecretExport` resource in the specified `namespace` for exporting the secret to developer namespaces, set `pull_secret.create_export` to `true`.

Alternatively, if `create_export` is set to `false`, you must manually create the `SecretExport` resource in the referenced `namespace`.

Do one of the following if you're reusing the secret that already existed in your cluster:

- Ensure that it's not exported by any other process
- Set this flag to `false` and ensure that it is exportable to developer namespaces by using a `SecretExport` resource

Create the SecretExport resource

If you left `create_export` as `true` in `tap-values.yaml`, skip this procedure. If you set the `create_export` to `false`, apply the following YAML in `tap-values.yaml` to create the `SecretExport` resource:

Use this YAML for `push-secret`:

```
---
apiVersion: secretgen.carvel.dev/v1alpha1
kind: SecretExport
metadata:
  name: lsp-push-credentials
  namespace: tap-install
spec:
  toNamespace: tap-local-source-system
```

Use this YAML for `pull-secret`:

```
---
apiVersion: secretgen.carvel.dev/v1alpha1
kind: SecretExport
metadata:
  name: lsp-pull-credentials
  namespace: tap-install
spec:
  toNamespace: *
```

Customize the installation

You can configure specific Local Source Proxy resources by using the following properties in `tap-values.yaml`, as described in the following sections.

Override default RBAC permissions to access the proxy service

When this section is not provided, the default behavior is to employ the `system:authenticated` group as the chosen option.

```
local_source_proxy:
  rbac_subjects_for_proxy_access:
  - kind: "Group"
    name: "system:authenticated"
    apiGroup: "rbac.authorization.k8s.io"
```

To grant access for a specific user or group to push images through Local Source Proxy, use the `rbac_subjects_for_proxy_access` property in the `local_source_proxy` configuration:

- Set `rbac_subjects_for_proxy_access.kind` to either `"User"` or `"Group"`.
- Set `rbac_subjects_for_proxy_access.name` to the user name or group name that requires authorization.
- Set `rbac_subjects_for_proxy_access.apiGroup` to either `rbac.authorization.k8s.io` or the custom `apiGroup` associated with the specified kind.

For more information about RoleBinding, see the Kubernetes documentation. These settings enable you to customize RBAC permissions for accessing the proxy service according to your specific user or group requirements.

Important

If you define the `rbac_subjects_for_proxy_access` configuration in the `tap-values.yaml` file, it supersedes the default `system:authenticated` role binding with the one specified in `tap-values.yaml`. This allows platform operators to restrict access to the proxy server exclusively to a predefined set of groups, users, or service accounts.

For example:

```
local_source_proxy:
  rbac_subjects_for_proxy_access:
  - kind: "Group"
    name: "alpha-group"
    apiGroup: "rbac.authorization.k8s.io"
```

Override default CPU and memory limits for controller pods

To configure the compute resource limits for the Local Source Proxy server, you can use the `proxy_configuration` section within the `local_source_proxy` configuration in `tap-values.yaml`.

Specify the following properties to set the resource limits:

- `proxy_configuration.limits.cpu`: Set the maximum CPU limit for the Local Source Proxy server.
- `proxy_configuration.limits.memory`: Configure the maximum memory limit available for the Local Source Proxy server.

For example:

```
local_source_proxy:
  proxy_configuration:
    limits:
      cpu: 500m
      memory: 100Mi
```

Use AWS Identity and Access Management (IAM) roles for ECR

If your Tanzu Application Platform installation is both

- On AWS with Amazon Elastic Kubernetes Service (EKS)
- Using the AWS Elastic Container Registry (ECR) for storing local source code

then write the IAM role that has push and pull permissions for `aws_iam_role_arn`. For example:

```
local_source_proxy:
  repository: 123456789012.dkr.ecr.us-east-1.amazonaws.com/local-source
```

```
  push_secret:
    aws_iam_role_arn: arn:aws:iam::123456789012:role/tap-local-source-proxy
```

You specify this IAM role in `aws_iam_role_arn` to assign it to the Kubernetes service account that the Local Source Proxy server uses. For the steps to create an IAM role and add the Amazon Resource Name (ARN) to the Kubernetes service account used by Local Source Proxy, see Prerequisites for Local Source Proxy.

Doing this allows the Local Source Proxy server to handle incoming image push requests with the appropriate IAM role-based permissions.

Increase or decrease the number of replicas

By default, the Local Source Proxy instance is configured with one replica in the deployment. You can increase or decrease the number of replicas by changing the `proxy_configuration.replicas` value.

For example:

```
local_source_proxy:
  proxy_configuration:
    replicas: 3
```

Specify CA certificate data for registries that use self-signed certificates

If you have a custom TLS certificate or a self-signed certificate for your registry server, and it uses a private certificate authority, you can set up the public CA certificate data by providing the necessary configuration under `local_source_proxy.ca_cert_data` in the `tap.values.yaml` file.

This allows you to provide the necessary certificate information for secure communication with the registry server. For example:

```
local_source_proxy:
  ca_cert_data: |
    -----BEGIN CERTIFICATE-----
    ...
    -----END CERTIFICATE-----
```

Local Source Proxy detects when `shared.ca_cert_data` is provided in `tap-values.yaml` and imports the CA certificate data from that key.

Troubleshoot Local Source Proxy

This topic helps you troubleshoot issues you might encounter with Local Source Proxy (LSP).

View Local Source Proxy server logs

Symptom

You encounter an error and need to view the Local Source Proxy server logs to investigate it.

Solution

Run

```
kubectl -n tap-local-source-system logs deployments/local-source-proxy
```

Use `-f` to follow the log output.

View Apps CLI plug-in health messages

Symptom

You need to read the Apps CLI plug-in health messages to assess the status of Local Source Proxy and its connectivity with the upstream repository.

Solution

Run

```
tanzu apps lsp health
```

Example:

```
$ tanzu apps lsp health
user_has_permission: true
reachable: true
upstream_authenticated: true
overall_health: true
message: All health checks passed
```

User does not have RBAC permission to list services

Symptom

You encounter any of these error messages:

```
$ tanzu apps workload apply
Error: Either Local Source Proxy is not installed on the Cluster or you don't have per
missions to access it
Reason: The current user does not have permission to access the local source proxy.
Messages:
- services "http:local-source-proxy:5001" is forbidden: User "abc@example.com" cannot
get resource "services/proxy" in API group "" in the namespace "tap-local-source-syste
m": requires one of ["container.services.proxy"] permission(s).
```

```
$ tanzu apps lsp health
user_has_permission: false
reachable: false
upstream_authenticated: false
overall_health: false
message: |-
  The current user does not have permission to access the local source proxy.
  Messages:
  - services "http:local-source-proxy:5001" is forbidden: User "abc@example.com" canno
t get resource "services/proxy" in API group "" in the namespace "tap-local-source-sys
tem": requires one of ["container.services.proxy"] permission(s).
```

Cause

Typically, this situation arises when a custom user or group is specified within the `rbac_subjects_for_proxy_access` section of `tap-values.yaml`.

Solution

Ensure that the user or group listed is valid. For more information about overriding default RBAC permissions to access the proxy service, see Override default RBAC permissions to access the proxy service.

Missing repository in Tanzu Application Platform values

Symptom

You encounter one of these error messages:

```
$ tanzu apps workload apply
Error: Local source proxy failed to upload source to the repository
Reason: Local source proxy is not healthy.
Messages:
- registry server configuration in the cluster is invalid
```

```
$ tanzu apps lsp health
user_has_permission: true
reachable: true
upstream_authenticated: false
overall_health: false
message: |
  Local source proxy is not healthy.
  Messages:
  - registry server configuration in the cluster is invalid
```

Cause

The cause might be that `tap-values.yaml` lacks a valid value for the repository.

Solution

Add a valid repository value to `tap-values.yaml` and wait for the app reconciliation to complete.

Missing or misconfigured registry secret

Symptom

You encounter one of these error messages:

```
$ tanzu apps workload apply
Error: Local source proxy failed to upload source to the repository
Reason: Local source proxy was unable to authenticate against the target registry.
Messages:
- GET https://gcr.io/v2/token?scope=repository:abc-playground/lsp-source:pull,push&ser
vice=gcr.io: UNAUTHORIZED: You don't have the needed permissions to perform this opera
tion, and you may have invalid credentials. To authenticate your request, follow the s
teps in: https://cloud.google.com/container-registry/docs/advanced-authentication
```

```
$ tanzu apps lsp health
user_has_permission: true
reachable: true
upstream_authenticated: false
overall_health: false
message: |-
  Local source proxy was unable to authenticate against the target registry.
  Messages:
  - GET https://gcr.io/v2/token?scope=repository:abc-playground/lsp-source:pull,push&s
ervice=gcr.io: UNAUTHORIZED: You don't have the
```

```
 needed permissions to perform this operation, and you may have invalid credentials. T
o authenticate your request, follow the steps in: https:/
/cloud.google.com/container-registry/docs/advanced-authentication
```

Cause

Potential causes include:

- A missing registry secret:
  - `push_secret` information is not available in the `local_source_proxy` section of `tap-values.yaml`.
  - `image_registry.secret` information is not available in the `shared` section of `tap-values.yaml`.
- If `push_secret` is used, the secret was not exported to the Local Source Proxy namespace. The credentials used in the secret do not match the configured external registry.

Solution

1. Ensure that at least one of the following entries is found in `tap-values.yaml`:
   - `push_secret` information in the `local_source_proxy` section
   - `image_registry.secret` information in the `shared` section
2. If `push_secret` is used, make sure that it can be exported to the Local Source Proxy namespace.
3. Ensure that the credentials used in the secret match the configured external registry.

Invalid credentials

Symptom

You encounter one of these error messages:

```
$ tanzu apps workload apply
Error: Local source proxy failed to upload source to the repository
Reason: Local source proxy was unable to authenticate against the target registry.
Messages:
- GET https://gcr.io/v2/token?scope=repository:abc-playground/lsp-source:pull,push&ser
vice=gcr.io: UNAUTHORIZED: Not Authorized.
```

```
$ tanzu apps lsp health # when using Harbor
user_has_permission: true
reachable: true
upstream_authenticated: false
overall_health: false
message: |-
  Local source proxy was unable to authenticate against the target registry.
  Messages:
  - 401 Unauthorized
```

```
$ tanzu apps lsp health # when using GCR
user_has_permission: true
reachable: true
upstream_authenticated: false
overall_health: false
message: |-
  Local source proxy was unable to authenticate against the target registry.
  Messages:
```

```
  - GET https://gcr.io/v2/token?scope=repository:abc-playground/lsp-source:pull,push&s
ervice=gcr.io: UNAUTHORIZED: Not Authorized.
```

Cause

The cause is the use of invalid credentials.

Solution

Change the credentials used in the secret to match those in the configured external registry.

Local Source Proxy doesn't automatically detect changes to `podspec`

Symptom

Local Source Proxy doesn't automatically detect changes to `podspec`.

Cause

AWS Elastic Container Registry (ECR) is configured as the external registry in `tap-values.yaml`.

Solution

Delete the old pods so that the new pods can mount the expected `podspec`, enabling access to the registry through the Identity and Access Management (IAM) role Amazon Resource Name (ARN).

Error: unknown command "lsp" for "apps"

Symptom

When running `tanzu apps lsp health` the CLI returns the error message

```
Error: unknown command "lsp" for "apps"
```

Cause

Tanzu CLI and the apps plug-in are out of date.

Solution

1. Install Tanzu CLI v0.12.0 or later.
2. Upgrade the apps plug-in by running:

   ```
   tanzu plugin upgrade apps
   ```

Error: i/o timeout

Symptom

When you run `tanzu apps lsp health` or `tanzu apps workload apply`, after a few minutes the CLI returns the following error message:

```
connect: i/o timeout
```

Cause

TCP port 5002 is not open between your control plane nodes and your worker nodes.

Solution

1. Open the port.
2. Run the command again.

Reference for Local Source Proxy

This topic gives you reference information for Local Source Proxy (LSP).

Default resources

Local Source Proxy comes with the standard `iterate` and `full` Tanzu Application Platform installation profiles. The default set of resources provisioned in a namespace is mostly predefined. However, certain resources are defined based on the configuration entries in `tap-values.yaml` under the `local_source_proxy` section.

For more information about installation profiles, see Installation profiles in Tanzu Application Platform.

The following table shows the list of resources that are templated in the installation of applicable profiles:

Namespace	Kind	Name	Reconcile
tap-local-source-system	Service	local-source-proxy	No
tap-local-source-system	Secret	local-source-proxy-values	Yes
local_source_proxy.push_secret.namespace (tap-values.yaml)	SecretExport	local_source_proxy.push_secret.name	Yes
tap-local-source-system	SecretImport	local_source_proxy.push_secret.name	Yes
tap-local-source-system	Deployment	local-source-proxy	No
tap-local-source-system	Role	local-source-proxy-manager	No
tap-local-source-system	RoleBinding	proxy-manager	No
tap-local-source-system	ServiceAccount	proxy-manager	No
tap-local-source-system	Role	push-artifact	No
tap-local-source-system	RoleBinding	service-proxy-role-binding	Yes

Overview of Namespace Provisioner

Namespace Provisioner provides a secure, automated way for you to provision namespaces with the resources and namespace-level privileges required for your workloads to function as intended in Tanzu Application Platform (commonly known as TAP).

Description

Namespace Provisioner enables platform operators to add additional customized namespace-scoped resources using GitOps to meet their organization's requirements and provides continuous

reconciliation using the kapp-controller to maintain the desired state of the namespace-scoped resources.

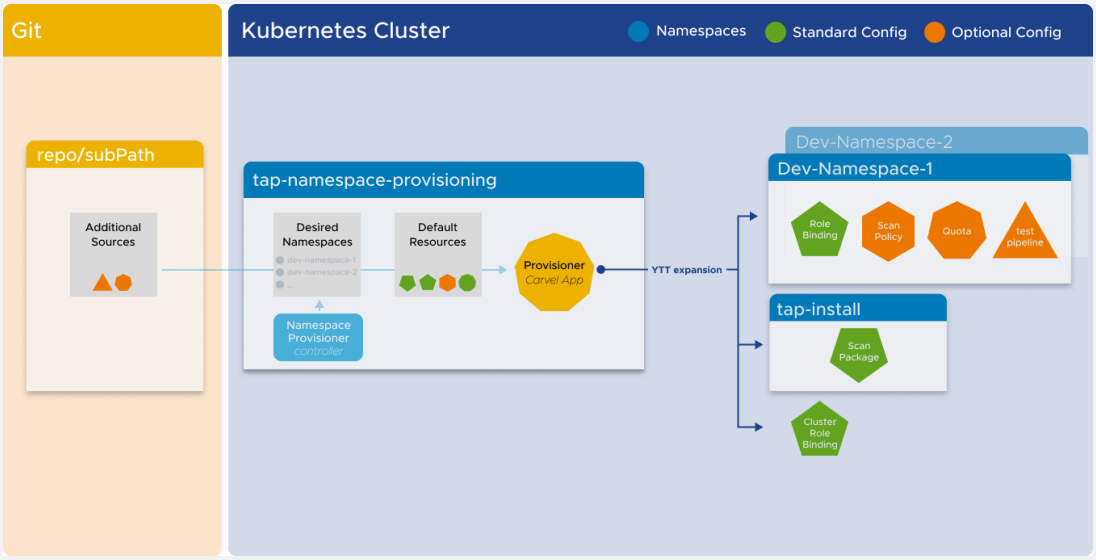
Namespace Provisioner enables operators that are new to Kubernetes to automate the provisioning of multiple developer namespaces in a shared cluster. For organizations that have already adopted Kubernetes, Namespace Provisioner is also compatible with existing Kubernetes tooling.

Modes

Use Namespace Provisioner with one of the following modes:

Controller mode

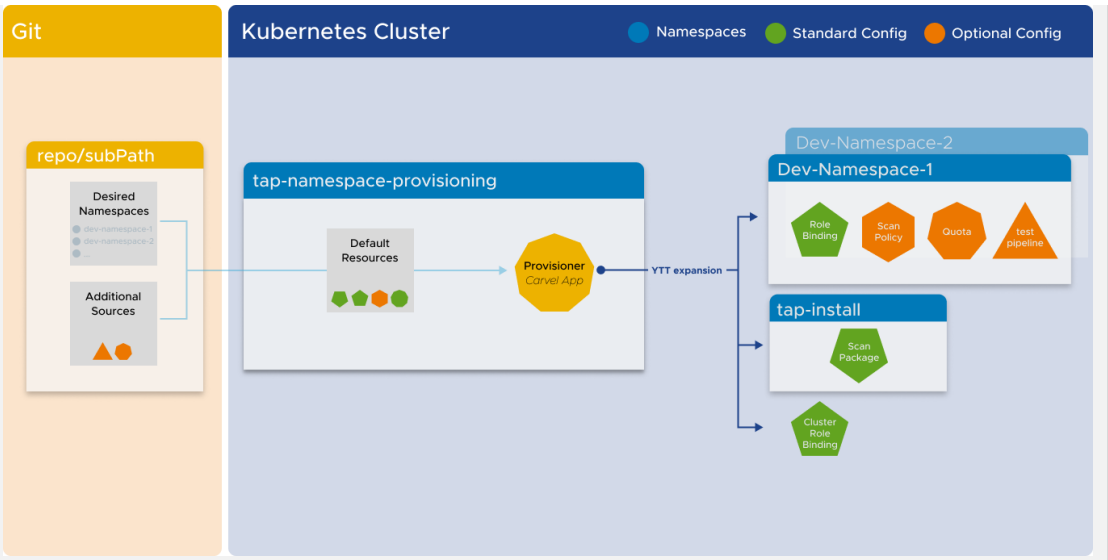
Controller mode has the following characteristics:



- The list of developer namespaces is managed by the Namespace Provisioner controller using a label selector `apps.tanzu.vmware.com/tap-ns=""`
- Namespace Provisioner creates default resources in all managed namespaces.
- Namespace Provisioner creates additional Platform Operator templated resources stored in Git repository locations specified under the `additional_sources` section in Namespace Provisioner configuration. For more information, see Customize Installation of Namespace Provisioner.

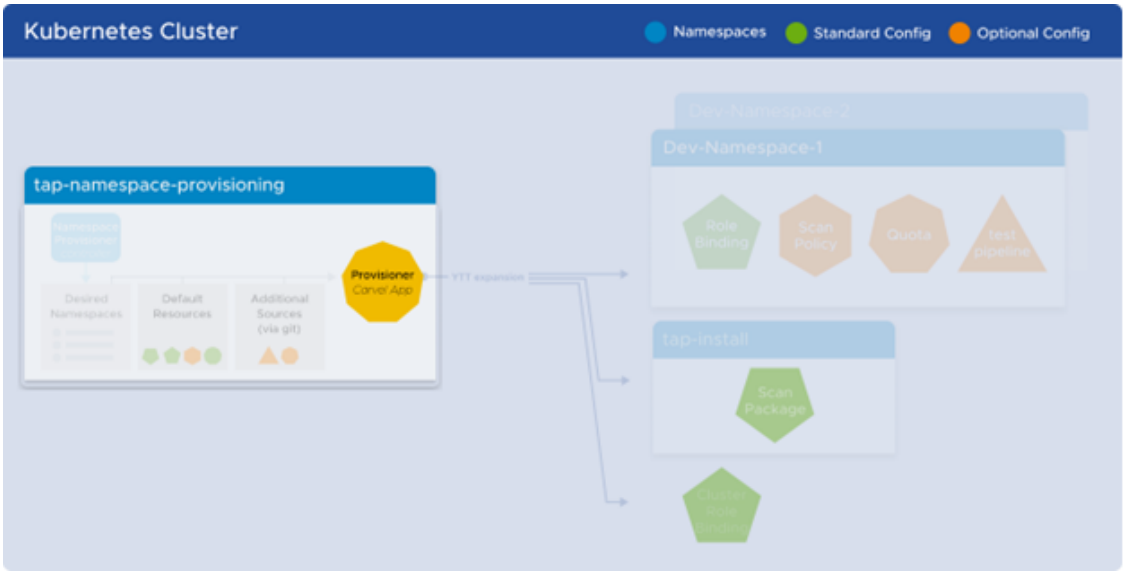
GitOps mode

Gitops mode has the following characteristics



- The list of developer namespaces is managed in a Git repository that is specified in the `gitops_install` section of the Namespace Provisioner configuration.
- Namespace Provisioner creates default resources that are shipped Out of the Box in all managed namespaces.
- Namespace Provisioner creates additional Platform Operator templated resources stored in Git repositories specified under `additional_sources` in Namespace Provisioner configuration. For more information, see Customize Installation of Namespace Provisioner.

Provisioner Carvel application



Namespace Provisioner consists of a Carvel application called `provisioner` that facilitates the creation of resources in the managed developer namespaces. The `provisioner` application uses ytt to templatize a set of resources into installations in multiple namespaces.

Desired namespaces

The following section describes how the list of desired developer namespaces is managed in controller and GitOps modes.

Controller mode
In controller mode, the list of desired namespaces used by the `provisioner` application to create resources in, is maintained in the `desired-namespaces` ConfigMap. This ConfigMap is managed by the Namespace Provisioner controller and it provides a declarative way to indicate which namespaces should be populated with resources. The ConfigMap consists of a list of namespace objects, with a required `name` parameter, and optional additional parameters which are used as `data.values` for customizing defined resources.

For example,

```
---
apiVersion: v1
kind: ConfigMap
metadata:
    name: desired-namespaces
    namespace: tap-namespace-provisioning
    annotations:
        kapp.k14s.io/create-strategy: fallback-on-update
        namespace-provisioner.apps.tanzu.vmware.com/no-overwrite: "" #! This annotat
ion tells the provisioner app to not override this configMap as this is your desired
state.
data:
    namespaces.yaml: |
        #@data/values
        ---
        namespaces:
        - name: dev-ns1
        # additional parameters about dev-ns1 added via label/annotations or GitOps
        - name: dev-ns2
        # additional parameters about dev-ns1 added via label/annotations or GitOps
```

GitOps mode
In the GitOps mode, the list of desired namespaces used by the `provisioner` application to create resources in, is maintained in a Git repository as a ytt data values file as shown in this sample file. This file provides a declarative way to indicate which namespaces should be populated with resources. For more information, see the `Options if using GitOps` section in Customize Install.

Namespace Provisioner controller

The Namespace Provisioner controller (controller) is installed by default and manages the content contained in the `desired-namespaces` ConfigMap. The controller watches namespaces in the cluster and updates the `desired-namespaces` ConfigMap with a list of all namespaces that match the namespace label selector.The default namespace label selector is `apps.tanzu.vmware.com/tap-ns`. For more information, see Use a different label selector than default.

Overview of Namespace Provisioner

Namespace Provisioner provides a secure, automated way for you to provision namespaces with the resources and namespace-level privileges required for your workloads to function as intended in Tanzu Application Platform (commonly known as TAP).

Description

Namespace Provisioner enables platform operators to add additional customized namespace-scoped resources using GitOps to meet their organization's requirements and provides continuous reconciliation using the kapp-controller to maintain the desired state of the namespace-scoped resources.

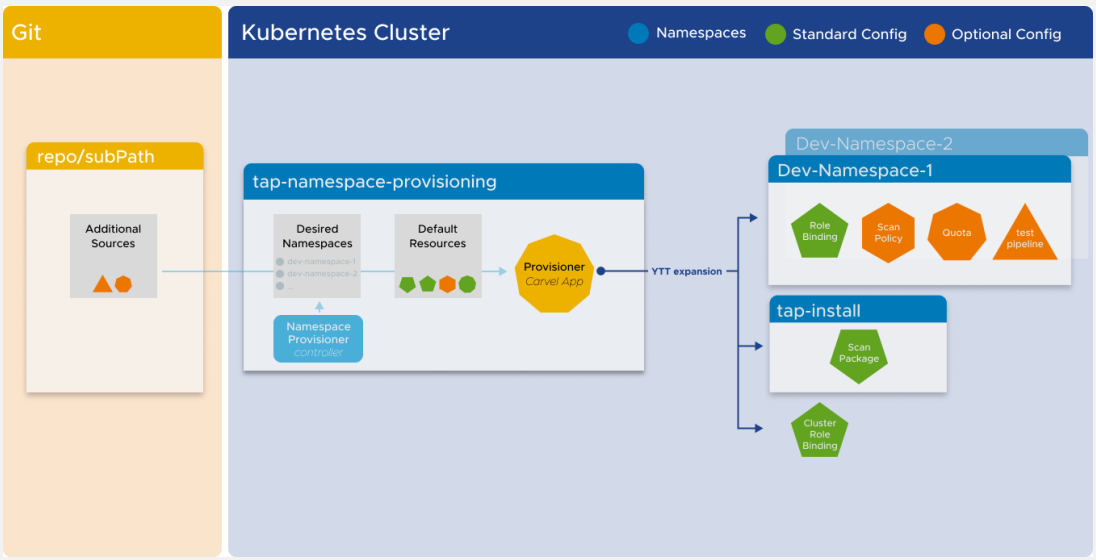
Namespace Provisioner enables operators that are new to Kubernetes to automate the provisioning of multiple developer namespaces in a shared cluster. For organizations that have already adopted Kubernetes, Namespace Provisioner is also compatible with existing Kubernetes tooling.

Modes

Use Namespace Provisioner with one of the following modes:

Controller mode

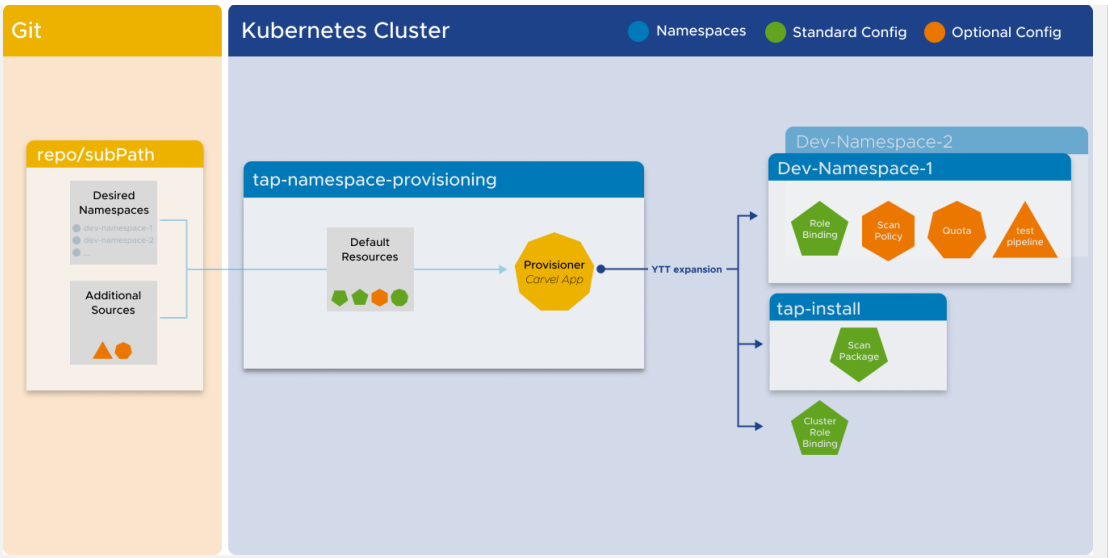
Controller mode has the following characteristics:



- The list of developer namespaces is managed by the Namespace Provisioner controller using a label selector `apps.tanzu.vmware.com/tap-ns=""`
- Namespace Provisioner creates default resources in all managed namespaces.
- Namespace Provisioner creates additional Platform Operator templated resources stored in Git repository locations specified under the `additional_sources` section in Namespace Provisioner configuration. For more information, see Customize Installation of Namespace Provisioner.

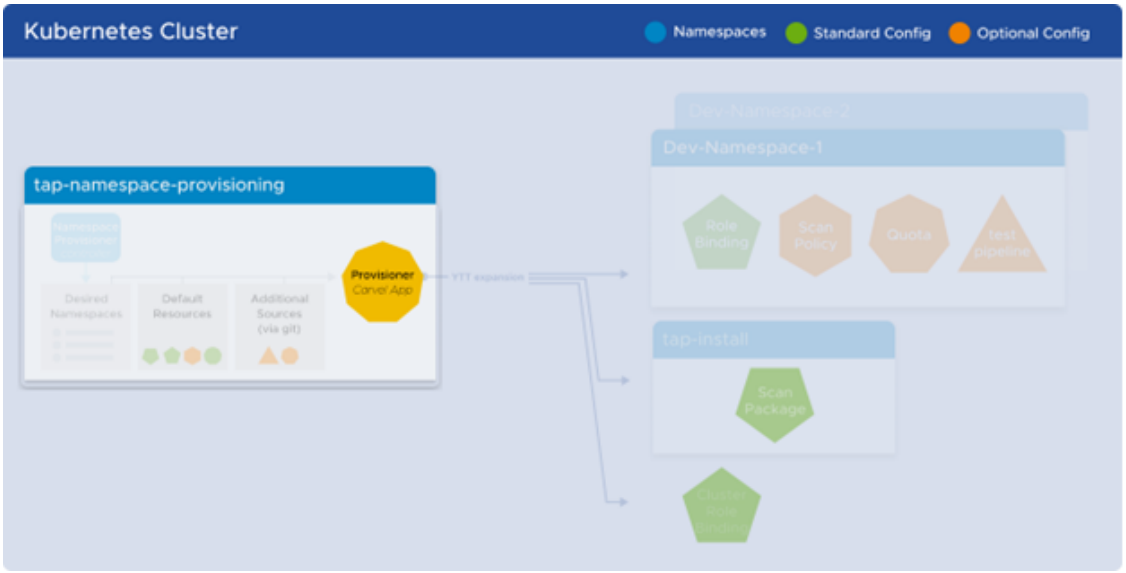
GitOps mode

Gitops mode has the following characteristics



- The list of developer namespaces is managed in a Git repository that is specified in the `gitops_install` section of the Namespace Provisioner configuration.
- Namespace Provisioner creates default resources that are shipped Out of the Box in all managed namespaces.
- Namespace Provisioner creates additional Platform Operator templated resources stored in Git repositories specified under `additional_sources` in Namespace Provisioner configuration. For more information, see Customize Installation of Namespace Provisioner.

Provisioner Carvel application



Namespace Provisioner consists of a Carvel application called `provisioner` that facilitates the creation of resources in the managed developer namespaces. The `provisioner` application uses ytt to templatize a set of resources into installations in multiple namespaces.

Desired namespaces

The following section describes how the list of desired developer namespaces is managed in controller and GitOps modes.

Controller mode
In controller mode, the list of desired namespaces used by the `provisioner` application to create resources in, is maintained in the `desired-namespaces` ConfigMap. This ConfigMap is managed by the Namespace Provisioner controller and it provides a declarative way to indicate which namespaces should be populated with resources. The ConfigMap consists of a list of namespace objects, with a required `name` parameter, and optional additional parameters which are used as `data.values` for customizing defined resources.

For example,

```
---
apiVersion: v1
kind: ConfigMap
metadata:
    name: desired-namespaces
    namespace: tap-namespace-provisioning
    annotations:
        kapp.k14s.io/create-strategy: fallback-on-update
        namespace-provisioner.apps.tanzu.vmware.com/no-overwrite: "" #! This annotat
ion tells the provisioner app to not override this configMap as this is your desired
state.
data:
    namespaces.yaml: |
        #@data/values
        ---
        namespaces:
        - name: dev-ns1
        # additional parameters about dev-ns1 added via label/annotations or GitOps
        - name: dev-ns2
        # additional parameters about dev-ns1 added via label/annotations or GitOps
```

GitOps mode
In the GitOps mode, the list of desired namespaces used by the `provisioner` application to create resources in, is maintained in a Git repository as a ytt data values file as shown in this sample file. This file provides a declarative way to indicate which namespaces should be populated with resources. For more information, see the `Options if using GitOps` section in Customize Install.

Namespace Provisioner controller

The Namespace Provisioner controller (controller) is installed by default and manages the content contained in the `desired-namespaces` ConfigMap. The controller watches namespaces in the cluster and updates the `desired-namespaces` ConfigMap with a list of all namespaces that match the namespace label selector.The default namespace label selector is `apps.tanzu.vmware.com/tap-ns`. For more information, see Use a different label selector than default.

Get started with Namespace Provisioner

This topic provides a list of topics to help you get started with Namespace Provisioner.

Provision Developer Namespaces

Customize Installation of Namespace Provisioner

Setup for OOTB Supply Chains

Provision developer namespaces in Namespace Provisioner

This topic tells you how to use Namespace Provisioner to provision developer namespaces in Tanzu Application Platform (commonly known as TAP).

Prerequisite

- The Namespace Provisioner package is installed and reconciled.
- The registry-credential secret referenced by the supply chain components for pulling and pushing images is added to **tap-install** and exported to all namespaces.

Example secret creation, exported to all namespaces:

```
tanzu secret registry add registry-credentials --server REGISTRY-SERVER --username REG
ISTRY-USERNAME --password REGISTRY-PASSWORD --export-to-all-namespaces --yes --namespa
ce tap-install
```

Important

Namespace Provisioner creates a secret called registries-credentials in each managed namespace which is a placeholder secret filled indirectly by secretgen-controller with all the registry credentials exported for that managed namespace.

Manage a list of developer namespaces

There are two ways to manage the list of developer namespaces that are managed by Namespace Provisioner.

Using Namespace Provisioner Controller

`tap-values.yaml` configuration example:

```
namespace_provisioner:
  controller: true
```

The imperative way is to create the namespace using kubectl or using other means and label it using the default selector.

1. Create a namespace using kubectl or any other means

   ```
   kubectl create namespace YOUR-NEW-DEVELOPER-NAMESPACE
   ```

2. Label your new developer namespace with the default *namespace_selector* `apps.tanzu.vmware.com/tap-ns=""`.

   ```
   kubectl label namespaces YOUR-NEW-DEVELOPER-NAMESPACE apps.tanzu.vmware.com/t
   ap-ns=""
   ```

   - This label tells the Namespace Provisioner controller to add this namespace to the desired-namespaces ConfigMap.
   - By default, the label's value can be anything, including "".

- If required, you can change the default label selector, see Customize Installation of Namespace Provisioner.

3. Run the following command to verify the default resources have been created in the namespace:

```
kubectl get secrets,serviceaccount,rolebinding,pods,workload,configmap,limitr
ange -n YOUR-NEW-DEVELOPER-NAMESPACE
```

For example:

```
NAME                              TYPE                                  DATA   AGE
secret/app-tls-cert               kubernetes.io/tls                     3      19s
secret/registries-credentials     kubernetes.io/dockerconfigjson        1      26s
secret/scanner-secret-ref         kubernetes.io/dockerconfigjson        1      20s

NAME                              SECRETS   AGE
serviceaccount/default            1         4h7m
serviceaccount/grype-scanner      2         20s

NAME                                                                  ROLE
AGE
rolebinding.rbac.authorization.k8s.io/default-permit-deliverable   ClusterRol
e/deliverable   26s
rolebinding.rbac.authorization.k8s.io/default-permit-workload      ClusterRol
e/workload      26s

NAME                            DATA   AGE
configmap/kube-root-ca.crt      1      38h

NAME                              CREATED AT
limitrange/dev-lr   2023-03-08T04:18:58Z
```

Using GitOps

The GitOps approach provides a fully declarative way to create developer namespaces managed by Namespace Provisioner.

`tap-values.yaml` configuration example:

```
namespace_provisioner:
  controller: false
  gitops_install:
    ref: origin/main
    subPath: ns-provisioner-samples/gitops-install
    url: https://github.com/vmware-tanzu/application-accelerator-samples.git
```

This GitOps configuration does the following things:

- `controller: false` - The Namespace Provisioner package does not install the controller. The list of namespaces is managed in a GitOps repository instead.
- The `gitops-install` directory specified as the `subPath` value includes two files:
    1. desired-namespace.yaml contains the list of developer namespaces in a ytt data.values format.
    2. namespaces.yaml contains a Kubernetes namespace object.

Note

If you have another tool like Tanzu Mission Control or some other process that is taking care of creating namespaces for you, and you don't want a Namespace

Provisioner to create the namespaces, you can delete this file from your GitOps install repository.

Important The `tap-values.yaml` configuration example above creates the following two namespaces: `dev` and `qa`. If these namespaces already exist in your cluster, remove them or rename the namespaces in your GitOps repository so they do not conflict with existing resources.

Run the following command to verify the default resources are created in the namespace:

```
kubectl get secrets,serviceaccount,rolebinding,pods,workload,configmap,limitrange -n
dev
```

For example:

```
NAME                              TYPE                                  DATA   AGE
secret/app-tls-cert               kubernetes.io/tls                     3      52s
secret/registries-credentials     kubernetes.io/dockerconfigjson        1      59s
secret/scanner-secret-ref         kubernetes.io/dockerconfigjson        1      53s

NAME                              SECRETS   AGE
serviceaccount/default            1         59s
serviceaccount/grype-scanner      2         53s

NAME                                                                  ROLE
AGE
rolebinding.rbac.authorization.k8s.io/default-permit-deliverable      ClusterRole/deliv
erable   59s
rolebinding.rbac.authorization.k8s.io/default-permit-workload         ClusterRole/workl
oad      59s

NAME                            DATA   AGE
configmap/kube-root-ca.crt      1      59s

NAME                  CREATED AT
limitrange/dev-lr     2023-03-08T04:22:20Z
```

For more information, see the GitOps section of Customize Installation of Namespace Provisioner.

Enable additional users with Kubernetes RBAC

Namespace Provisioner does not support enabling additional users with Kubernetes RBAC. Support is planned for an upcoming release. Until Namespace Provisioner support is provided, follow the instructions in Enable additional users with Kubernetes RBAC.

Customize Namespace Provisioner installation

This topic tells you how to customize a standard installation of Namespace Provisioner in Tanzu Application Platform (commonly known as TAP).

Namespace Provisioner is packaged and distributed using a set of Carvel tools. The Namespace Provisioner package is installed as part of all the standard installation profiles except the View profile. For more information about installation profiles, see Installation profiles in Tanzu Application Platform.

The default set of resources provisioned in a namespace is based on a combination of the Tanzu Application Platform installation profile employed and the supply chain that is installed on the

cluster. For a list of what resources are created for different profile and supply chain combinations, see the Default Resources mapping table.

To see the Namespace Provisioner Package Schema for all configurable values, run:

```
tanzu package available get namespace-provisioner.apps.tanzu.vmware.com/0.3.0 --values
-schema -n tap-install
```

Different package customization options are available depending on what method you use to manage the list of developer namespaces:

Add additional resources to your namespaces from your GitOps repository

- `additional_sources`: This is an array of Git repository locations that contain Platform Operator templated resources to create in the provisioned namespaces, in addition to the default resources. The format of the Git repository locations must follow the “fetch” section of the kapp controller App specification, and only the Git type fetch is supported.
- `additional_sources[].git` This entry can include a secretRef specified for providing authentication details for connecting to a private Git repository. For more information, see Git Authentication for Private repository. The following parameters are available:
    - `name`: The name of the secret to be imported and used as valuesFrom in kapp.
    - `namespace`: The namespace where the secret exists.
    - `create_export`: A Boolean flag that controls the creation of a SecretExport resource in the namespace. The default value is false. If the secret is already exported, make sure that it is exported to the `tap-namespace-provisioning` namespace.
    - `path`: (**Optional**) This must start with the prefix `_ytt_lib/`. Namespace Provisioner mounts all the additional sources as a ytt library so it can expand the manifests in the additional sources for all managed namespaces using the logic in the expansion template. The path after the `_ytt_lib` prefix can be any string value, and must be unique across all additional sources. If you do not provide a `path`, Namespace Provisioner generates a `path` using `url` and `subPath`.

Important

Namespace Provisioner relies on kapp-controller for any tasks involving communication with external services, such as registries or Git repositories. When operating in air-gapped environments or other scenarios where external services are secured by a Custom CA certificate, you must configure kapp-controller with the CA certificate data to prevent X.509 certificate errors. For more information, see Deploy onto Cluster in the Cluster Essentials for VMware Tanzu documentation.

If the additional sources contain a resource that is scoped to a specific namespace, it is created in that namespace with a modified name that includes the developer namespace name. For example, the resource name will be “{resource name}-{developer namespace name}”.

If the additional sources include resources without any specified namespaces, and these resources are not cluster-scoped, Namespace Provisioner creates those resources in all of the namespaces it manages. However, if the resource is cluster-scoped, only a single instance of the resource is created.

Sample `tap-values.yaml` configuration:

Using Namespace Provisioner Controller

The Git repository is configured under `additional_sources`.

```
namespace_provisioner:
  controller: true
  additional_sources:
  - git:
      ref: origin/main
      subPath: ns-provisioner-samples/testing-scanning-supplychain
      url: https://github.com/vmware-tanzu/application-accelerator-samples.git
      # secretRef section is only needed if connecting to a Private Git repo
      secretRef:
        name: git-auth
        namespace: tap-install
        create_export: true
    path: _ytt_lib/testing-scanning-supplychain-setup
```

Using GitOps

The Git repository is configured under `additional_sources`.

```
namespace_provisioner:
  controller: false
  additional_sources:
  - git:
      ref: origin/main
      subPath: ns-provisioner-samples/testing-scanning-supplychain
      url: https://github.com/vmware-tanzu/application-accelerator-samples.git
      # secretRef section is only needed if connecting to a Private Git repo
      secretRef:
        name: git-auth
        namespace: tap-install
        create_export: true
    path: _ytt_lib/testing-scanning-supplychain-setup
  gitops_install:
    ref: origin/main
    subPath: ns-provisioner-samples/gitops-install
    url: https://github.com/vmware-tanzu/application-accelerator-samples.git
```

If a path is not specified in the `additional_sources` configuration, Namespace Provisioner automatically generates a path as follows: `_ytt_lib/applicaton-accelerator-samples-git-ns-provisioner-samples-testing-scaning-supplychain-0`

For more information, see Git Authentication for Private repository.

Adjust sync period of Namespace Provisioner

The `sync_period` parameter is the interval at which the Namespace Provisioner reconciles. It must be specified in the format of time + unit. The minimum allowed `sync_period` is 30 seconds. If a value lower than 30 seconds is specified in the `tap-values.yaml` file, Namespace Provisioner automatically sets the `sync_period` to 30 seconds. If no value is specified, the default `sync_period` is `1m0s`.

Sample `tap-values.yaml` configuration:

Using Namespace Provisioner Controller

Use the `sync_period` key.

```
namespace_provisioner:
  sync_period: 2m0s
```

Using GitOps
Use the `sync_period` key.

```
namespace_provisioner:
  controller: false
  sync_period: 1m0s
  gitops_install:
    ref: origin/main
    subPath: ns-provisioner-samples/gitops-install
    url: https://github.com/vmware-tanzu/application-accelerator-samples.git
```

Import user defined secrets in YAML format as ytt data.values

The `import_data_values_secrets` is an array of additional secrets in YAML format that can be imported into the Namespace Provisioner as data.values under the `data.values.imported` key. Namespace Provisioner creates a SecretImport for each secret listed in the array in the `tap-namespace-provisioning` namespace. Alternatively, you can manually create a SecretExport for the same secrets and export them to the `tap-namespace-provisioning` namespace. The following parameters are available:

- `name`: The name of the secret to be imported to use as valuesFrom in kapp.
- `namespace`: The namespace where the secret exists.
- `create_export`: A Boolean flag that indicates whether a `SecretExport` resource is created in the namespace. The default value is `false`. If the secret is already exported, ensure that it is exported to the `tap-namespace-provisioning` namespace.

Note

The `stringData` key of the secret must have `.yaml` or `.yml` suffix.

Example secret:

```
# Format of the secret that is importable under data.values.imported
apiVersion: v1
kind: Secret
metadata:
  name: user-defined-secrets
type: Opaque
stringData:
  # Key needs to have .yaml or .yml at the end
  content.yaml: |
    key1: value1
    key2: value2
```

Sample `tap-values.yaml` configuration:

Using Namespace Provisioner Controller
The list of secrets are imported under `import_data_values_secrets`.

```
namespace_provisioner:
  controller: true
  import_data_values_secrets:
  - name: user-defined-secrets
```

```
    namespace: tap-install
    create_export: true
```

Using GitOps

The list of secrets are imported under `import_data_values_secrets`.

```
namespace_provisioner:
  controller: false
  import_data_values_secrets:
  - name: user-defined-secrets
    namespace: tap-install
    create_export: true
  gitops_install:
    ref: origin/main
    subPath: ns-provisioner-samples/gitops-install
    url: https://github.com/vmware-tanzu/application-accelerator-samples.git
```

Use AWS IAM roles

If you are installing Tanzu Application Platform on Amazon Elastic Kubernetes Service (EKS), you can use the IAM Role specified in `aws_iam_role_arn` to configure the Kubernetes service account used by the workload and the supply chain components. For additional details on the process of creating the IAM Role for workloads and obtaining the `aws_iam_role_arn`, see Create AWS Resources for Tanzu Application Platform.

Sample `tap-values.yaml` configuration:

Using Namespace Provisioner Controller

Add the AWS IAM Role to `aws_iam_role_arn`.

```
namespace_provisioner:
  controller: yes
  aws_iam_role_arn: "arn:aws:iam::123456789012:role/EKSIAMRole"
```

Using GitOps

Add the AWS IAM Role to `aws_iam_role_arn`.

```
namespace_provisioner:
  controller: false
  aws_iam_role_arn: "arn:aws:iam::123456789012:role/EKSIAMRole"
  gitops_install:
    ref: origin/main
    subPath: ns-provisioner-samples/gitops-install
    url: https://github.com/vmware-tanzu/application-accelerator-samples.git
```

Apply default parameters to all namespaces

The `default_parameters` is an array of parameters that are applied to all namespaces. Use these parameters as ytt, such as `data.values.default_parameters` for templating default and additional resources.

Sample `tap-values.yaml` configuration:

Using Namespace Provisioner Controller

Use the `default_parameters` with the desired parameter.

```
namespace_provisioner:
  controller: yes
  default_parameters:
    limits:
      default:
        cpu: 1.7
        memory: 1Gi
      defaultRequest:
        cpu: 100m
        memory: 1Gi
```

Using GitOps

Use the `default_parameters` with the desired parameter.

```
namespace_provisioner:
  controller: false
  default_parameters:
    limits:
      default:
        cpu: 1.7
        memory: 1Gi
      defaultRequest:
        cpu: 100m
        memory: 1Gi
  gitops_install:
    ref: origin/main
    subPath: ns-provisioner-samples/gitops-install
    url: https://github.com/vmware-tanzu/application-accelerator-samples.git
```

Import overlay secrets

The `overlay_secrets` is a list of secrets that contains Carvel ytt overlay definitions. These overlays are applied to the resources created by the Namespace Provisioner. If the secrets are located in a different namespace, they are imported to the `namespace-provisioner` namespace.

Note

The `stringData` key of the secret must have `.yaml` or `.yml` suffix.

Sample secret with overlay to be used:

```
cat << EOF | kubectl apply -f -
apiVersion: v1
kind: Secret
metadata:
  name: grype-package-overlay
  namespace: tap-install
  annotations:
    kapp.k14s.io/change-rule: "delete after deleting tap"
stringData:
  grype-package-overlay.yaml: |
    #@  load("@ytt:overlay", "overlay")
    #@
    #@  def matchGrypeScanners(index, left, right):
    #@    if left["apiVersion"] != "packaging.carvel.dev/v1alpha1" or left["kind"] !=
"PackageInstall":
    #@      return False
    #@    end
    #@    return "metadata" in left and "name" in left["metadata"] and left["metadat
```

```
a"]["name"].startswith("grype-scanner")
    #@  end

    #@overlay/match by=matchGrypeScanners, expects="0+"
    ---
    metadata:
      annotations:
        #@overlay/match expects="0+"
        ext.packaging.carvel.dev/ytt-paths-from-secret-name.0: my-grype-overlay-secret
EOF
```

Sample `tap-values.yaml` configuration:

Using Namespace Provisioner Controller

The list of secrets with the overlay are set under `overlay_secrets`.

```
namespace_provisioner:
  controller: true
  overlay_secrets:
  - name: grype-package-overlay
    namespace: tap-install
    create_export: true
```

Using GitOps

The list of secrets with the overlay are set under `overlay_secrets`.

```
namespace_provisioner:
  controller: false
  overlay_secrets:
  - name: grype-package-overlay
    namespace: tap-install
    create_export: true
  gitops_install:
    ref: origin/main
    subPath: ns-provisioner-samples/gitops-install
    url: https://github.com/vmware-tanzu/application-accelerator-samples.git
```

Furthermore, you have the following options for customization:

Options if using Controller

If you are using the controller to manage the list of developer namespaces, you have the following additional customization options available:

- Use a different label selector than default
- Override the default CPU and memory limits for controller pods
- Customize the label and annotation prefixes that controller watches

Use a different label selector than default

Use the `namespace_selector` to specify the label selector used by the controller to identify the namespaces that will be included in the desired-namespaces ConfigMap.

Sample `tap-values.yaml` configuration:

```
namespace_provisioner:
  controller: true
  namespace_selector:
    matchExpressions:
    - key: apps.tanzu.vmware.com/tap-ns
      operator: Exists
```

Override the default CPU and memory limits for controller pods

To configure the compute resources for the Namespace Provisioner controllers, you can use the `controller_resources` section in the Namespace Provisioner configuration in `tap-values.yaml`.

To set the maximum CPU and memory limits for the controllers, edit the `controller_resources.resources.limits.cpu` and `controller_resources.resources.limits.memory` values.

Similarly, you can configure the minimum CPU capacity and memory requests for the controllers by adjusting the `controller_resources.resources.requests.cpu` and `controller_resources.resources.requests.memory` settings.

Sample `tap-values.yaml` configuration:

```
namespace_provisioner:
  controller: true
  controller_resources:
    resources:
      limits:
        cpu: 500m
        memory: 100Mi
      requests:
        cpu: 100m
        memory: 20Mi
```

Customize the label and annotation prefixes that controller watches

The `parameter_prefixes` is an array of label and annotation prefixes that the Namespace Provisioner controller uses to identify and include namespace-specific parameters in the desired-namespaces ConfigMap. These parameters can then be used as ytt data.values for templating both default and additional resources.

For example, if the value `tap.tanzu.vmware.com` is specified in `parameter_prefixes`, the Namespace Provisioner controller searches for annotations or labels in a provisioned namespace that begin with the prefix `tap.tanzu.vmware.com/`. It extracts those annotations or labels and uses them as parameters for further configuration and customization.

Sample `tap-values.yaml` configuration:

```
namespace_provisioner:
  controller: yes
  parameter_prefixes:
  - tmc.cloud.vmware.com
  - tap.tanzu.vmware.com
```

Options if using GitOps

If you are using GitOps to manage the list of developer namespaces, you have the following customization option:

Use GitOps to manage developer namespaces list

`gitops_install` is a Git repository configuration with the list of namespaces to be provisioned.

Only use the gitops_install section when `controller: false` is set. If this section is used in conjunction with `controller: true`, the Namespace Provisioner package fails to reconcile, resulting in an error message stating `controller: false when using 'gitops_install' in provided values`.

Files in the Git repository must have a `.yaml` or `.yml` extension.

The `gitops_install` section can have the following entries:

- `url`: The Git repository URL (required)

- `subPath`: The Git repository subpath where the file is
- `ref`: The Git repository reference, the default is origin/main
- `secretRef`: If the repository needs authentication, the reference to the secret is set here
    - `name`: The name of the secret to be used for the repository authentication, see Git Authentication for Private repository.
    - `namespace`: The namespace where the secret is created. Namespace Provisioner creates a Carvel secretgen SecretImport from this namespace to the Namespace Provisioner namespace.
    - `create_export`: A Boolean flag to create a Carvel secretgen SecretExport from the given namespace to Namespace Provisioner namespace. The default value is `false`.

  Sample `gitops_install` repository file:

  Note

  The Carvel data header (#@data/values) is required in this file.

```
#@data/values
---
namespaces:
- name: dev
- name: qa
```

```
#@ load("@ytt:data", "data")
#! This loop will now loop over the namespace list in
#! in ns.yaml and will create those namespaces.
#@ for ns in data.values.namespaces:
---
apiVersion: v1
kind: Namespace
metadata:
  name: #@ ns.name
#@ end
```

This file in the sample repository creates the namespaces in the namespaces list so no manual intervention is required.

Sample `tap-values.yaml` configuration:

```
namespace_provisioner:
  controller: false
  gitops_install:
    ref: origin/main
    subPath: ns-provisioner-samples/gitops-install
    url: https://github.com/vmware-tanzu/application-accelerator-samples.git
```

Set up Out of the Box Supply Chains in Namespace Provisioner

This topic tells you how to set up Namespace Provisioner to automate resource creation needed for workloads to run on Out of the Box Supply Chain Basic and Out of the Box Supply Chain with Testing.

Out of the Box Supply Chain Basic

To create a developer namespace, see Provision Developer Namespaces.

Namespace Provisioner creates a set of default resources in all managed namespaces which are sufficient to run a workload through the Out of the Box Supply Chain Basic.

Run the following Tanzu CLI command to create a workload in your developer namespace.

Using the Tanzu CLI:

- Create workload using Tanzu apps CLI command:

```
tanzu apps workload apply tanzu-java-web-app \
--git-repo https://github.com/sample-accelerators/tanzu-java-web-app \
--git-branch main \
--type web \
--app tanzu-java-web-app \
--namespace DEVELOPER-NAMESPACE \
--tail \
--yes
```

Using a workload YAML:

- Create a `workload.yaml` file:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  labels:
    app.kubernetes.io/part-of: tanzu-java-web-app
    apps.tanzu.vmware.com/workload-type: web
  name: tanzu-java-web-app
  namespace: DEVELOPER-NAMESPACE
spec:
  source:
    git:
      ref:
        branch: main
      url: https://github.com/sample-accelerators/tanzu-java-web-app
```

Out of the Box Supply Chain with Testing

The Out of the Box Supply Chain with Testing adds the **source-tester** step in the supply chain which tests the source code pulled by the supply chain. For source code testing to work in the supply chain, Tekton Pipelines must exist in the same namespace as the Workload so that the Tekton PipelineRun object that is created to run the tests can reference the developer-provided Pipeline.

By default, the workload is matched to the corresponding pipeline to run using labels. Pipelines must have the label `apps.tanzu.vmware.com/pipeline: test`. This provides a default match if no other labels are provided, but you can add additional labels. The pipeline expects two parameters:

- `source-url` is an HTTP address with a `.tar.gz` file containing all the source code to test.
- `source-revision` is the revision of the commit or image reference, such as setting `workload.spec.source.image` instead of `workload.spec.source.git`.

For example:

```
apiVersion: tekton.dev/v1beta1
kind: Pipeline
metadata:
```

```
  name: tekton-pipeline-java
  labels:
    apps.tanzu.vmware.com/pipeline: test      # (!) required
spec:
  params:
    - name: source-url                        # (!) required
    - name: source-revision                   # (!) required
  tasks:
    - name: test
      params:
        - name: source-url
          value: $(params.source-url)
        - name: source-revision
          value: $(params.source-revision)
      taskSpec:
        params:
          - name: source-url
          - name: source-revision
        steps:
          - name: test
            image: gradle
            script: |-
              cd `mktemp -d`
              wget -qO- $(params.source-url) | tar xvz -m
              ./mvnw test
```

Add Java Tekton Pipelines to your developer namespace

To create a developer namespace, see the Provision Developer Namespaces.

Namespace Provisioner can automate the creation of a Tekton pipeline needed for the workload to run on an Out of the Box Supply Chain with Testing. You can create an example pipeline in your GitOps repository and add your GitOps repository as an additional source in Namespace Provisioner configuration in `tap-values.yaml`. See Customize Installation of Namespace Provisioner.

Add the following configuration to `tap-values.yaml` to add this example java pipeline to your developer namespace:

Using Namespace Provisioner Controller:

- Example `tap-values.yaml` configuration:

```
namespace_provisioner:
  controller: true
  additional_sources:
  - git:
      ref: origin/main
      subPath: ns-provisioner-samples/testing-supplychain
      url: https://github.com/vmware-tanzu/application-accelerator-samples.git
```

Using GitOps:

- Example `tap-values.yaml` configuration:

```
namespace_provisioner:
  controller: false
  additional_sources:
  - git:
      ref: origin/main
      subPath: ns-provisioner-samples/testing-supplychain
      url: https://github.com/vmware-tanzu/application-accelerator-samples.git
  gitops_install:
    ref: origin/main
```

```
    subPath: ns-provisioner-samples/gitops-install
    url: https://github.com/vmware-tanzu/application-accelerator-samples.git
```

The example pipeline resource has the following ytt logic which creates this pipeline only if the following conditions are met:

- `supply_chain` in your `tap-values.yaml` file is either `testing` or `testing_scanning`
- `profile` in your `tap-values.yaml` file is either `full, iterate`, or `build`.

```
#@ load("@ytt:data", "data")
#@ def in_list(key, list):
#@  return hasattr(data.values.tap_values, key) and (data.values.tap_values[key] in li
st)
#@ end
#@ if/end in_list('supply_chain', ['testing', 'testing_scanning']) and in_list('profil
e', ['full', 'iterate', 'build']):
```

After adding the additional source to your `tap-values.yaml` file, you can see the `tekton-pipeline-java` created in your developer namespace. To verify that the pipeline is created correctly:

```
kubectl get pipeline.tekton.dev -n DEVELOPER-NAMESPACE
```

Where `DEVELOPER-NAMESPACE` is the name of the new developer namespace you want to use.

Run the following Tanzu CLI command to create a workload in your developer namespace:

Using the Tanzu CLI:

- Create workload using Tanzu apps CLI command.

```
tanzu apps workload apply tanzu-java-web-app \
--git-repo https://github.com/sample-accelerators/tanzu-java-web-app \
--git-branch main \
--type web \
--app tanzu-java-web-app \
--label apps.tanzu.vmware.com/has-tests="true" \
--namespace DEVELOPER-NAMESPACE \
--tail \
--yes
```

Using workload YAML:

- Create a `workload.yaml` file:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  labels:
    app.kubernetes.io/part-of: tanzu-java-web-app
    apps.tanzu.vmware.com/has-tests: "true"
    apps.tanzu.vmware.com/workload-type: web
  name: tanzu-java-web-app
  namespace: DEVELOPER-NAMESPACE
spec:
  source:
    git:
      ref:
        branch: main
      url: https://github.com/sample-accelerators/tanzu-java-web-app
```

Out of the Box Supply Chain with Testing and Scanning

The Out of the Box Supply Chain with Testing and Scanning adds the `source-tester`, `source-scanner`, and `image-scanner` steps in the supply chain. See Scan Types for Supply Chain Security Tools - Scan. These steps test the source code pulled by the supply chain and scans for CVEs on the source and the image built by the supply chain. For these new testing and scanning steps to work, the following additional resources must exist in the same namespace as the workload:

- `Pipeline:` defines how to run the tests on the source code pulled by the supply chain and which image to use that has the tools to run those tests.
- `ScanTemplate`: defines how to run a scan, you can change how the scan is run, either for images or source code.
    - A ScanTemplate defines the PodTemplateSpec used by a Job to run a particular scan, such as an image or source. When the supply chain initiates an ImageScan or SourceScan, they reference these templates which must be in the same namespace as the workload.
    - Grype scanner is automatically installed in all the namespaces managed by Namespace Provisioner. For more information, see About Source and Image Scans.
- `ScanPolicy` defines how to evaluate whether the artifacts scanned are compliant. For example, allowing one to be restrictive about particular vulnerabilities found.
    - When an ImageScan or a SourceScan is created to run a scan, they reference a policy, the policy name must match the following example ScanPolicy.
    - See Writing Policy Templates.

Add Java Tekton Pipelines Grype Scan Policy to your developer namespace

To create a developer namespace, see Provision Developer Namespaces.

Namespace Provisioner can automate the creation of a Tekton pipeline and a ScanPolicy that is needed for the workload to run on an Out of the Box Supply Chain with Testing and Scanning. Create an example Pipeline and a ScanPolicy in your GitOps repository and add your GitOps repository as an additional source in Namespace Provisioner configuration in `tap-values.yaml`. See Customize Installation of Namespace Provisioner.

Add the following configuration to your `tap-values.yaml` file to add the example java pipeline and grype scan policy to your developer namespace. See application-accelerator-samples in GitHub.

Using Namespace Provisioner Controller:

- Sample `tap-values.yaml` configuration:

```
namespace_provisioner:
  controller: true
  additional_sources:
  - git:
      ref: origin/main
      subPath: ns-provisioner-samples/testing-scanning-supplychain
      url: https://github.com/vmware-tanzu/application-accelerator-samples.git
```

Using GitOps:

- Example `tap-values.yaml` configuration:

```
namespace_provisioner:
  controller: false
  additional_sources:
  - git:
      ref: origin/main
```

```
      subPath: ns-provisioner-samples/testing-scanning-supplychain
      url: https://github.com/vmware-tanzu/application-accelerator-samples.git
  gitops_install:
    ref: origin/main
    subPath: ns-provisioner-samples/gitops-install
    url: https://github.com/vmware-tanzu/application-accelerator-samples.git
```

The example Pipeline resource have the following ytt logic which creates this pipeline only if

- `supply_chain` in your `tap-values.yaml` file is either `testing` or `testing_scanning`
- `profile` in your `tap-values.yaml` file is either `full, iterate`, or `build`.

```
#@ load("@ytt:data", "data")
#@ def in_list(key, list):
#@  return hasattr(data.values.tap_values, key) and (data.values.tap_values[key] in li
st)
#@ end
#@ if/end in_list('supply_chain', ['testing', 'testing_scanning']) and in_list('profil
e', ['full', 'iterate', 'build']):
```

The example ScanPolicy resource have the following ytt logic which creates this pipeline only if

- `supply_chain` in your `tap-values.yaml` file is `testing_scanning`
- `profile` in your `tap-values.yaml` file is either `full` or `build`.

After adding the additional source to your `tap-values.yaml` file, you can see the `tekton-pipeline-java and scan-policy` created in your developer namespace. To verify that the pipeline is created correctly:

```
kubectl get pipeline.tekton.dev,scanpolicies -n DEVELOPER-NAMESPACE
```

Where `DEVELOPER-NAMESPACE` is the name of the new developer namespace you want to use.

Run the following Tanzu CLI command to create a workload in your developer namespace:

Using the Tanzu CLI:

- Create workload using Tanzu apps CLI command.

  ```
  tanzu apps workload apply tanzu-java-web-app \
  --git-repo https://github.com/sample-accelerators/tanzu-java-web-app \
  --git-branch main \
  --type web \
  --app tanzu-java-web-app \
  --label apps.tanzu.vmware.com/has-tests="true" \
  --namespace DEVELOPER-NAMESPACE \
  --tail \
  --yes
  ```

Using a workload YAML:

- Create a workload.yaml file:

  ```
  apiVersion: carto.run/v1alpha1
  kind: Workload
  metadata:
    labels:
      app.kubernetes.io/part-of: tanzu-java-web-app
      apps.tanzu.vmware.com/has-tests: "true"
      apps.tanzu.vmware.com/workload-type: web
    name: tanzu-java-web-app
    namespace: DEVELOPER-NAMESPACE
  spec:
    source:
  ```

```
    git:
      ref:
        branch: main
      url: https://github.com/sample-accelerators/tanzu-java-web-app
```

Namespace Provisioner use cases and examples

Review the following Namespace Provisioner uses cases:

Use multiple tekton pipelines and Scan policies in the same namespace in Namespace Provisioner

Add Tekton pipelines and scan policies using namespace parameters in Namespace Provisioner

Working with private Git repositories in Namespace Provisioner

Customize default resources in Namespace Provisioner

Install multiple scanners in the developer namespace in Namespace Provisioner

Apply ScanTemplate overlays in air-gapped environments in Namespace Provisioner

Use multiple Tekton pipelines and scan policies in the same namespace in Namespace Provisioner

This topic tells you how to use Namespace Provisioner to configure developer namespaces to include multiple Tekton pipelines and ScanPolices in Tanzu Application Platform (commonly known as TAP).

For information about, how to create a developer namespace, see Provision Developer Namespaces.

This sample GitOps location has a Java, Python and a Golang testing pipeline as well as a Strict and a Lax grype ScanPolicy.

Using Namespace Provisioner Controller

Add the following configuration to your `tap-values.yaml` file to add multiple tekton pipelines and scan policies to your developer namespace:

```
namespace_provisioner:
  controller: true
  additional_sources:
  - git:
      ref: origin/main
      subPath: ns-provisioner-samples/testing-scanning-supplychain-polyglot
      url: https://github.com/vmware-tanzu/application-accelerator-samples.git
```

Using GitOps

Add the following configuration to your `tap-values.yaml` file to add multiple tekton pipelines and scan policies to your developer namespace:

```
namespace_provisioner:
  controller: false
  additional_sources:
  - git:
      ref: origin/main
      subPath: ns-provisioner-samples/testing-scanning-supplychain-polyglot
      url: https://github.com/vmware-tanzu/application-accelerator-samples.git
  gitops_install:
    ref: origin/main
```

```
    subPath: ns-provisioner-samples/gitops-install
    url: https://github.com/vmware-tanzu/application-accelerator-samples.git
```

The sample Pipeline resource have the following ytt logic which creates this pipeline only if

- `supply_chain` in your `tap-values.yaml` file is either `testing` or `testing_scanning`
- `profile` in your `tap-values.yaml` file is either `full, iterate` or `build`.

```
#@ load("@ytt:data", "data")
#@ def in_list(key, list):
#@  return hasattr(data.values.tap_values, key) and (data.values.tap_values[key] in li
st)
#@ end
#@ if/end in_list('supply_chain', ['testing', 'testing_scanning']) and in_list('profil
e', ['full', 'iterate', 'build']):
```

All pipelines have an additional label `apps.tanzu.vmware.com/language` to differentiate between them.

The sample ScanPolicy resource have the following ytt logic which creates this pipeline only if

- `supply_chain` in your `tap-values.yaml` file is `testing_scanning`
- `profile` in your `tap-values.yaml` file is either `full` or `build`.

The strict ScanPolicy does not allow any workloads that have Critical and High vulnerabilities to pass through the supply chain whereas the lax ScanPolicy allows the workloads to pass regardless of CVEs detected. The allowed severity level is configured using the `notAllowedSeverities := []` part of the rego file section of ScanPolicy.

Caution

The lax ScanPolicy is just added for tutorial purposes but it is not advised to use such a policy in Production workloads.

After adding the additional source to your `tap-values.yaml` file, you should be able to see the `tekton-pipeline-java, tekton-pipeline-golang, tekton-pipeline-python`, `scan-policy` and `lax-scan-policy` created in your developer namespace. Run the following command to see if the pipelines are created correctly.

```
kubectl get pipeline.tekton.dev,scanpolicies -n YOUR-NEW-DEVELOPER-NAMESPACE
```

Run the following Tanzu CLI command to create a workload in your developer namespace:

Using Tanzu CLI

Create workload using tanzu apps CLI command

```
tanzu apps workload apply tanzu-java-web-app \
--git-repo https://github.com/sample-accelerators/tanzu-java-web-app \
--git-branch main \
--type web \
--app tanzu-java-web-app \
--label apps.tanzu.vmware.com/has-tests="true" \
--param-yaml testing_pipeline_matching_labels='{"apps.tanzu.vmware.com/language": "j
ava"}' \
--param scanning_source_policy="lax-scan-policy" \
--param scanning_image_policy="lax-scan-policy" \
--namespace YOUR-NEW-DEVELOPER-NAMESPACE \
```

```
--tail \
--yes
```

Using workload yaml

Create a workload.yaml file with the details as below.

```
---
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  generation: 1
  labels:
    app.kubernetes.io/part-of: tanzu-java-web-app
    apps.tanzu.vmware.com/has-tests: "true"
    apps.tanzu.vmware.com/workload-type: web
  name: tanzu-java-web-app
  namespace: YOUR-NEW-DEVELOPER-NAMESPACE
spec:
  params:
  - name: scanning_source_policy
    value: lax-scan-policy
  - name: scanning_image_policy
    value: lax-scan-policy
  - name: testing_pipeline_matching_labels
    value:
      apps.tanzu.vmware.com/language: java
  source:
    git:
      ref:
        branch: main
      url: https://github.com/sample-accelerators/tanzu-java-web-app
```

Note

`--param-yaml testing_pipeline_matching_labels` tells the supply chain to use the selector that matches the Java pipeline. To use the Python or Golang pipelines, use the selector that matches the language label in those resources.`--param scanning_source_policy="lax-scan-policy"` tells the supply chain to use the lax ScanPolicy for the workload.

Add Tekton pipelines and scan policies using namespace parameters in Namespace Provisioner

This topic tells you how to use Namespace Provisioner to parameterize your additional resources and pass those parameters to namespaces in Tanzu Application Platform (commonly known as TAP).

Instead of creating all the pipelines in all provisioned namespaces, create a Tekton pipeline and ScanPolicy that is bespoke to namespaces that are running workloads using a specific language stack.

For information about, how to create a developer namespace, see Provision Developer Namespaces.

This use case looks at the pipelines and ScanPolicies in this sample GitOps location.

Using Namespace Provisioner controller

Use controller to pass the parameters to a namespace via labels and annotations on the namespace. To enable this, set the `parameter_prefixes` in `tap-values.yaml`. The controller looks for labels and annotations starting with that prefix to populate parameters for a given namespace. For more information, see Customize the label and annotation prefixes that controller watches.

Add the following configuration to your `tap-values.yaml` file to add parameterized Tekton pipelines and scan policies to your developer namespace:

```
namespace_provisioner:
  controller: true
  additional_sources:
  - git:
      ref: origin/main
      subPath: ns-provisioner-samples/testing-scanning-supplychain-parameterized
      url: https://github.com/vmware-tanzu/application-accelerator-samples.git
  parameter_prefixes:
  - tap.tanzu.vmware.com
```

Note

This example adds `tap.tanzu.vmware.com` as a parameter_prefixes in Namespace Provisioner configuration. This tells the Namespace Provisioner controller to look for the annotations and labels on a provisioned namespace that start with the prefix `tap.tanzu.vmware.com` and use those as parameters.

The sample pipelines have the following ytt logic which creates this pipeline only if

- `supply_chain` in your `tap-values.yaml` file is either `testing` or `testing_scanning`
- `profile` in your `tap-values.yaml` file is either`full, iterate` or `build. pipeline` parameter that matches the language for which the pipeline is for.

```
#@ load("@ytt:data", "data")
#@ def in_list(key, list):
#@  return hasattr(data.values.tap_values, key) and (data.values.tap_values[key] in
list)
#@ end
#@ if/end in_list('supply_chain', ['testing', 'testing_scanning']) and in_list('prof
ile', ['full', 'iterate', 'build']) and hasattr(data.values, 'pipeline') and data.va
lues.pipeline == 'java':
```

The sample ScanPolicy resource have the following ytt logic which creates this pipeline only if

- `supply_chain` in your `tap-values.yaml` file is `testing_scanning`
- `profile` in your `tap-values.yaml` file is either `full` or `build`.
- `scanpolicy`parameter matches either `strict` or `lax`

```
#@ load("@ytt:data", "data")
#@ def in_list(key, list):
#@  return hasattr(data.values.tap_values, key) and (data.values.tap_values[key] in
list)
#@ end
#@ if/end in_list('supply_chain', ['testing_scanning']) and in_list('profile', ['ful
l', 'build']) and hasattr(data.values, 'scanpolicy') and data.values.scanpolicy ==
'lax':
```

Label your developer namespace using the `parameter_prefixes` with the parameter to be used in the `additional_sources` as follows:

```
kubectl label namespaces YOUR-NEW-DEVELOPER-NAMESPACE tap.tanzu.vmware.com/scanpolic
y=lax
```

```
kubectl label namespaces YOUR-NEW-DEVELOPER-NAMESPACE tap.tanzu.vmware.com/pipeline=
java
```

Using GitOps

Pass the parameters to a namespace by adding them to the `data.values` file located in the GitOps repository. Use this sample file as an example.

Add the following configuration to your `tap-values.yaml` file to add parameterized Tekton pipelines and scan policies to your developer namespace:

```
namespace_provisioner:
  controller: false
  additional_sources:
  - git:
      ref: origin/main
      subPath: ns-provisioner-samples/testing-scanning-supplychain-parameterized
      url: https://github.com/vmware-tanzu/application-accelerator-samples.git
  gitops_install:
    ref: origin/main
    subPath: ns-provisioner-samples/gitops-install-with-params
    url: https://github.com/vmware-tanzu/application-accelerator-samples.git
```

`gitops_install` uses this sample GitOps location to create the namespaces and manage the desired namespaces from GitOps. For more information, see GitOps section of Customize Installation of Namespace Provisioner.

Sample of `gitops_install` files:

```
#@data/values
---
namespaces:
- name: dev
  scanpolicy: lax
  pipeline: java
- name: qa
  scanpolicy: strict
  pipeline: java
```

```
#@ load("@ytt:data", "data")
#! This loop will now loop over the namespace list in
#! in ns.yaml and will create those namespaces.
#@ for ns in data.values.namespaces:
---
apiVersion: v1
kind: Namespace
metadata:
  name: #@ ns.name
#@ end
```

The sample pipelines have the following ytt logic which creates this pipeline only if the following conditions are met:

- `supply_chain` in your `tap-values.yaml` file is either `testing` or `testing_scanning`
- `profile` in your `tap-values.yaml` file is either`full, iterate` or `build`.
- `pipeline` parameter that matches the language for which the pipeline is for.

```
#@ load("@ytt:data", "data")
#@ def in_list(key, list):
#@  return hasattr(data.values.tap_values, key) and (data.values.tap_values[key] in
list)
#@ end
#@ if/end in_list('supply_chain', ['testing', 'testing_scanning']) and in_list('prof
ile', ['full', 'iterate', 'build']) and hasattr(data.values, 'pipeline') and data.va
lues.pipeline == 'java':
```

The sample ScanPolicy resource have the following ytt logic which creates this pipeline only if the following conditions are me:

- `supply_chain` in your `tap-values.yaml` file is `testing_scanning`
- `profile` in your `tap-values.yaml` file is either `full` or `build`.
- `scanpolicy`parameter matches either `strict` or `lax`

```
#@ load("@ytt:data", "data")
#@ def in_list(key, list):
#@  return hasattr(data.values.tap_values, key) and (data.values.tap_values[key] in
list)
#@ end
#@ if/end in_list('supply_chain', ['testing_scanning']) and in_list('profile', ['ful
l', 'build']) and hasattr(data.values, 'scanpolicy') and data.values.scanpolicy ==
'lax':
```

Run the following Tanzu CLI command to create a workload in your developer namespace:

Using Tanzu CLI

Create a workload using Tanzu Apps CLI plug-in command

```
tanzu apps workload apply tanzu-java-web-app \
--git-repo https://github.com/sample-accelerators/tanzu-java-web-app \
--git-branch main \
--type web \
--app tanzu-java-web-app \
--label apps.tanzu.vmware.com/has-tests="true" \
--namespace YOUR-NEW-DEVELOPER-NAMESPACE \
--tail \
--yes
```

Using workload yaml

Create a workload.yaml file with the details as below.

```
---
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  labels:
    app.kubernetes.io/part-of: tanzu-java-web-app
    apps.tanzu.vmware.com/has-tests: "true"
    apps.tanzu.vmware.com/workload-type: web
  name: tanzu-java-web-app
  namespace: YOUR-NEW-DEVELOPER-NAMESPACE
spec:
  source:
    git:
      ref:
        branch: main
      url: https://github.com/sample-accelerators/tanzu-java-web-app
```

Run the following command to verify the resources have been created in the namespace:

```
kubectl get secrets,serviceaccount,rolebinding,pods,workload,configmap,limitrange,pipeline,scanpolicies -n YOUR-NEW-DEVELOPER-NAMESPACE
```

Work with private Git repositories in Namespace Provisioner

This topic tells you how to configure Namespace Provisioner to use private Git repositories for storing GitOps based installation files, and platform operator templated resources that you want to create in your developer namespace in Tanzu Application Platform (commonly known as TAP).

Git Authentication for using a private Git repository

Authentication is provided using a secret in the `tap-namespace-provisioning` namespace, or an existing secret in another namespace referred to in the secretRef in the `additional_sources`. For more details, see Customize Installation of Namespace Provisioner.

Create the Git Authentication secret in tap-namespace-provisioning namespace

The secrets for Git authentication allow the following keys: ssh-privatekey, ssh-knownhosts, username, and password. If ssh-knownhosts is not specified, Git does not perform strict host checking.

Important

Namespace Provisioner relies on kapp-controller for any tasks involving communication with external services, such as registries or Git repositories. When operating in air-gapped environments or other scenarios where external services are secured by a Custom CA certificate, you must configure kapp-controller with the CA certificate data to prevent X.509 certificate errors. For more information, see Deploy onto Cluster in the Cluster Essentials for VMware Tanzu documentation.

1. Create the Git secret:

   Using HTTP(s) based Authentication
   If you are using Username and Password for authentication:

   ```
   cat << EOF | kubectl apply -f -
   apiVersion: v1
   kind: Secret
   metadata:
     name: git-auth
     namespace: tap-namespace-provisioning
   type: Opaque
   stringData:
     username: GIT-USERNAME
     password: GIT-PASSWORD
   EOF
   ```

   Using SSH based Authentication
   If you are using SSH private key for authentication:

```
cat << EOF | kubectl apply -f -
apiVersion: v1
kind: Secret
metadata:
  name: git-auth
  namespace: tap-namespace-provisioning
type: Opaque
stringData:
  ssh-privatekey: |
      -----BEGIN OPENSSH PRIVATE KEY-----
      ..
      -----END OPENSSH PRIVATE KEY-----
EOF
```

2. Add the `secretRef` section to the `additional_sources` and the `gitops_install` section of your `tap-values.yaml` file:

Using Namespace Provisioner Controller

Description

```
namespace_provisioner:
  controller: true
  additional_sources:
  - git:
      ref: origin/main
      subPath: sources
      # This example URL is for SSH auth. Use https:// path if using HTTPS au
th
      url: git@github.com:private-repo-org/repo.git
      secretRef:
        name: git-auth
```

Using GitOps

Description

In this example, the location where the list of namespaces resides is also a private repository. So you must create a secret named `git-auth-install` with the same authentication details.

```
namespace_provisioner:
  controller: false
  additional_sources:
  - git:
      ref: origin/main
      subPath: tekton-pipelines
      # This example URL is for SSH auth. Use https:// path if using HTTPS au
th
      url: git@github.com:private-repo-org/repo.git
      secretRef:
        name: git-auth
  gitops_install:
    ref: origin/main
    subPath: gitops-install
    # This example URL is for SSH auth. Use https:// path if using HTTPS auth
    url: git@github.com:private-repo-org/repo.git
    secretRef:
      name: git-auth-install
```

Import from another namespace

If you already have a Git secret created in a namespace other than `tap-namespace-provisioning` namespace and you want to refer to that, the `secretRef` section should have the namespace mentioned with the `create_export` flag. The default value for `create_export` is false as it assumes the Secret is already exported for `tap-namespace-provisioning` namespace, but allows you to specify if you want the Namespace Provisioner to create a `Carvel SecretExport` for that secret.

The example refers to `git-auth` secret from `tap-install` in the secretRef section.

Using Namespace Provisioner Controller

Description

```
namespace_provisioner:
  controller: true
  additional_sources:
  - git:
      ref: origin/main
      subPath: sources
      #! This example URL is for SSH auth. Use https:// path if using HTTPS auth
      url: git@github.com:private-repo-org/repo.git
      secretRef:
          name: git-auth
          namespace: tap-install
          #! If this secret is already exported for this namespace, you can ignore t
he create_export key as it defaults to false
          create_export: true
```

Using GitOps

Description

```
namespace_provisioner:
  controller: false
  additional_sources:
  - git:
      ref: origin/main
      subPath: tekton-pipelines
      #! This example URL is for SSH auth. Use https:// path if using HTTPS auth
      url: git@github.com:private-repo-org/repo.git
      secretRef:
          name: git-auth
          namespace: tap-install
          #! If this secret is already exported for this namespace, you can ignore t
he create_export key as it defaults to false
          create_export: true
  gitops_install:
    ref: origin/main
    subPath: gitops-install
    #! This example URL is for SSH auth. Use https:// path if using HTTPS auth
    url: git@github.com:private-repo-org/repo.git
    secretRef:
      name: git-auth-install
      namespace: tap-install
      #! If this secret is already exported for this namespace, you can ignore the c
reate_export key as it defaults to false
      create_export: true
```

After reconciling, Namespace Provisioner creates:

- SecretExport for the secret in the provided namespace (tap-install in the above example) to the Namespace Provisioner namespace.

- SecretImport for the secret in Namespace Provisioning namespace (tap-namespace-provisioning) so Carvel secretgen-controller can create the required secret for the Namespace Provisioner to connect to the private Git repository.

Git Authentication for Private Repository for Workloads and Supply chain

To either fetch or push source code from or to a repository that requires credentials, you must provide those through a Kubernetes secret object referenced by the intended Kubernetes object created for performing the action. The following sections provide details about how to appropriately set up Kubernetes secrets for carrying those credentials forward to the proper resources.

This section provides instructions on how to configure the `default` service account to work with private Git repositories for workloads and supply chain using Namespace Provisioner.

To configure the service account to work with private Git repositories, follow the steps below:

1. Create a secret in the `tap-install` namespace or any namespace of your preference, that contains the Git credentials in YAML format.
    - `host`, `username`, and `password`, or `personal access token` values for HTTP based Git Authentication.
    - `ssh-privatekey`, `identity`, `identity_pub`, and `known_hosts` for SSH based Git Authentication.

Note

The `stringData` key of the secret must have **.yaml** or **.yml** suffix at the end.

Using HTTP(s) based Authentication

If using Username and Password for authentication.

```
cat << EOF | kubectl apply -f -
apiVersion: v1
kind: Secret
metadata:
  name: workload-git-auth
  namespace: tap-install
type: Opaque
stringData:
  content.yaml: |
    git:
      #! For HTTP Auth. Recommend using https:// for the git server.
      host: GIT-SERVER
      username: GIT-USERNAME
      password: GIT-PASSWORD
EOF
```

Using SSH based Authentication

If you are using SSH private key for authentication, create the Git secret with authentication details as follows:

```
cat << EOF | kubectl apply -f -
apiVersion: v1
kind: Secret
metadata:
  name: workload-git-auth
  namespace: tap-install
```

```
type: Opaque
stringData:
  content.yaml: |
    git:
      host: GIT-SERVER
      #! For SSH Auth
      ssh_privatekey: SSH-PRIVATE-KEY
      identity: SSH-PRIVATE-KEY
      identity_pub: SSH-PUBLIC-KEY
      known_hosts: GIT-SERVER-PUBLIC-KEYS
EOF
```

2. To create a secret that will be added to the service account in the developer namespace within the GitOps repository, use this example or follow the example provided below.

   Instead of directly including the actual user name and password in the Git repository secret, use the `data.values.imported` keys to add references to the values from the git-auth secret created in Step 1.

   This secret represents the actual Git secret that will be created by the Namespace Provisioner in each managed namespace. It should be included in your Git repository linked in the `additional_sources` section of `tap-values.yaml` mentioned in Step 4.

   Using HTTP(s) based Authentication
   If using Username and Password for authentication.

   ```
   #@ load("@ytt:data", "data")
   ---
   apiVersion: v1
   kind: Secret
   metadata:
     name: git
     annotations:
       tekton.dev/git-0: #@ data.values.imported.git.host
   type: kubernetes.io/basic-auth
   stringData:
     username: #@ data.values.imported.git.username
     password: #@ data.values.imported.git.token
   ```

   Using SSH based Authentication
   If using SSH private key for authentication:

   ```
   #@ load("@ytt:data", "data")
   ---
   apiVersion: v1
   kind: Secret
   metadata:
     name: git
     annotations:
       tekton.dev/git-0: #@ data.values.imported.git.host
   type: kubernetes.io/ssh-auth
   stringData:
     identity: #@ data.values.imported.git.identity
     identity.pub: #@ data.values.imported.git.identity_pub
     known_hosts: #@ data.values.imported.git.known_hosts
     ssh-privatekey: #@ data.values.imported.git.ssh_privatekey
   ```

3. Combine this `tap-values.yaml`:

   Using Namespace Provisioner Controller

Add the following configuration to `tap-values.yaml`:

```
namespace_provisioner:
  controller: true
  additional_sources:
  - git:
      ref: origin/main
      subPath: ns-provisioner-samples/credentials
      url: https://github.com/vmware-tanzu/application-accelerator-samples.gi
t
  import_data_values_secrets:
  - name: workload-git-auth
    namespace: tap-install
    create_export: true
  default_parameters:
    supply_chain_service_account:
      secrets:
      - git
```

Using GitOps

Add the following configuration to `tap-values.yaml`:

```
namespace_provisioner:
  controller: false
  additional_sources:
  - git:
      ref: origin/main
      subPath: ns-provisioner-samples/credentials
      url: https://github.com/vmware-tanzu/application-accelerator-samples.gi
t
  gitops_install:
    ref: origin/main
    subPath: ns-provisioner-samples/gitops-install
    url: https://github.com/vmware-tanzu/application-accelerator-samples.git
  import_data_values_secrets:
  - name: workload-git-auth
    namespace: tap-install
    create_export: true
  default_parameters:
    supply_chain_service_account:
      secrets:
      - git
```

- First additional source points to the location where the templated Git secret resides which will be created in all developer namespaces.
- Import the newly created `workload-git-auth` secret into Namespace Provisioner to use in `data.values.imported` by adding the secret to the `import_data_values_secrets`.
- Add the secret to be added to the ServiceAccount in the `default_parameters`. For more information, see Customize service accounts.

Note

`create_export` is set to `true` in `import_data_values_secrets`, as a result, a SecretExport is created for the `workload-git-auth` secret in the `tap-install` namespace automatically by Namespace Provisioner. After the changes are reconciled, the secret named `git` is in all provisioned

namespaces and is also added to the default service account of those namespaces.

4. In the `ootb_supply_chain_*.gitops.credentials_secret` and `ootb_supply_chain_*.source.credentials_secret` section of your `tap-values.yaml` file, edit the name of the Git secret that contains the credentials. This is necessary for the supply chain to include the `secretRef` when creating the Flux `GitRepository` resource. Here is an example:

```
ootb_supply_chain_testing_scanning:
  gitops:
    credentials_secret: git  # Replace with the actual name of your GitOps Git
secret for the workload, if different.
  source:
    credentials_secret: git  # Replace with the actual name of your source Git
secret for the workload, if different.
```

By providing this configuration, the supply chain associates the created GitRepository resource with the specified Git secret managed by the Namespace Provisioner.

Customize default resources in Namespace Provisioner

This topic tells you how to deactivate Grype in Namespace Provisioner and how to configure the `default` service account to work with private Git repositories in Tanzu Application Platform (commonly known as TAP).

Deactivate Grype install

Grype is installed with Namespace Provisioner by default. If you prefer to use a different scanner for namespaces instead of Grype, you can deactivate the installation of the default Grype scanner.

Deactivate Grype for all namespaces

To deactivate the default installation of Grype for all namespaces managed by the Namespace Provisioner, set the `skip_grype` parameter to `true` in the `default_parameters` section of the `tap-values.yaml`:

```
namespace_provisioner:
  default_parameters:
    skip_grype: true
```

By enabling the `skip_grype: true` setting, the PackageInstall and the secret `grype-scanner-{namespace}` are not generated in the `tap-install` namespace for any namespaces that are managed by the Namespace Provisioner.

Deactivate Grype for a specific namespace

Using Namespace Provisioner Controller
To deactivate the installation of Grype for a specific namespace, annotate or label the namespace by setting the reserved parameter `skip_grype` to `true`. Use the default or customized `parameter_prefixes`. For more information, see Customize the label and annotation prefixes that controller watches.

```
kubectl annotate ns YOUR-NEW-DEVELOPER-NAMESPACE param.nsp.tap/skip_grype=true
```

Using GitOps

Add the parameter `skip_grype` with the value `true` in the namespaces file in the GitOps repository.

```
#@data/values
---
namespaces:
- name: dev
  skip_grype: true
- name: qa
```

Customize service accounts

This section provides instructions on how to configure the `default` service account to work with private Git repositories for workloads and supply chain using Namespace Provisioner.

To configure the service account to work with private Git repositories, follow the steps below:

1. Create a secret in the `tap-install` namespace, or any namespace that contains the Git credentials in the YAML format.
    - `host`, `username`, and `password` values for HTTP based Git Authentication.
    - `ssh-privatekey`, `identity`, `identity_pub`, and `known_hosts` for SSH based Git Authentication.

    Note

    stringData key of the secret must have **.yaml** or **.yml** suffix at the end.

    ```
    #! Example shows HTTP as well as SSH based authentication
    cat << EOF | kubectl apply -f -
    apiVersion: v1
    kind: Secret
    metadata:
      name: workload-git-auth
      namespace: tap-install
    type: Opaque
    stringData:
      content.yaml: |
        git:
          #! For HTTP Auth. Recommend using https:// for the git server.
          host: GIT-SERVER
          username: GIT-USERNAME
          token: GIT-PASSWORD
          #! For SSH Auth
          ssh_privatekey: SSH-PRIVATE-KEY
          identity: SSH-PRIVATE-KEY
          identity_pub: SSH-PUBLIC-KEY
          known_hosts: GIT-SERVER-PUBLIC-KEYS
    EOF
    ```

2. Create a scaffolding of a Git secret, this must be added to the service account in your developer namespace in your GitOps repository. A sample secret is available in the vmware-tanzu/application-accelerator-samples Git repository. Instead of putting the user name and password in the secret in your Git repository, use the `data.values.imported` keys to put the reference to the values in the git-auth secret created in step 1. For example:

```
#@ load("@ytt:data", "data")
#@ load("@ytt:base64", "base64")
---
apiVersion: v1
kind: Secret
metadata:
  name: git
  annotations:
    tekton.dev/git-0: #@ data.values.imported.git.host
type: kubernetes.io/basic-auth
stringData:
  username: #@ base64.encode(data.values.imported.git.username)
  password: #@ base64.encode(data.values.imported.git.token)
```

3. Complete the process by customizing the SupplyChain ServiceAccount for all or specific namespaces as described in the following sections.

Update ServiceAccount for all namespaces

Customize the SupplyChain ServiceAccount by adding additional `secrets` or `imagePullSecrets` for all namespaces managed by the Namespace Provisioner. Edit the `supply_chain_service_account` parameter in the `default_parameters` section of the `tap-values.yaml` file. If you have a separate Service Account for delivery purposes, configure it using the `delivery_service_account` parameter. For example:

```
namespace_provisioner:
  controller: true
  additional_sources:
  - git:
      ref: origin/main
      subPath: ns-provisioner-samples/credentials
      url: https://github.com/vmware-tanzu/application-accelerator-samples.git
  import_data_values_secrets:
  - name: workload-git-auth
    namespace: tap-install
    create_export: true
  default_parameters:
    supply_chain_service_account:
      secrets:
      - git
      imagePullSecrets: [] #! optional
    delivery_service_account: #! Not required, specify only if the Service account is
different from the Supply chain service account.
      secrets: [] #! optional
      imagePullSecrets: [] #! optional
```

- This adds the `git` secret to the Service Account mentioned in `ootb_supply_chain_*.service_account`. If not specified, it takes the `default` service account.
- `additional_sources` points to the location where the templated Git secret resides which will be created in all developer namespaces.
- Import the newly created `workload-git-auth` secret into Namespace Provisioner to use in `data.values.imported` by adding the secret to the `import_data_values_secrets`.
- Add the secret to be added to the ServiceAccount in the `default_parameters`

Update ServiceAccount for a specific namespace

To customize the SupplyChain ServiceAccount for a specific namespace managed by the Namespace Provisioner and include additional `secrets` or `imagePullSecrets`, use the

`supply_chain_service_account` parameter. This parameter allows you to edit the ServiceAccount and add any required `secrets` or `imagePullSecrets`.

If you have a separate ServiceAccount for delivery purposes, you can also configure it using the `delivery_service_account` parameter.

Using Namespace Provisioner Controller

Add the following configuration to your `tap-values.yaml` file:

```
namespace_provisioner:
  controller: true
  additional_sources:
  - git:
      ref: origin/main
      subPath: ns-provisioner-samples/credentials
      url: https://github.com/vmware-tanzu/application-accelerator-samples.git
  import_data_values_secrets:
  - name: workload-git-auth
    namespace: tap-install
    create_export: true
```

- `additional_sources` points to the location where the templated Git secret resides which will be created in all developer namespaces.
- Import the newly created `workload-git-auth` secret into Namespace Provisioner to use in `data.values.imported` by adding the secret to the `import_data_values_secrets`.

Annotate the namespace with the parameter so the ServiceAccount is updated

```
kubectl annotate ns dev param.nsp.tap/supply_chain_service_account.secrets='["git"]'
```

The `desired-namespaces` ConfigMap will look like:

```
#@data/values
---
namespaces:
- name: dev
  supply_chain_service_account:
    secrets:
    - git
```

If the ServiceAccount for delivery is different, then:

```
kubectl annotate ns dev param.nsp.tap/delivery_service_account.secrets='["git"]'
```

The `desired-namespaces` ConfigMap will look like:

```
#@data/values
---
namespaces:
- name: dev
  supply_chain_service_account:
    secrets:
    - git
  delivery_service_account:
    secrets:
    - git
```

Using GitOps

Add the following configuration to your `tap-values.yaml` file:

```
namespace_provisioner:
  controller: false
  additional_sources:
  - git:
      ref: origin/main
      subPath: ns-provisioner-samples/credentials
      url: https://github.com/vmware-tanzu/application-accelerator-samples.git
  gitops_install:
    ref: origin/main
    subPath: ns-provisioner-samples/gitops-install-params-sa
    url: https://github.com/vmware-tanzu/application-accelerator-samples.git
  import_data_values_secrets:
  - name: workload-git-auth
    namespace: tap-install
    create_export: true
```

- `additional_sources` points to the location where the templated Git secret resides which will be created in all developer namespaces.
- Configure the desired namespaces yaml in the GitOps repository with the parameter in the namespace. Check the sample file where you are adding the `git` secret to the supply chain service account.
- Import the newly created `workload-git-auth` secret into Namespace Provisioner to use in `data.values.imported` by adding the secret to the `import_data_values_secrets`.

Note

`create_export` is set to `true` in `import_data_values_secrets` meaning that a SecretExport is created for the `workload-git-auth` secret in the `tap-install` namespace automatically by Namespace Provisioner. After the changes are reconciled, the secret named **git** is in all provisioned namespaces and is also added to the default service account of those namespaces.

Customize Limit Range defaults

Namespace Provisioner creates the LimitRange resources on Run clusters in all Namespace Provisioner managed namespaces. For more information, see Default Resources.

You can opt-in to have the LimitRange resource created on Full and Iterate clusters. For more information, see Set/Update LimitRange defaults for all namespaces and Set/Update LimitRange defaults for a specific namespace.

Namespace Provisioner does not create LimitRange resource in Build and View clusters.

Default values in LimitRange resource are as follows:

```
limits:
  default:
    cpu : 1500m
    memory : 1Gi
  defaultRequest:
    cpu : 100m
    memory : 1Gi
```

Set or Update LimitRange defaults for all namespaces

To update the values in LimitRange for all Namespace Provisioner managed namespaces, specify the `default_parameters` configuration in `tap-values.yaml` as follows:

```
namespace_provisioner:
  default_parameters:
    # overwrite default limits set by the OOTB LimitRange (in Run Cluster) for all nam
espaces
    # set default limits for Full and Iterate Cluster in all namespaces
    limits:
      default:
        cpu: 1000m
        memory: 1Gi
      defaultRequest:
        cpu: 200m
        memory: 500Mi
```

Set or Update LimitRange defaults for a specific namespace

Override the LimitRange for specific namespaces as follows:

Using Namespace Provisioner Controller

Annotate or label a namespace using the default *parameter_prefix* `param.nsp.tap/` followed by the YAML path to CPU or memory limits as follows:

```
kubectl annotate ns YOUR-NEW-DEVELOPER-NAMESPACE param.nsp.tap/limits.default.cpu=11
00m

kubectl annotate ns YOUR-NEW-DEVELOPER-NAMESPACE param.nsp.tap/limits.default.memory
=2Gi

kubectl annotate ns YOUR-NEW-DEVELOPER-NAMESPACE param.nsp.tap/limits.defaultReques
t.cpu=1500m

kubectl annotate ns YOUR-NEW-DEVELOPER-NAMESPACE param.nsp.tap/limits.defaultReques
t.memory=1Gi
```

- The controller detects the annotations and labels with the `param.nsp.tap/` prefix, and adds the keys and values in the desired-namespace ConfigMaps as parameters for that namespace.
- If you want the controller to search for a custom prefix, instead of the default `param.nsp.tap`, prefix, use the `parameter_prefixes` configuration option in the tap-values.yaml file. For more information, see Customize the label and annotation prefixes that controller watches.

Note

Labels take precedence over annotations if the same key is provided in both.

Using GitOps

Add the following configuration to your `tap-values.yaml` file to add parameterized limits to your developer namespace:

```
namespace_provisioner:
  controller: false
  gitops_install:
    ref: origin/main
    subPath: ns-provisioner-samples/gitops-install-with-params
    url: https://github.com/vmware-tanzu/application-accelerator-samples.git
```

This adds `gitops_install` with this sample GitOps location to create the namespaces and manage the desired namespaces from GitOps. For more information, see the GitOps tab in Customize Installation of Namespace Provisioner.

Sample of `gitops_install` files:

```
#@data/values
---
namespaces:
- name: dev
  limits:
    default:
      cpu: 1200m
      memory: 1.5Gi
    defaultRequest:
      cpu: 300m
      memory: 30Mi
- name: qa
```

```
#@ load("@ytt:data", "data")
#! This loop will now loop over the namespace list in
#! in ns.yaml and will create those namespaces.
#@ for ns in data.values.namespaces:
---
apiVersion: v1
kind: Namespace
metadata:
  name: #@ ns.name
#@ end
```

The Namespace Provisioner creates a LimitRange with default values for `qa` namespace and with the given values for `dev` namespace.

Deactivate LimitRange Setup

The Namespace Provisioner generates a Kubernetes LimitRange object as a default resource in the namespaces it manages within the Run profile clusters. Additionally, the Namespace Provisioner offers the capability for Platform operators to enable LimitRange object stamping in Full and Iterate profile clusters using namespace parameters. The following options are available to deactivate the installation of the default LimitRange object:

Deactivate for all namespaces

To exclude the installation of the default LimitRange, set the `skip_limit_range` parameter to `true` in the `default_parameters` section of the `tap-values.yaml` file as shown here:

```
namespace_provisioner:
  default_parameters:
    skip_limit_range: true
```

Deactivate for a specific namespace

Using Namespace Provisioner Controller
To deactivate the LimitRange for a specific developer namespace, annotate or label the namespace using the parameter `skip_grype` and set its value to `true`. Use the default or customized `parameter_prefixes`, for more information, as explained in the Customize the label and annotation prefixes that controller watches section.

```
kubectl annotate ns YOUR-NEW-DEVELOPER-NAMESPACE param.nsp.tap/skip_limit_range=true
```

Using GitOps

Add the parameter `skip_limit_range` with the value `true` in the namespaces file in the GitOps repository as shown below:

```
#@data/values
---
namespaces:
- name: dev
  skip_limit_range: true
  limits:
    default:
      cpu: 1200m
      memory: 1.5Gi
    defaultRequest:
      cpu: 300m
      memory: 30Mi
- name: qa
```

Install multiple scanners in the developer namespace in Namespace Provisioner

This topic tells you how to use Namespace Provisioner to automate multiple scanner installations in the developer namespace in Tanzu Application Platform (commonly known as TAP).

Grype scanner is installed by default in all namespaces managed by Namespace Provisioner.

The following steps describe how to install Snyk scanner and Grype in the developer namespace and use both together in the supply chain. Grype is used for Source scans and Snyk is used for Image scans.

For information about, how to create a developer namespace, see Provision Developer Namespaces.

1. Create a secret in the `tap-install` namespace or any namespace of your preference that contains the Snyk token in YAML format. It must have .yaml or .yml in the key as shown here:

   ```
   cat << EOF | kubectl apply -f -
   apiVersion: v1
   kind: Secret
   metadata:
     name: scanner-auth
     namespace: tap-install
   type: Opaque
   stringData:
     content.yaml: |
       scanners:
         snyk_api_token: "" # Paste your snyk API token here
   EOF
   ```

2. Add the following configuration to your `tap-values.yaml` file to create the supply-chain and scanners:

Using Namespace Provisioner Controller

Add the following configuration to your `tap-values.yaml` file:

```
namespace_provisioner:
  controller: true
  additional_sources:
  - git:
      ref: origin/main
      subPath: ns-provisioner-samples/testing-scanning-supplychain-multiple-scanners
      url: https://github.com/vmware-tanzu/application-accelerator-samples.git
  import_data_values_secrets:
  - name: scanner-auth
    namespace: tap-install
    create_export: true
```

Using GitOps

Add the following configuration to your `tap-values.yaml` file:

```
namespace_provisioner:
  controller: false
  additional_sources:
  - git:
      ref: origin/main
      subPath: ns-provisioner-samples/testing-scanning-supplychain-multiple-scanners
      url: https://github.com/vmware-tanzu/application-accelerator-samples.git
  import_data_values_secrets:
  - name: scanner-auth
    namespace: tap-install
    create_export: true
  gitops_install:
    ref: origin/main
    subPath: ns-provisioner-samples/gitops-install
    url: https://github.com/vmware-tanzu/application-accelerator-samples.git
```

Additional source points to the location of the sample GitOps repo which has the following custom resources:

- `tekton-pipeline-java.yaml`: Use this to create a Tekton pipeline for running tests on the Java workload.
- `scanpolicy-grype.yaml and scanpolicy-snyk.yaml`: Use to create Scan policies for Grype and Snyk scanners.
- `snyk-token-secret.yaml`: This is a Snyk token secret that must be created in the developer namespace. Instead of putting the actual Snyk token in the secret in the Git repository, put the reference to the values in the scanner-auth secret created in Step 1 by using the `data.values.imported` keys.
- `snyk-scanner-install.yaml`: This contains the PackageInstall for installing the Snyk package for the developer namespace. The namespace `tap-install` is mentioned in the PackageInstall resource. This causes Namespace Provisioner to create a PackageInstall resource for all provisioned namespaces in the same namespace and add `-{namespace}` as the suffix in the name to avoid name collisions.

Run the following command to apply a workload in your developer namespace that uses Grype for source scan and Snyk for Image scan:

Using Tanzu CLI

Create workload using tanzu apps CLI command

```
tanzu apps workload apply tanzu-java-web-app \
--git-repo https://github.com/sample-accelerators/tanzu-java-web-app \
--git-branch main \
--type web \
```

```
--app tanzu-java-web-app \
--label apps.tanzu.vmware.com/has-tests="true" \
--param scanning_image_policy=snyk-scan-policy \
--param scanning_image_template=snyk-private-image-scan-template \
--namespace YOUR-NEW-DEVELOPER-NAMESPACE \
--tail \
--yes
```

Using workload yaml

Create a `workload.yaml` file:

```
---
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  labels:
    app.kubernetes.io/part-of: tanzu-java-web-app
    apps.tanzu.vmware.com/has-tests: "true"
    apps.tanzu.vmware.com/workload-type: web
  name: tanzu-java-web-app
  namespace: YOUR-NEW-DEVELOPER-NAMESPACE
spec:
  params:
  - name: scanning_image_policy
    value: snyk-scan-policy
  - name: scanning_image_template
    value: snyk-private-image-scan-template
  source:
    git:
      ref:
        branch: main
      url: https://github.com/sample-accelerators/tanzu-java-web-app
```

Apply ScanTemplate overlays in air-gapped environments in Namespace Provisioner

This topic tells you how to use Namespace Provisioner to customize the ScanTemplates created by the `grype-scanner` PackageInstall in Namespace Provisioner. Use annotations to apply an overlay to the ScanTemplates in Tanzu Application Platform (commonly known as TAP).

Namespace Provisioner includes a pre-configured `grype-scanner` PackageInstall for each developer namespace. For more information about default resources, see Default resources.

If you require customization of the ScanTemplate created by the PackageInstall, you must apply overlays to the ScanTemplate through package customization as Namespace Provisioner does not directly create the ScanTemplate. For more information on how to customize a package installation, see Customize a package.

For information about potential customizations of the `grype-scanner` and troubleshooting tips, see Use vulnerability scanning in offline and air-gapped environments.

1. To enable updates to the ScanTemplates, create an overlay specifically designed for this purpose. When the package is processed, the overlay is applied to the ScanTemplate. It is done by the reference to this overlay in the annotation `ext.packaging.carvel.dev/ytt-paths-from-secret-name`:

   ```
   cat << EOF | kubectl apply -f -
   apiVersion: v1
   kind: Secret
   metadata:
   ```

```
  name: grype-airgap-override-stale-db-overlay
  namespace: tap-install #! namespace where tap is installed
stringData:
  patch.yaml: |
    #@ load("@ytt:overlay", "overlay")

    #@overlay/match by=overlay.subset({"kind":"ScanTemplate"}),expects="1+"
    ---
    spec:
      template:
        initContainers:
          #@overlay/match by=overlay.subset({"name": "scan-plugin"}), expects
="1+"
          - name: scan-plugin
            #@overlay/match missing_ok=True
            env:
              #@overlay/append
              - name: GRYPE_DB_MAX_ALLOWED_BUILT_AGE #! see note on best practi
ces
                value: "240h"
EOF
```

2. To enhance the functionality of the `grype-scanner` PackageInstall created by the Namespace Provisioner, create an overlay that adds the `ext.packaging.carvel.dev/ytt-paths-from-secret-name` annotation. This annotation enables the PackageInstall to retrieve information from the created secret with the overlay and apply it to the ScanTemplate.

```
cat << EOF | kubectl apply -f -
apiVersion: v1
kind: Secret
metadata:
  name: grype-airgap-override-stale-db-overlay-for-nsp
  namespace: tap-install # or any other namespaces from where nsp will import t
he secret
stringData:
  patch-grype-install-in-nsp.yaml: |
    #@ load("@ytt:overlay", "overlay")
    #@ def matchGrypeScanners(index, left, right):
      #@ if left["apiVersion"] != "packaging.carvel.dev/v1alpha1" or left["kin
d"] != "PackageInstall":
        #@ return False
      #@ end
      #@ return left["metadata"]["name"].startswith("grype-scanner")
    #@ end
    #@overlay/match by=matchGrypeScanners, expects="0+"
    ---
    metadata:
      annotations:
        #@overlay/match missing_ok=True
        ext.packaging.carvel.dev/ytt-paths-from-secret-name.0: grype-airgap-ove
rride-stale-db-overlay
        #! The value of the above annotation is the name of the secret that con
tains the grype overlay
EOF
```

3. Update the `tap-values.yaml` file as follows so the overlay is applied to the PackageInstall. For more information, see Import overlay secrets.

```
namespace_provisioner:
  overlay_secrets:
  - create_export: true
    name: grype-airgap-override-stale-db-overlay-for-nsp
```

```
    namespace: tap-install # or any other namespaces from where nsp will import
the secret
```

Work with Git repositories in air-gapped environments with Namespace Provisioner

This topic provides instructions for configuring Namespace Provisioner to use air-gapped Git repositories. This allows you to store GitOps-based installation files and platform operator-templated resources intended for creation in your developer namespace in Tanzu Application Platform (TAP).

Git authentication

Authentication is established through a secret in the `tap-namespace-provisioning` namespace or an existing secret in another namespace referenced in the `secretRef` in `additional_sources`. For more details, refer to Customize Installation of Namespace Provisioner.

Create the Git authentication secret in `tap-namespace-provisioning` namespace

The Git authentication secrets support the following keys: `ssh-privatekey`, `ssh-knownhosts`, `username`, and `password`. If `ssh-knownhosts` is not specified, Git does not perform strict host checking.

Important

In air-gapped environments or other scenarios where external services are secured by a Custom CA certificate, configure kapp-controller with the CA certificate data to prevent X.509 certificate errors. For more information, see Deploy onto Cluster in the Cluster Essentials for VMware Tanzu documentation.

1. Create the Git secret:

   Using HTTP(s) based authentication
   If you are using user name and password for authentication:

   ```
   cat << EOF | kubectl apply -f -
   apiVersion: v1
   kind: Secret
   metadata:
     name: git-auth
     namespace: tap-namespace-provisioning
   type: Opaque
   stringData:
     username: GIT-USERNAME
     password: GIT-PASSWORD
   EOF
   ```

   Using SSH based authentication
   If you are using SSH private key for authentication:

   ```
   cat << EOF | kubectl apply -f -
   apiVersion: v1
   kind: Secret
   metadata:
     name: git-auth
   ```

```
  namespace: tap-namespace-provisioning
type: Opaque
stringData:
  ssh-privatekey: |
      -----BEGIN OPENSSH PRIVATE KEY-----
      ...
      -----END OPENSSH PRIVATE KEY-----
EOF
```

2. Add the `secretRef` section to the `additional_sources` and the `gitops_install` section of your `tap-values.yaml` file:

Using Namespace Provisioner Controller
Description

```
namespace_provisioner:
  controller: true
  additional_sources:
  - git:
      ref: origin/main
      subPath: sources
      # This example URL is for SSH auth. Use https:// path if using HTTPS au
th
      url: git@git-airgap-server:private-repo-org/repo.git
      secretRef:
        name: git-auth
```

Using GitOps
Description

Caution In kapp-controller v0.46.0 and earlier, there is a limitation that prevents the reuse of the same Git secret multiple times. If you have multiple additional sources using repositories with identical credentials, you must create distinct secrets, each with the same authentication details.

In this example, the list of namespaces resides in a repository. Therefore, you must create a secret named `git-auth-install` with the same authentication details for this location.

```
namespace_provisioner:
  controller: false
  additional_sources:
  - git:
      ref: origin/main
      subPath: tekton-pipelines
      # This example URL is for SSH auth. Use https:// path if using HTTPS au
th
      url: git@git-airgap-server:private-repo-org/repo.git
      secretRef:
        name: git-auth
  gitops_install:
    ref: origin/main
    subPath: gitops-install
    # This example URL is for SSH auth. Use https:// path if using HTTPS auth
    url: git@git-airgap-server:private-repo-org/repo.git
    secretRef:
      name: git-auth-install
```

Import from another namespace

If you already have a Git secret created in a namespace other than the `tap-namespace-provisioning` namespace and you want to refer to it, the `secretRef` section must include the namespace and the `create_export` flag. The default value for `create_export` is `false`, assuming the secret is already exported for the `tap-namespace-provisioning` namespace. However, you can specify if you want Namespace Provisioner to create a Carvel `SecretExport` for that secret.

In this example, the `secretRef` section refers to the `git-auth` secret from the `tap-install` namespace.

Using Namespace Provisioner Controller

Description

```
namespace_provisioner:
  controller: true
  additional_sources:
  - git:
      ref: origin/main
      subPath: sources
      #! This example URL is for SSH auth. Use https:// path if using HTTPS auth
      url: git@git-airgap-server:private-repo-org/repo.git
      secretRef:
          name: git-auth
          namespace: tap-install
          #! If this secret is already exported for this namespace, you can ignore t
he create_export key as it defaults to false
          create_export: true
```

Using GitOps

Description

```
namespace_provisioner:
  controller: false
  additional_sources:
  - git:
      ref: origin/main
      subPath: tekton-pipelines
      #! This example URL is for SSH auth. Use https:// path if using HTTPS auth
      url: git@git-airgap-server:private-repo-org/repo.git
      secretRef:
          name: git-auth
          namespace: tap-install
          #! If this secret is already exported for this namespace, you can ignore t
he create_export key as it defaults to false
          create_export: true
  gitops_install:
    ref: origin/main
    subPath: gitops-install
    #! This example URL is for SSH auth. Use https:// path if using HTTPS auth
    url: git@git-airgap-server:private-repo-org/repo.git
    secretRef:
      name: git-auth-install
      namespace: tap-install
      #! If this secret is already exported for this namespace, you can ignore the c
reate_export key as it defaults to false
      create_export: true
```

After reconciliation, Namespace Provisioner creates:

- SecretExport for the secret in the provided namespace, exporting it to the Namespace Provisioner namespace, for example, `tap-install`
- SecretImport for the secret in the `tap-namespace-provisioning` namespace. This enables Carvel secretgen-controller to create the required secret, allowing Namespace Provisioner to connect to the Git repository.

Git authentication for workloads and supply chain

When fetching or pushing source code to a repository that requires credentials, it's essential to provide those credentials through a Kubernetes secret object referenced by the corresponding Kubernetes object created for the action. The following sections describe setting up Kubernetes secrets to securely pass these credentials to the relevant resources. This procedure provides the steps to configure the `default` service account to interact with Git repositories for workloads and supply chain using Namespace Provisioner.

Set up the service account to interact with Git repositories:

1. Create a secret in the `tap-install` namespace or any preferred namespace, containing Git credentials in YAML format.
    - `host`, `username`, `caFile` and `password` or `personal access token` values for HTTP-based Git authentication.
    - `ssh-privatekey`, `identity`, `identity_pub`, and `known_hosts` for SSH-based Git authentication.

Note

The `stringData` key of the secret must end with either the `.yaml` or `.yml` suffix.

Using HTTP(s) based authentication
If using user name and password for authentication.

In this configuration for an air-gapped environment, the Git repository server has a custom certificate of authority that cannot be verified against public issuers, so you must provide the `caFile` content to log in against it.

```
cat << EOF | kubectl apply -f -
apiVersion: v1
kind: Secret
metadata:
  name: workload-git-auth
  namespace: tap-install
type: Opaque
stringData:
  content.yaml: |
    git:
      #! For HTTP Auth. Recommend using https:// for the git server.
      host: GIT-SERVER
      username: GIT-USERNAME
      password: GIT-PASSWORD
      caFile: |
        -----BEGIN CERTIFICATE-----
        ...
        -----END CERTIFICATE-----
EOF
```

Using SSH based authentication
To use an SSH private key for authentication, create the Git secret with the authentication details as follows:

```
cat << EOF | kubectl apply -f -
apiVersion: v1
kind: Secret
metadata:
  name: workload-git-auth
  namespace: tap-install
type: Opaque
stringData:
  content.yaml: |
    git:
      host: GIT-SERVER
      #! For SSH Auth
      ssh_privatekey: SSH-PRIVATE-KEY
      identity: SSH-PRIVATE-KEY
      identity_pub: SSH-PUBLIC-KEY
      known_hosts: GIT-SERVER-PUBLIC-KEYS
EOF
```

2. To create a secret to be added to the service account in the developer namespace in the GitOps repository, use this example for HTTP-based or this example for `setings.xml`-based, or follow the example below.

   Rather than directly including the actual user name and password in the Git repository secret, use the `data.values.imported` keys to add references to the values from the `git-auth` secret created in the previous step.

   This secret represents the Git secret that is created by the Namespace Provisioner in each managed namespace. It must be included in your Git repository linked in the `additional_sources` section of `tap-values.yaml` mentioned in the next step.

   Using HTTP(s) based authentication
   If using user name and password for authentication.

   In this configuration for an air-gapped environment, the Git repository server has a custom certificate of authority that cannot be verified against public issuers, so you must provide the `caFile` content to log in against it.

   ```
   #@ load("@ytt:data", "data")
   ---
   apiVersion: v1
   kind: Secret
   metadata:
    name: git
    annotations:
      tekton.dev/git-0: #@ data.values.imported.git.host
   type: kubernetes.io/basic-auth
   stringData:
    username: #@ data.values.imported.git.username
    password: #@ data.values.imported.git.token
    caFile: #@ data.values.imported.git.caFile
   ```

   Using settings.xml based authentication for Java applications
   If using user name and password for authentication.

   ```
   #@ load("@ytt:data", "data")
   ```

```
apiVersion: v1
kind: Secret
metadata:
 name: settings-xml
type: service.binding/maven
stringData:
 type: maven
 provider: sample
 #@yaml/text-templated-strings
 settings.xml: |
   <settings xmlns="http://maven.apache.org/SETTINGS/1.0.0" xmlns:xsi="htt
p://www.w3.org/2001/XMLSchema-instance"
     xsi:schemaLocation="http://maven.apache.org/SETTINGS/1.0.0 https://mave
n.apache.org/xsd/settings-1.0.0.xsd">
       <mirrors>
           <mirror>
               <id>reposilite</id>
               <name>Accelerator samples</name>
               <url>(@= data.values.imported.git.host @)/vmware-tanzu/applica
tion-accelerator-samples</url>
               <mirrorOf>*</mirrorOf>
           </mirror>
       </mirrors>
       <servers>
           <server>
               <id>reposilite</id>
               <username>(@= data.values.imported.git.username @)</username>
               <password>(@= data.values.imported.git.password @)</password>
           </server>
       </servers>
   </settings>
```

Using SSH based authentication

If using SSH private key for authentication:

```
#@ load("@ytt:data", "data")
---
apiVersion: v1
kind: Secret
metadata:
  name: git
  annotations:
    tekton.dev/git-0: #@ data.values.imported.git.host
type: kubernetes.io/basic-auth
stringData:
  identity: #@ data.values.imported.git.identity
  identity.pub: #@ data.values.imported.git.identity_pub
  known_hosts: #@ data.values.imported.git.known_hosts
  ssh-privatekey: #@ data.values.imported.git.ssh_privatekey
```

3. Combine this `tap-values.yaml`:

Using Namespace Provisioner Controller

Add the following configuration to `tap-values.yaml`:

```
namespace_provisioner:
  controller: true
  additional_sources:
  - git:
      ref: origin/main
      subPath: ns-provisioner-samples/credentials
      url: https://git-airgap-server/application-accelerator-samples.git
  import_data_values_secrets:
```

```
  - name: workload-git-auth
    namespace: tap-install
    create_export: true
  default_parameters:
    supply_chain_service_account:
      secrets:
      - git
```

Where `https://git-airgap-server/application-accelerator-samples.git` is a fork of the application-accelerator-samples repository.

Using GitOps

Add the following configuration to `tap-values.yaml`:

```
namespace_provisioner:
  controller: false
  additional_sources:
  - git:
      ref: origin/main
      subPath: ns-provisioner-samples/credentials
      url: https://git-airgap-server/vmware-tanzu/application-accelerator-sam
ples.git
  gitops_install:
    ref: origin/main
    subPath: ns-provisioner-samples/gitops-install
    url: https://git-airgap-server/vmware-tanzu/application-accelerator-sampl
es.git
  import_data_values_secrets:
  - name: workload-git-auth
    namespace: tap-install
    create_export: true
  default_parameters:
    supply_chain_service_account:
      secrets:
      - git
```

Where `https://git-airgap-server/application-accelerator-samples.git` is a fork of the application-accelerator-samples repository.

- `additional sources` points to the location where the templated Git secret resides, which is created in all developer namespaces.
- Import the newly created `workload-git-auth` secret into Namespace Provisioner to use in `data.values.imported` by adding the secret to `import_data_values_secrets`.
- Add the secret to be included in the ServiceAccount in the `default_parameters`. For more information, see Customize service accounts.

Note

`create_export` is set to `true` in `import_data_values_secrets`. As a result, a SecretExport is automatically created for the `workload-git-auth` secret in the `tap-install` namespace by Namespace Provisioner. After the changes are reconciled, the secret named `git` is present in all provisioned namespaces and is also added to the default service account of those namespaces.

4. In the `ootb_supply_chain_*.gitops.credentials_secret` and `ootb_supply_chain_*.source.credentials_secret` section of your `tap-values.yaml` file, edit

the name of the Git secret containing the credentials. This is necessary for the supply chain to include the `secretRef` when creating the Flux `GitRepository` resource. For example:

```
ootb_supply_chain_testing_scanning:
gitops:
  credentials_secret: git  # Replace with the actual name of your GitOps Git se
cret for the workload, if different.
source:
  credentials_secret: git  # Replace with the actual name of your source Git se
cret for the workload, if different.
```

By providing this configuration, the supply chain associates the created `GitRepository` resource with the specified Git secret managed by Namespace Provisioner.

5. Create the workload:

Using HTTP/HTTPS or SSH-based
If using user name and password for authentication.

```
tanzu apps workload apply APP-NAME \
--git-repo GIT-REPO \
--git-branch BRANCH \
--type web \
--app APP-NAME \
--label apps.tanzu.vmware.com/has-tests="true" \
--namespace DEV-NAMESPACE \
--tail \
--yes
```

Using settings.xml based authentication for Java applications
If using user name and password for authentication.

```
tanzu apps workload apply APP-NAME \
--git-repo GIT_REPO \
--git-branch BRANCH \
--type web \
--app APP-NAME \
--label apps.tanzu.vmware.com/has-tests="true" \
--namespace DEV-NAMESPACE \
--param-yaml buildServiceBindings='[{"name": "settings-xml", "kind": "Secre
t"}]'
--tail \
--yes
```

Troubleshoot Namespace Provisioner

This topic tells you how to troubleshoot Namespace Provisioner in Tanzu Application Platform (commonly known as TAP).

Air-gapped installation

Namespace Provisioner relies on kapp-controller for any tasks involving communication with external services, such as registries or Git repositories. When operating in air-gapped environments or other scenarios where external services are secured by a Custom CA certificate, you must configure kapp-controller with the CA certificate data to prevent X.509 certificate errors. For more information, see Deploy onto Cluster in the Cluster Essentials for VMware Tanzu documentation.

View controller logs

To get the logs when using the controller workflow, run the following kubectl command:

```
kubectl -n tap-namespace-provisioning logs deployments/controller-manager
```

Use `-f` to follow the log output.

Provisioner application error

After the Namespace Provisioner is installed in the Tanzu Application Platform cluster, the main resource to check is the provisioner Carvel Application in the `tap-namespace-provisioning` namespace. To check for the status of the Application, run the following kubectl command:

```
kubectl -n tap-namespace-provisioning get app/provisioner --template={{.status.usefulE
rrorMessage}}
```

Common errors

You might encounter one of the following errors:

Namespace selector malformed

When using the controller and customizing the `namespace_selector` from `tap_values.yaml`, the match expression must be compliant with the Kubernetes label selector. If it is not compliant, the Namespace Provisioner controller fails and log an error message in the controller logs.

For example, if the configured `namespace_selector` is as follows:

```
namespace_provisioner:
  controller: true
  namespace_selector:
    matchExpressions:
    - key: apps.tanzu.vmware.com/tap-ns
      operator: exists
```

This is not compliant as the operator must be `Exist` instead of `exists`. When labeling the namespace `dev` with `apps.tanzu.vmware.com/tap-ns`, the controller produces an error message similar to the following, (followed by some reconciliation messages)

```
{"level":"error","ts":"2022-12-14T15:41:44.639402794Z","logger":".0.1.NamespaceSelecto
rReconciler","msg":"unable to sync","controller":"namespace","controllerGroup":"","con
trollerKind":"Namespace","Namespace":{"name":"dev"},"namespace":"","name":"dev","recon
cileID":"26395d34-418b-446d-9b5e-a4a73cc657ed","resourceType":"/v1, Kind=Namespace","e
rror":"\"exists\" is not a valid pod selector operator","stacktrace":"..."}
```

Debugging ytt templating errors in additional sources

When working with ytt, templating errors in the additional sources in your GitOps repository can cause the Provisioner Carvel application to go into `Reconcile Failed` state. To debug the Application, run the following command:

```
kubectl -n tap-namespace-provisioning get app/provisioner --template={{.status.usefulE
rrorMessage}}
```

Sample Error message from Application when there is a ytt templating error:

```
ytt: Error:
- library.eval: Evaluating library 'witherror':
    in <toplevel>
      template.yaml:155 | #@          instances = overlay.apply(instance.eval(), custo
mize())
    reason:
     - struct has no .gl_secret_user field or method
         in <toplevel>
           _ytt_lib/witherror/secrets.yaml:12 |   username: #@ data.values.gl_secret_u
ser
```

Unable to delete namespace

When a user tries to delete a namespace that was managed by Namespace Provisioner, it gets stucks in the `Terminating` status.

Possible Cause 1: When a provisioned namespace that has a Cartographer Workload in it is deleted, the namespace will likely remain in the Terminating state because some resources can not be deleted. One of the causes of this behavior is that the Cartographer Workload using the Out of the Box supply chains and delivery creates a Carvel Kapp App for the workload that references the ServiceAccount in the namespace. Deleting the namespace deletes the Service Account that Kapp relies on before the App itself is deleted. As a result, the Carvel App blocks the namespace termination while waiting for the ServiceAccount to exist with a `finalizer` (`finalizers.kapp-ctrl.k14s.io/delete`) message.

Solution: Remove the Kapp App finalizer in the Kapp App

Possible Cause 2: If you try to delete a namespace that was previously managed by the controller, and the namespace was not cleaned up before disabling the controller, it gets stuck in the `Terminating` state. This happens because the controller adds a `finalizer` to the namespaces (`namespace-provisioner.apps.tanzu.vmware.com/finalizer`) it manages, and is no longer there to clean up that finalizer as it was deactivated by the user.

Solution: Remove manually the finalizer in the namespace

Namespace Provisioner reference

This section tells you about known issues and limitations, default resources, and parameters in Namespace Provisioner.

Known limitations and issues

Default resources

Parameters

Known limitations and issues in Namespace Provisioner

This topic tells you about the known issues and limitations for Namespace Provisioner in Tanzu Application Platform (commonly known as TAP).

- If you are using a GitOps repository to manage the list of namespaces, all the namespaces in the list must exist in the cluster. The provisioner application fails to reconcile if the namespaces do not exist on the cluster.
- To use different private repositories, the secret used for each entry must be a unique name, for example, `gitops_install`, or `additional_sources`. Reusing the same secret is not supported due to a limitation in kapp-controller.

  Note

This limitation is resolved in Tanzu Cluster Essentials v1.6.0 and later.

- Before performing any operations, such as uninstalling the Namespace Provisioner or changing from Controller mode to GitOps mode, ensure that you edit the namespaces managed by the Namespace Provisioner in the `namespace-provisioner.apps.tanzu.vmware.com/finalizer` finalizer. Either remove the label used to set the namespaces as managed or edit the namespace manifest and remove the finalizer entry. For more information, see Manage a list of developer namespaces.

Default resources

This topic tells you about the resources that are templated in the default-resources secret for the different installation profile and supply chain value combinations in Tanzu Application Platform (commonly known as TAP).

Namespace Provisioner is installed as part of the full, iterate, build, and run installation profiles. The default set of resources provisioned in a namespace is based on a combination of the installation profile employed and the supply chain that is installed on the cluster. For more information about installation profiles, see Installation profiles in Tanzu Application Platform.

The following table shows the list of resources that are templated in the default-resources secret for each installation profile and supply chain value combination:

Namespace	Kind	Name	supply_chain	Install Profile	Reconcile
tap-install	PackageInstall	grype-scanner-{ns}	testing_scanning	full, build	Yes
tap-install	Secret	grype-scanner-{ns}	testing_scanning	full, build	Yes
Developer Namespace	Secret	registries-credentials	n/a	full, iterate, build, run	Yes
Developer Namespace	ServiceAccount	From: ootb_supply_chain_{supply_chain}.service_account (default: “default”)	n/a	full, iterate, build, run	No
Developer Namespace	ServiceAccount	From: ootb_delivery_basic.service_account (default: “default”)	n/a	full, iterate, run	No
Developer Namespace	RoleBinding	default-permit-deliverable	n/a	full, iterate, run	Yes
Developer Namespace	RoleBinding	default-permit-workload	n/a	full, iterate, build	Yes
Developer Namespace	LimitRange	{namespace}-lr	n/a	run	Yes

For installing additional resources for OOTB Supply Chain with Testing and Scanning, see Supply Chain Security Tools - Scan.

Customize namespaces in Namespace Provisioner

This topic tells you how to use Namespace Provisioner to customize namespaces in controller mode in Tanzu Application Platform (commonly known as TAP).

When managing multiple developer namespaces in a cluster, it is often necessary to customize each namespace individually. To customize a namespace in controller mode, add parameters to a

namespace through labels and annotations using either the default prefix or a custom-defined prefix.

In GitOps mode, you can configure these parameters in the GitOps file. For more information, see Customize the label and annotation prefixes that controller watches.

Caution

If a parameter is initially created through annotations and later a label with the same key is used, the annotation is overwritten.

Parameter key

- The format for specifying the parameter is: `<prefix>/<parameter-key>=<parameter-value>`.
- The parameter key can be a single string or a pseudo JSON-path structure, for example, `kye1.inner-key1.inner-key3.inner-key4`. This is translated into a structured format in the values.
- The label value can only be a string.
- If you need to pass a list or another object as the parameter value, annotations should be used instead. Annotations support using `[]` to define lists and `{}` to define objects
- All parameters created with labels and annotations can be utilized when using templates for resources in ytt `additional_sources` from `data.values`.

Examples:

1. To define a list of tools used by the namespace:

   ```
   kubectl annotate ns dev param.nsp.tap/project.tools='["git", "maven"]'
   ```

   The `desired-namespaces` ConfigMap will look like:

   ```
   #@data/values
   ---
   namespaces:
   - name: dev
    project:
      tools:
      - git
      - maven
   ```

2. To add a list of objects:

   ```
   kubectl annotate ns dev param.nsp.tap/volume.claims='[{"name": "logs", "mountPa
   th": "/var/logs/app"}, {"name": "truststore", "mountPath": "/opt/app/ssl"}]
   ```

   The `desired-namespaces` ConfigMap will look like:

   ```
   #@data/values
   ---
   namespaces:
   - name: dev
    volume:
      claims:
      - name: logs
      mountPath: /var/logs/app
   ```

```
    - name: truststore
    mountPath: /opt/app/ssl
```

3. Simple key-value:

   ```
   kubectl annotate ns dev param.nsp.tap/scanpolicy=relaxed
   ```

   The `desired-namespaces` ConfigMap will look like:

   ```
   #@data/values
   ---
   namespaces:
   - name: dev
    scanpolicy: relaxed
   ```

4. Object as value:

   ```
   kubectl annotate ns dev param.nsp.tap/maven.values='{"username":"user", "passwo
   rd":"my-pass","repo":"myrepo","version":"0.1.1-alpha.0"}'
   ```

   The `desired-namespaces` ConfigMap will look like:

   ```
   #@data/values
   ---
   namespaces:
   - name: dev
    maven:
      values:
        username: user
        password: my-pass
        repo: myrepo
        Version: 0.1.1-alpha.0
   ```

Reserved Namespace Parameters

Namespace Provisioner reserves certain parameters for its use. The following is a list of parameters used by the Namespace Provisioner, which apply to both the `default_parameters` in `tap-values.yaml` and the namespace parameters through labels and annotations:

- `limits` (object): Use to configure the LimitRange. For more information, see Customize Limit Range defaults.
- `skip_limit_range` (boolean): Use to determine if the LimitRange should be created. For more information, see Customize Limit Range defaults.
- `skip_grype` (boolean): Use to determine if Grype scanner resources are going to be created. For more information, see Deactivate Grype install.
- `supply_chain_service_account` (object): Contains the secrets and imagePullSecrets to be added to the Supply Chain ServiceAccount. For more information, see Customize service accounts.
- `delivery_service_account` (object): Contains the secrets and imagePullSecrets to be added to the delivery ServiceAccount. For more information, see Customize service accounts.

Overview of Service Bindings

This topic tells you about using Service Bindings in Tanzu Application Platform (commonly know as TAP).

Supported service binding specifications

Service Bindings packages the Service Binding for Kubernetes open source project.

It implements the Service Binding Specification for Kubernetes v1.0.

This implementation provides support for:

- Provisioned Service
- Workload Projection
- Service Binding
- Direct Secret Reference
- Role-Based Access Control (RBAC)

The following are not supported:

- Workload Resource Mapping
- Extensions including:
    - Binding Secret Generation Strategies

Overview of Service Bindings

This topic tells you about using Service Bindings in Tanzu Application Platform (commonly know as TAP).

Supported service binding specifications

Service Bindings packages the Service Binding for Kubernetes open source project.

It implements the Service Binding Specification for Kubernetes v1.0.

This implementation provides support for:

- Provisioned Service
- Workload Projection
- Service Binding
- Direct Secret Reference
- Role-Based Access Control (RBAC)

The following are not supported:

- Workload Resource Mapping
- Extensions including:
    - Binding Secret Generation Strategies

Install Service Bindings

This topic tells you how to install Service Bindings from the Tanzu Application Platform (commonly known as TAP) package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install Service Bindings. For more information about profiles, see Components and installation profiles.

Prerequisites

Before installing Service Bindings:

- Complete all prerequisites to install Tanzu Application Platform (commonly knows as TAP). For more information, see Prerequisites.

Install Service Bindings

Use the following procedure to install Service Bindings:

1. List version information for the package by running:

```
tanzu package available list servicebinding.tanzu.vmware.com --namespace tap-in
stall
```

For example:

```
$ tanzu package available list servicebinding.tanzu.vmware.com --namespace tap-
install
- Retrieving package versions for servicebinding.tanzu.vmware.com...
  NAME                              VERSION  RELEASED-AT
  servicebinding.tanzu.vmware.com   0.10.3   2023-12-05T08:26:41Z
```

2. Install the package by running:

```
tanzu package install service-bindings -p servicebinding.tanzu.vmware.com  -v
0.10.3 -n tap-install
```

Example output:

```
/ Installing package 'servicebinding.tanzu.vmware.com'
| Getting namespace 'tap-install'
- Getting package metadata for 'servicebinding.tanzu.vmware.com'
| Creating service account 'service-bindings-tap-install-sa'
| Creating cluster admin role 'service-bindings-tap-install-cluster-role'
| Creating cluster role binding 'service-bindings-tap-install-cluster-rolebindi
ng'
\ Creating package resource
| Package install status: Reconciling

 Added installed package 'service-bindings' in namespace 'tap-install'
```

3. Verify the package install by running:

```
tanzu package installed get service-bindings -n tap-install
```

Example output:

```
- Retrieving installation details for service-bindings...
NAME:                    service-bindings
PACKAGE-NAME:            servicebinding.tanzu.vmware.com
PACKAGE-VERSION:         0.10.3
STATUS:                  Reconcile succeeded
```

```
CONDITIONS:              [{ReconcileSucceeded True  }]
USEFUL-ERROR-MESSAGE:
```

4. Run the following command:

   ```
   kubectl get pods -n service-bindings
   ```

   For example:

   ```
   $ kubectl get pods -n service-bindings
   NAME                                                READY   STATUS    RESTARTS
   AGE
   servicebinding-controller-manager-7856497ddd-bmgv2   1/1     Running   0
   5m59s
   ```

   Verify that `STATUS` is `Running`

Troubleshoot Service Bindings

This topic tells you how to troubleshoot Service Bindings in Tanzu Application Platform (commonly known as TAP).

Collect logs

To help identify issues when troubleshooting, you can retrieve and examine logs from the service binding manager.

To retrieve pod logs from the `manager` running in the `service-bindings` namespace, run:

```
kubectl -n service-bindings logs -l role=manager
```

For example:

```
$ kubectl -n service-bindings logs -l role=manager

2021/11/05 15:25:28 Registering 3 clients
2021/11/05 15:25:28 Registering 3 informer factories

```

Service Bindings resource specification

This topic tells you about the Service Bindings resource specification in Tanzu Application Platform (commonly known as TAP).

The `ServiceBinding` resource shape and behavior is defined by the following specification:

```
apiVersion: servicebinding.io/v1alpha3
kind: ServiceBinding
metadata:
  name: account-db
spec:
  service:
    apiVersion: mysql.example/v1alpha1
    kind: MySQL
    name: account-db
  workload:
    apiVersion: apps/v1
    kind: Deployment
    name: account-service
```

Version matrix for Service Bindings

This topic provides you with a version matrix for the Service Bindings package (`servicebinding.tanzu.vmware.com`) and its open source components in Tanzu Application Platform v1.9 (commonly known as TAP).

To view this information for another Tanzu Application Platform version, select the version from the drop-down menu at the top of this page.

Service Binding Runtime is the community reference implementation of Service Binding.

The following table has the component versions for the Service Bindings package.

Component	Version
Service Bindings package version	0.12.0
Service Bindings runtime version	0.8.0

Note

Tanzu Application Platform patch releases are only added to the table when there is a change to one or more of the other versions in the table. Otherwise, the corresponding versions remain the same for each Tanzu Application Platform patch release.

Overview of Service Registry

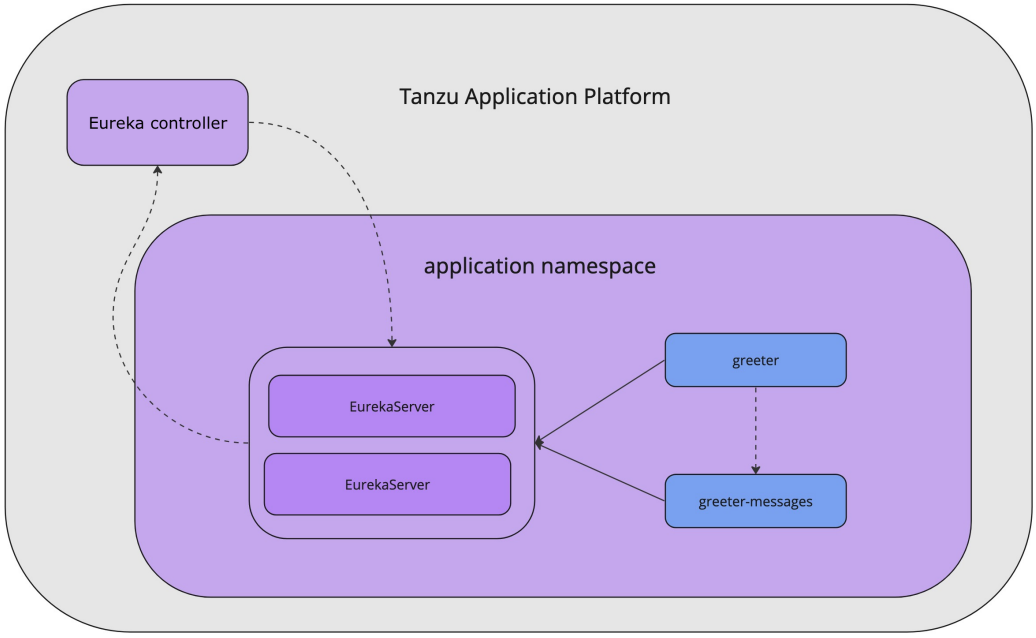
Service Registry for VMware Tanzu provides on-demand Eureka servers for your Tanzu Application Platform (commonly known as TAP) clusters. With Service Registry, you can create Eureka servers

in your namespaces and bind Spring Boot workloads to them. This provides a smooth transition from the past practice of using Spring Cloud Services for Tanzu Application Service to create Eureka servers.

On-demand namespaced Eureka server instances can be provisioned for microservices Spring Boot applications that rely on service discovery.

Architecture

Workloads communicate with the EurekaServer resources in the application namespace. From within Tanzu Application Platform, the Eureka controller communicates with the EurekaServer resources in the application namespace.



Capacity Requirements

Each node of the Eureka controller requires:

- 64 MiB of memory
- 10m of vCPU

with limits of:

- 128 MiB of memory
- 500m of vCPU

You can scale the controller horizontally for higher availability.

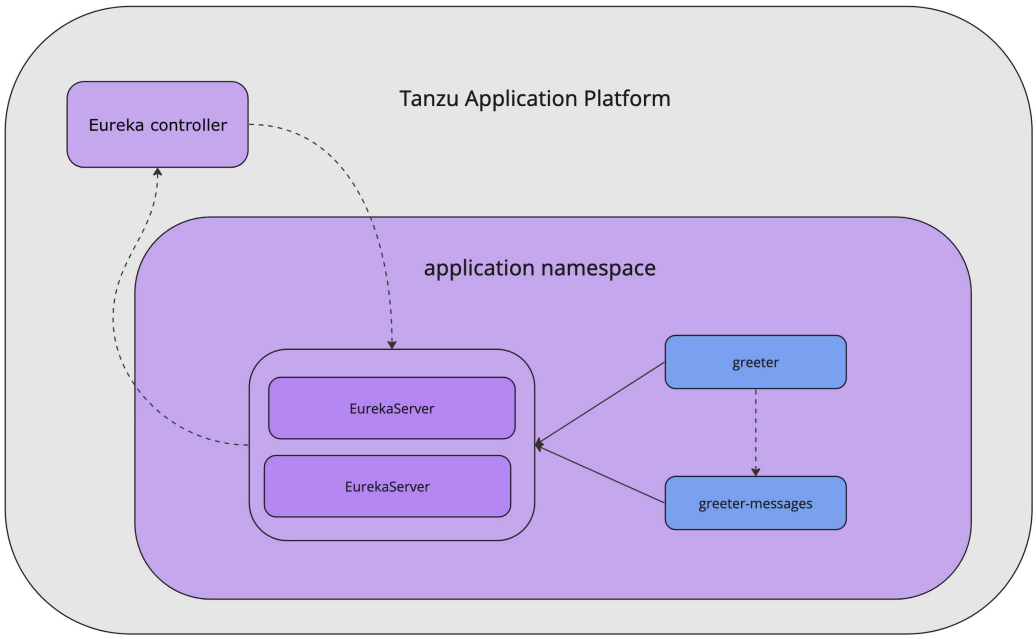
Overview of Service Registry

Service Registry for VMware Tanzu provides on-demand Eureka servers for your Tanzu Application Platform (commonly known as TAP) clusters. With Service Registry, you can create Eureka servers in your namespaces and bind Spring Boot workloads to them. This provides a smooth transition from the past practice of using Spring Cloud Services for Tanzu Application Service to create Eureka servers.

On-demand namespaced Eureka server instances can be provisioned for microservices Spring Boot applications that rely on service discovery.

Architecture

Workloads communicate with the EurekaServer resources in the application namespace. From within Tanzu Application Platform, the Eureka controller communicates with the EurekaServer resources in the application namespace.



Capacity Requirements

Each node of the Eureka controller requires:

- 64 MiB of memory
- 10m of vCPU

with limits of:

- 128 MiB of memory
- 500m of vCPU

You can scale the controller horizontally for higher availability.

Install Service Registry

This topic tells you how to install Service Registry from the Tanzu Application Platform (commonly known as TAP) package repository.

Prerequisites

Before installing Service Registry, you must:

- Fulfill all prerequisites for installing Tanzu Application Platform
- Install cert-manager

Install

To install Service Registry on a compliant Kubernetes cluster:

1. List version information for the package by running:

   ```
   tanzu package available list service-registry.spring.apps.tanzu.vmware.com --na
   mespace tap-install
   ```

   For example:

   ```
   $ tanzu package available list service-registry.spring.apps.tanzu.vmware.com --
   namespace tap-install
   NAME                                                VERSION  RELEASED-AT
   service-registry.spring.apps.tanzu.vmware.com       1.2.0    2023-09-12 19:00:0
   0 -0500 EST
   ```

2. Install the package by running:

   ```
   tanzu package install service-registry \
   --package service-registry.spring.apps.tanzu.vmware.com \
   --version VERSION -n tap-install
   ```

   Where `VERSION` is the version you want, such as `1.2.0`.

   For example:

   ```
   $ tanzu package install service-registry \
   --package service-registry.spring.apps.tanzu.vmware.com \
   --version 1.2.0 -n tap-install

   / Installing package 'service-registry.spring.apps.tanzu.vmware.com'
   | Getting namespace 'eureka-system'
   | Getting package metadata for 'service-registry.spring.apps.tanzu.vmware.com'
   | Creating service account 'service-registry-sa'
   | Creating cluster admin role 'service-registry-cluster-role'
   | Creating cluster role binding 'service-registry-cluster-rolebinding'
   / Creating package resource
   - Package install status: Reconciling

   Added installed package 'service-registry' in namespace 'tap-install'
   ```

   Note

   Because there are no customization options at this time, there is no need to include a `--values-file` option.

3. Verify that you installed the package by running:

   ```
   tanzu package installed get service-registry -n tap-install
   ```

   For example:

   ```
   $ tanzu package installed get service-registry -n tap-install

   NAMESPACE:          tap-install
   NAME:               service-registry
   PACKAGE-NAME:       service-registry.spring.apps.tanzu.vmware.com
   PACKAGE-VERSION:    1.2.0
   ```

```
STATUS:             Reconcile succeeded
CONDITIONS:         - type: ReconcileSucceeded
  status: "True"
  reason: ""
  message: ""
```

Create EurekaServer resources

This topic tells you about options when creating a `EurekaServer` resource.

Discover available parameters

Examine the available parameters when creating a `EurekaServer` resource by running:

```
kubectl explain eurekaservers.service-registry.spring.apps.tanzu.vmware.com.spec
```

For example:

```
$ kubectl explain eurekaservers.service-registry.spring.apps.tanzu.vmware.com.spec

GROUP:      service-registry.spring.apps.tanzu.vmware.com
KIND:       EurekaServer
VERSION:    v1alpha1

FIELD: spec <Object>

DESCRIPTION:
    EurekaServerSpec defines the desired state of EurekaServer

FIELDS:
  imagePullSecretName   <string>
    Name of secret to use for pulling the Eureka image

  replicas      <integer>
    Replica count for the EurekaServer StatefulSet
```

Create a EurekaServer resource

To create a `EurekaServer` resource:

1. Create a `EurekaServer` resource with two replicas by using the following YAML definition:

   ```
   ---
   apiVersion: service-registry.spring.apps.tanzu.vmware.com/v1alpha1
   kind: EurekaServer
   metadata:
     name: eurekaserver-sample
     namespace: my-apps
   spec:
     replicas: 2
   ```

2. Save the YAML definition as `eurekaserver.yaml`.

3. Apply the YAML definition by running:

   ```
   kubectl apply -f eurekaserver.yaml
   ```

4. Check the status of the `EurekaServer` resource by running:

   ```
   kubectl describe YOUR-ADDRESS RESOURCE-NAME
   ```

For example:

```
$ kubectl describe eurekaservers.service-registry.spring.apps.tanzu.vmware.com
eurekaserver

Name:         eurekaserver
Namespace:    my-apps
Labels:       <none>
Annotations:  <none>
API Version:  service-registry.spring.apps.tanzu.vmware.com/v1alpha1
Kind:         EurekaServer
Metadata:
 Creation Timestamp:  2023-08-30T14:51:04Z
 Generation:          1
 Resource Version:    4698719
 UID:                 4dd60698-6332-43bf-a27d-cef610579c98
Spec:
 Replicas:  2
Status:
 Binding:
   Name:  eureka-eurekaserver-client-binding-mvvlx
 Conditions:
   Last Transition Time:  2023-08-30T14:51:04Z
   Message:               EurekaServer reconciled
   Observed Generation:   1
   Reason:                EurekaServerReconciled
   Status:                True
   Type:                  Ready
 Observed Generation:     1
 Server Binding:
   Name:  eureka-eurekaserver-server-binding-2jq76
Events:    <none>
```

A successful `EurekaServer` resource has a `Ready` condition set to `true` and a `status.binding.name` field pointing to a secret containing connection information.

Configure workloads in Tanzu Application Platform by using Service Registry

This topic tells you how to configure Tanzu Application Platform (commonly known as TAP) workloads running Spring Boot applications to connect to Service Registry `EurekaServer` resources.

Prerequisite

Create a `EurekaServer` resource. For instructions, see Create Eureka Servers.

Claim credentials

Claim credentials from Tanzu CLI or by creating a `ResourceClaim` directly:

Using Tanzu CLI
Claim credentials by running:

```
tanzu service resource-claim create CLAIM-NAME \
    --resource-kind EurekaServer \
    --resource-api-version service-registry.spring.apps.tanzu.vmware.com/v1alpha1 \
    --resource-name RESOURCE-NAME \
    --resource-namespace RESOURCE-NAMESPACE \
    --namespace WORKLOAD-NAMESPACE
```

Where:

- `CLAIM-NAME` is a name you choose for your claim.
- `RESOURCE-NAME` is the name of the `EurekaServer` resource you want to claim.
- `RESOURCE-NAMESPACE` is the namespace that your `EurekaServer` resource is in.
- `WORKLOAD-NAMESPACE` is the namespace that your workload is in.

For example:

```
$ tanzu service resource-claim create eurekaserver-sample \
    --resource-kind EurekaServer \
    --resource-api-version service-registry.spring.apps.tanzu.vmware.com/v1alpha1 \
    --resource-name eurekaserver-sample \
    --resource-namespace my-apps \
    --namespace my-apps
```

Using a ResourceClaim

Create a YAML file, similar to the following example, and name it `resource-claim.yaml`:

```
---
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ResourceClaim
metadata:
  name: eurekaserver-sample
  namespace: my-apps
spec:
  ref:
    apiVersion: service-registry.spring.apps.tanzu.vmware.com/v1alpha1
    kind: EurekaServer
    name: eurekaserver-sample
    namespace: my-apps
```

In kubectl, create the `ResourceClaim` by running:

```
kubectl apply -f resource-claim.yaml
```

Inspect the progress of your claim

Inspect the progress of your claim creation by running:

```
tanzu service resource-claim get MY-CLAIM-NAME --namespace MY-NAMESPACE
```

or by running:

```
kubectl get resourceclaim MY-CLAIM-NAME --namespace MY-NAMESPACE --output yaml
```

Use Eureka for service discovery in workloads

To use Eureka for service discovery in workloads:

1. If you have an existing application already configured to use Spring Cloud Service Discovery, claim `EurekaServer` credentials to access the running Eureka servers by adding the following to the `spec.serviceClaims` section of a workload:

   ```
   serviceClaims:
     - name: eureka
       ref:
   ```

```
        apiVersion: services.apps.tanzu.vmware.com/v1alpha1
        kind: ResourceClaim
        name: eurekaserver-sample
```

By claiming the credentials, a workload has its Eureka client configured to interact with the referenced Eureka server.

For example, you can use the following workloads to deploy the greeting application.

`greeter-messages.yaml` example:

```
# greeter-messages.yaml
---
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: greeter-messages
  namespace: my-apps
  labels:
    apps.tanzu.vmware.com/workload-type: server
    apps.tanzu.vmware.com/has-tests: "true"
    app.kubernetes.io/part-of: greeter
spec:
  build:
    env:
      - name: BP_JVM_VERSION
        value: "17"
      - name: BP_GRADLE_BUILT_MODULE
        value: "greeter-messages"
      - name: BP_GRADLE_BUILD_ARGUMENTS
        value: "--no-daemon clean bootJar"
  env:
    - name: SPRING_PROFILES_ACTIVE
      value: "development"
  serviceClaims:
    - name: eureka
      ref:
        apiVersion: services.apps.tanzu.vmware.com/v1alpha1
        kind: ResourceClaim
        name: eurekaserver-sample
  source:
    git:
      url: https://github.com/spring-cloud-services-samples/greeting
      ref:
        branch: main
```

`greeter.yaml` example:

```
# greeter.yaml
---
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: greeter
  namespace: my-apps
  labels:
    apps.tanzu.vmware.com/workload-type: web
    apps.tanzu.vmware.com/has-tests: "true"
    app.kubernetes.io/part-of: greeter
spec:
  build:
    env:
      - name: BP_JVM_VERSION
        value: "17"
      - name: BP_GRADLE_BUILT_MODULE
```

```
        value: "greeter"
      - name: BP_GRADLE_BUILD_ARGUMENTS
        value: "--no-daemon clean bootJar"
  env:
    - name: SPRING_PROFILES_ACTIVE
      value: "development"
  serviceClaims:
    - name: eureka
      ref:
        apiVersion: services.apps.tanzu.vmware.com/v1alpha1
        kind: ResourceClaim
        name: eurekaserver-sample
  source:
    git:
      url: https://github.com/spring-cloud-services-samples/greeting
      ref:
        branch: main
```

2. Create the workloads. For example, for the greeter application you run:

```
tanzu apps workload create -f greeter-messages.yaml --yes
tanzu apps workload create -f greeter.yaml --yes
```

3. From the Tanzu CLI, retrieve the ingress route associated with the greeter application by running:

```
tanzu apps workload get greeter
```

   For example:

```
$ tanzu apps workload get greeter

# other output...

  Knative Services
  NAME      READY   URL
  greeter   Ready   https://greeter.my-apps.tap

To see logs: "tanzu apps workload tail greeter --timestamp --since 1h"
```

   Where `https://greeter.my-apps.tap` is the accessible ingress route to the greeter application

4. Visit `ROUTE/hello`, where `ROUTE` is the ingress route you just retrieved. The greeter application uses Service Registry to look up the Message Generation application and get a greeting message. This message initially is `Hello, Bob!`.

5. See what the Message Generation application is sending back from viewing its logs by running:

```
tanzu apps workload tail greeter-messages
```

   Example:

```
$ tanzu apps workload tail greeter-messages

greeter-messages-579d67c498-bf6zl[workload] 2023-10-20T17:52:17.001Z  INFO 1 --
- [nio-8080-exec-3] messages.MessagesController              : Now saying "Hi"
to John
```

6. Create a different greeting message by providing the `salutation` and `name` parameters. Example:

```
ROUTE/hello?salutation=Hi&name=John
```

The greeter application sends those parameters to the Message Generation application, and the resulting greeting is customized to match.

(Optional) Use Service Registry with an executable JAR file application

In the greeting application example, `BP_GRADLE_BUILD_ARGUMENTS` is set to include the `bootJar` task in addition to the default Gradle build arguments. This setting is necessary for this example base because the `build.gradle` file contains a `jar` section, and the Spring Boot buildpack will not inject the `spring-cloud-bindings` library into the application if it is an executable JAR file.

`spring-cloud-bindings` is required to process the `serviceClaim` into properties that tell the discovery client how to find the Eureka server.

To use Service Registry with an executable JAR file application, you must explicitly include spring-cloud-bindings v1.13.0 or later and set the `org.springframework.cloud.bindings.boot.enable=true` system property as described in the library README file in GitHub.

Overview of Services Toolkit

Services Toolkit is responsible for backing many of the most powerful service capabilities in Tanzu Application Platform (commonly known as TAP).

From the integration of an extensive list of cloud-based and on-prem services, through to the offering and discovery of those services, and finally to the claiming and binding of service instances to application workloads, Services Toolkit has the tools you need to make working with services on Tanzu Application Platform simple, easy, and effective.

Note

These docs apply to Services Toolkit v0.10 and later. To view the Services Toolkit documentation for v0.9 and earlier, see the previous Services Toolkit site.

Capabilities

The main capabilities on offer in Tanzu Application Platform through Services Toolkit are:

1. The classes and claims abstraction: provides a simple, but powerful, user experience to apps teams, while promoting a strong separation of concerns between apps teams and ops teams.
2. Dynamic provisioning of service instances: enables apps teams to create service instances that adhere to company policy. Apps teams can create instances on-demand as needed.
3. Seamless integration of almost any service, cloud-based or on-prem, into Tanzu Application Platform with minimal configuration overhead: provides a near-limitless range of services to help boost developer productivity.

Getting started

If this is your first time working with services on Tanzu Application Platform, you might want to start with Claim services on Tanzu Application Platform and Consume services on Tanzu Application Platform in the getting started guide. These guides run through the basics, after which you can

return here to the Services Toolkit component documentation to continue your services journey on Tanzu Application Platform.

How this documentation is organized

The Services Toolkit component documentation consists of the following sections that relate to what you are want to achieve:

- Concepts: To gain a deeper understanding of Services Toolkit.
- Tutorials: To learn through following examples.
- How-to guides: To find a set of steps to solve a specific problem.
- Reference material: To find specific information such as Services Toolkit's APIs, the Tanzu Service CLI plug-in, and troubleshooting information.

Tutorials and concepts are of most relevance when studying, while how-to guides and reference material are of most use while working.

The following is a selection of useful topics on offer:

For apps teams:

- Tutorial: Working with Bitnami Services

For ops teams:

- Tutorial: Setup Dynamic Provisioning of Service Instances
- Tutorial: Integrating Cloud Services (AWS, Azure, GCP, etc.) into Tanzu Application Platform
- How-to guide: Configure Dynamic Provisioning of AWS RDS Service Instances

For everyone:

- Concept: Four Levels of Service Consumption in Tanzu Application Platform

Install Services Toolkit

This topic tells you how to install Services Toolkit from the Tanzu Application Platform (commonly known as TAP) package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install Services Toolkit. For more information about profiles, see Components and installation profiles.

Prerequisites

Before installing Services Toolkit:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- Install cert-manager. For more information, see Install cert-manager.

Install Services Toolkit

To install Services Toolkit:

1. See what versions of Services Toolkit are available to install by running:

   ```
   tanzu package available list -n tap-install services-toolkit.tanzu.vmware.com
   ```

   For example:

   ```
   $ tanzu package available list -n tap-install services-toolkit.tanzu.vmware.com
   - Retrieving package versions for services-toolkit.tanzu.vmware.com...
     NAME                              VERSION           RELEASED-AT
     services-toolkit.tanzu.vmware.com  0.9.0             2022-09-08T00:00:00Z
   ```

2. Install Services Toolkit by running:

   ```
   tanzu package install services-toolkit \
     --package services-toolkit.tanzu.vmware.com \
     --version VERSION-NUMBER \
     --namespace tap-install
   ```

   Where `VERSION-NUMBER` is the Services Toolkit version you want to install. For example, `0.9.0`.

3. Verify that the package installed by running:

   ```
   tanzu package installed get services-toolkit -n tap-install
   ```

   In the output, confirm that the `STATUS` value is `Reconcile succeeded`.

   For example:

   ```
   $ tanzu package installed get services-toolkit -n tap-install
   | Retrieving installation details for services-toolkit...
   NAME:                    services-toolkit
   PACKAGE-NAME:            services-toolkit.tanzu.vmware.com
   PACKAGE-VERSION:         0.9.0
   STATUS:                  Reconcile succeeded
   CONDITIONS:              [{ReconcileSucceeded True  }]
   USEFUL-ERROR-MESSAGE:
   ```

Services Toolkit concepts

This section introduces you to Services Toolkit concepts.

In this section:

- The four levels of service consumption in Tanzu Application Platform
- Class claims vs resource claims

The four levels of service consumption in Tanzu Application Platform

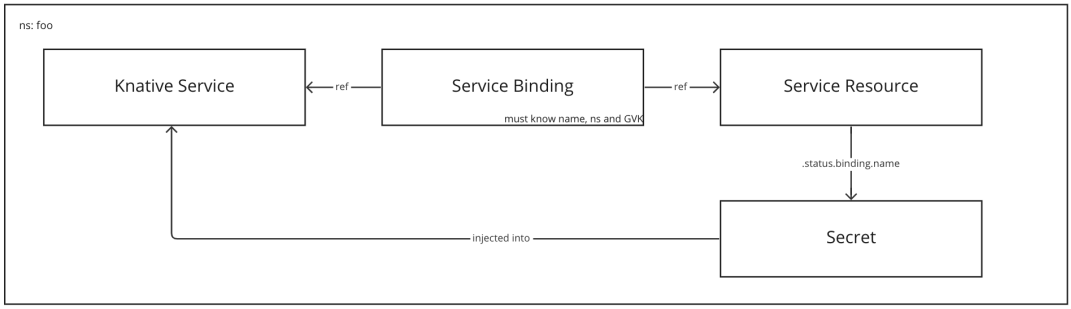
This topic describes the different levels of abstraction when using Services Toolkit and explains when and why you might choose to use one level over the other.

As Tanzu Application Platform has evolved, so has the way to offer and consume services on the platform. In this topic, the progress of this evolution is charted in terms of four levels of service consumption.

The introduction of a higher level does not automatically mean that all lower levels are made obsolete. In most cases, the higher levels build upon the foundations laid by the lower levels, and represent an abstraction that is higher-level and more opinionated.

Level 1 - direct bindings

Tanzu Application Platform v1.0 included support for service bindings, which back the level 1 concept of direct bindings.



For example, if you deploy an application workload to Tanzu Application Platform, this results in a Knative service in a namespace. An API resource in the same namespace that represents a service, such as a database or a cache, is called a service resource.

Using a service binding you can bind that service resource with the Knative service. This injects the credentials for the service resource into the Knative service, so that the application workload can consume it.

In this relatively straightforward scenario, there are only a few resources involved and they directly reference each other. In fact, users are not even directly exposed to the service binding. The service binding is created automatically as part of the Out of the Box Supply Chains whenever an application workload is configured to refer to a service.

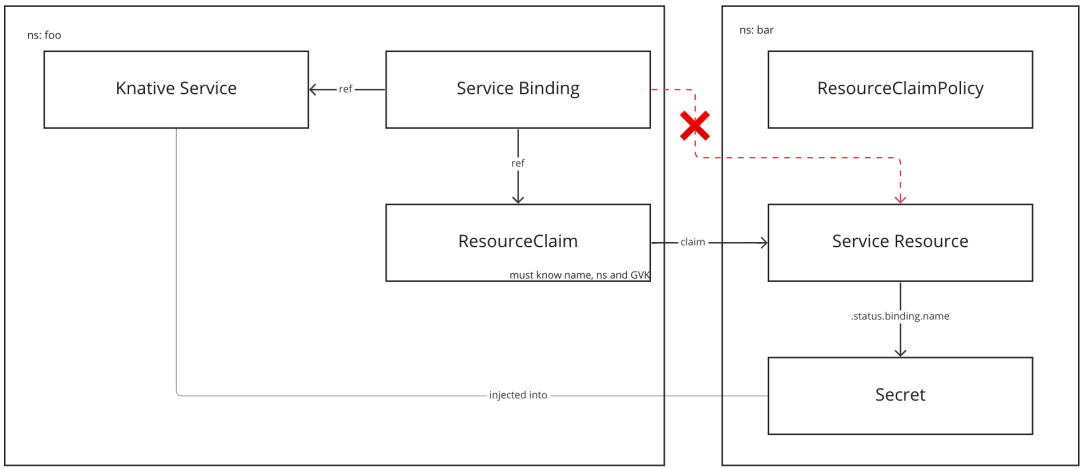
However, there are a number of limitations with this setup. The first is that the service resource must be bindable and which means it must adhere to the provisioned services definition in the service binding specification for Kubernetes. For more information, see Provisioned Service. There are some resources that adhere to this specification, primarily resources offered by VMware Tanzu's data services, but the overwhelming majority of resources don't.

The second limitation is that all resources have to be in the same namespace.

The third limitation is that the service binding must have detailed and specific information about the service resource, including its name, namespace, and API group, version, and kind. This is not a clear separation of concerns as it introduces tight coupling between app teams, who create the application workloads, and ops teams, who create the service resources.

Level 2 - resource claims

Level 2 addresses some limitations of direct bindings through the Services Toolkit feature resource claims. This feature coincided with the release of Tanzu Application Platform v1.0.



For example, if you have the same setup as in Level 1 - direct bindings, but you want the service resource to be in a separate namespace from the Knative service you cannot use direct bindings. This is because the schema for ServiceBinding provides no option to configure a `namespace` for the service.

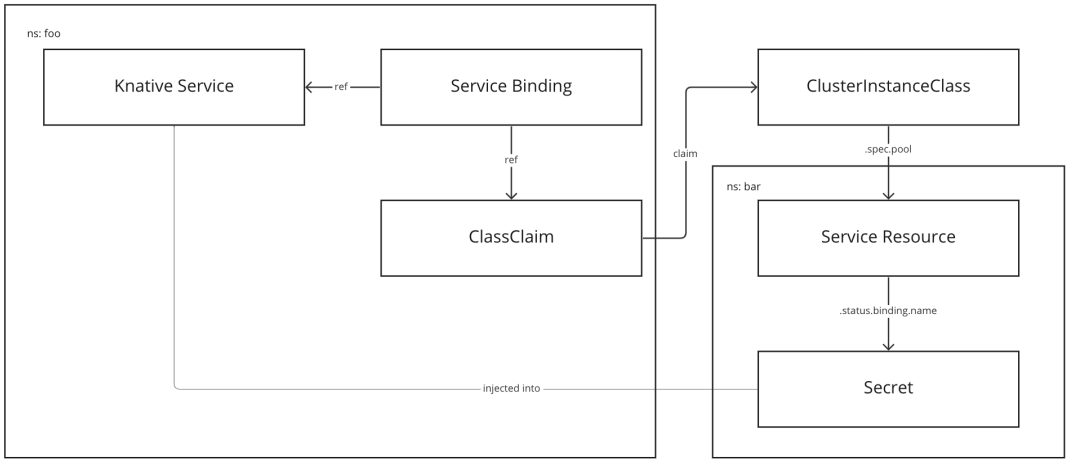
Resource claims allow you to claim a bindable service resource that exists in another namespace, and to then bind the application workload to the resource claim instead of to the service resource directly. Because you are now crossing namespace tenancy boundaries, you are only permitted to claim the service resource if you create a corresponding resource claim policy.

The advantage of level 2 over level 1 is that now the application workload and the service resource do not have to exist in the same namespace. This helps to promote a better separation of concerns. It is now possible for apps teams and ops teams to manage the life cycles of apps and services independently.

However, it's still not an ideal solution, and some limitations from level 1 still exist in level 2. The service resource still must be bindable, and apps teams still must know the name, namespace, and API group, version, and kind of the service resource. In addition, ops teams must ensure that the service resources exist. These resources must be manually provisioned and permitted to be claimed through policy, otherwise resource claims created by the apps teams remain in a pending state indefinitely.

Level 3 - class claims and pool-based classes

Level 3 introduces class claims and pool-based classes. Originally released with Tanzu Application Platform v1.4, class claims and pool-based classes help to alleviate the issue of apps teams having to know detailed information about service resources.



Level 3 builds on the example in level 2, which has an application workload in a namespace `foo` and a service resource in a namespace `bar`. Rather than relying on resource claim and resource claim policy, level 3 introduces a class claim and a pool-based class.

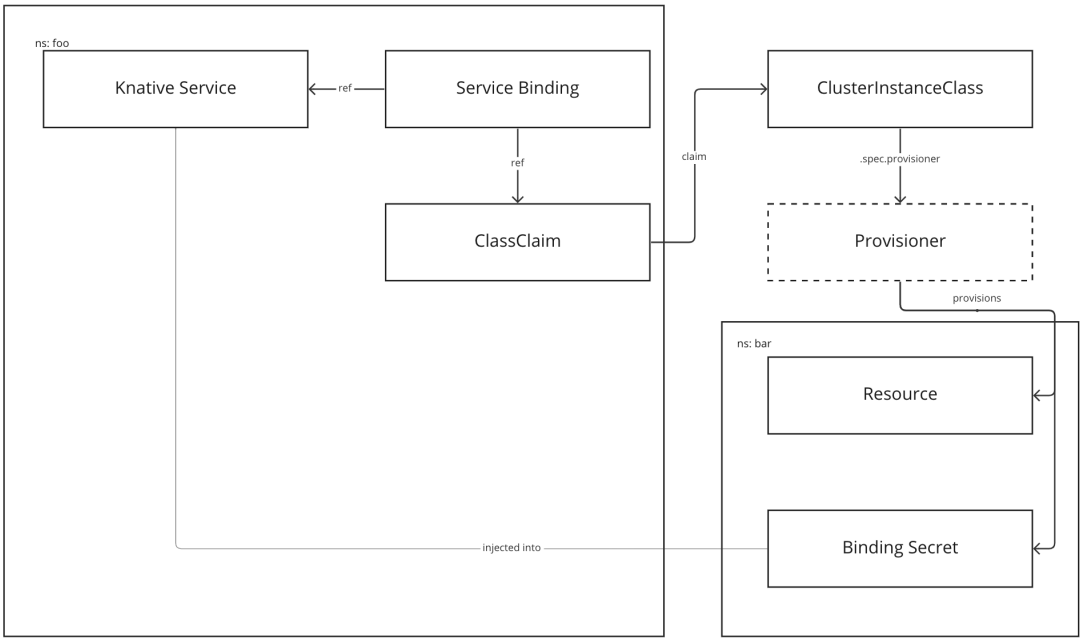
The pool-based class can pool service resources using label or field selectors from across all namespaces on the cluster. Ops teams create the service resources and then create a class to gather them all together into one logical group that apps teams can discover and claim from.

Apps teams can discover the available classes using the `tanzu service class list` command. Rather than creating a resource claim, they instead create a higher-level abstraction - a class claim. The class claim refers to the name of a class. You only need to create a class claim referring to a class and then bind your application workload to the class claim. There is no longer a need to provide detailed information such as the API group, version, and kind for the service resource behind the class.

Level 3 is much simpler for apps teams to consume services and the separation of concerns is much neater. A few limitations still remain. Service resources must still be bindable and ops teams still must manually provision the service resources to fill the pool.

Level 4 - class claims and provisioner-based classes (aka “Dynamic Provisioning”)

Level 4 is the current highest level of service consumption in Tanzu Application Platform. Released in Tanzu Application Platform v1.5, it introduces provisioner-based classes, which, together with class claims, power Tanzu Application Platform’s dynamic provisioning capability.



Level 4 builds on the example in level 3, but the class now defines a provisioner rather than a pool. Services Toolkit in Tanzu Application Platform v1.5 supports one provisioner type - Crossplane. Support for new provisioners might be added in the future.

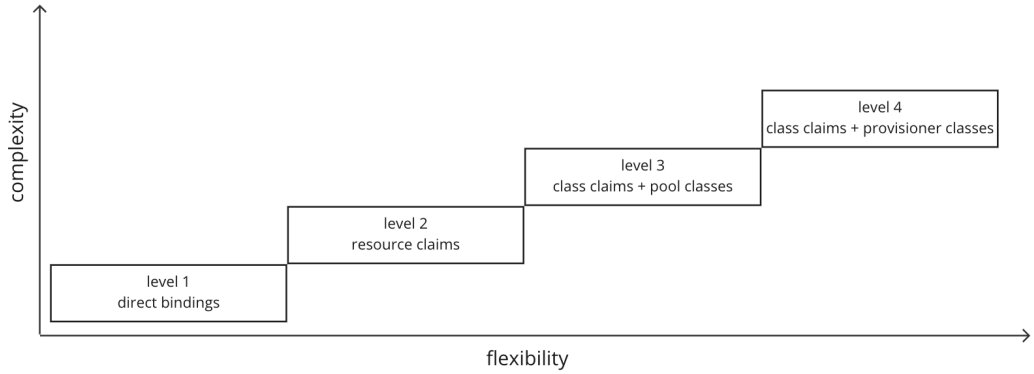
When you create a class claim that refers to a provisioner-based class, the Services Toolkit controller requests the provisioner to provision the resources necessary to create a service instance that can then be bound to application workloads. In this example, the provisioner creates a namespace, a service resource, and a secret that conforms to the binding specification. Then, that secret is wired all the way back through to the application workload.

Two big advantages are realized at level 4. Firstly, ops teams no longer need to manually provision service resources. They are now created on-demand as and when needed. This not only helps to remove unnecessary burden from ops teams, but also helps to provide better use of resources because service resources no longer need to remain in a pool waiting to be claimed. The second advantage is that service resources no longer need to be bindable. The provisioner can act almost like an adapter to bring pretty much any service you can think of into Tanzu Application Platform. The only requirement is that the provisioner create a binding-conforming secret that holds credentials for the provisioned service resources. You can configure this once during the dynamic provisioning setup.

While level 4 is very powerful and seemingly solves the problems mentioned so far, it's not entirely without its drawbacks. The main one being that all this flexibility comes at the cost of added complexity. There are many, many more moving parts involved at level 4 when compared to level 1. However, it might be a price worth paying to benefit from all that is on offer.

Summary

By now you have seen how each new level builds and improves upon the last. All levels are also valid use cases in their own right.



Tanzu Application Platform users can decide which level to operate at. Finding the level that is right for your situation depends on a number of factors, such as, the size of the organization you work for and the layout of apps teams and ops teams within the org.

If you work at a small startup in which there are no strict divides between apps teams and ops teams, level 1 might be suitable for your needs. However, if you work for a large organization with distinct and dedicated apps and ops teams, choosing one of the higher levels in which that separation is better catered to might make more sense. If you are not sure, it's probably best to start with level 4. Level 4 provides the ultimate services experience on Tanzu Application Platform, and as such will hopefully meet all your services needs.

Class claims compared to resource claims

There are two types of claim you can choose from when working with services on Tanzu Application Platform (commonly known as TAP). These are ClassClaim and ResourceClaim. This Services Toolkit topic explains the similarities and differences between the two and when using one is preferable over the other.

It is usually advisable to work with a ClassClaim where possible as they are easier to create and are more portable across multiple clusters. They are also used as the trigger mechanism for dynamic provisioning of service instances.

Similarities

- Both APIs express that you want to access to a service instance.
- Both APIs adhere to the ProvisionedService duck type. They both have the field `.status.binding.name` in their API. This means that you can target them using a ServiceBinding and, therefore, you can feed them into Cartographer's Workload API.
- Both APIs ensure that mutual exclusivity of claims on service instances. After using either a ClassClaim or a ResourceClaim to claim a service instance, no other ClassClaim or a ResourceClaim can claim that same service instance.

Using a ResourceClaim

A ResourceClaim targets a specific resource in the Kubernetes cluster. To target that resource, the ResourceClaim needs the name, namespace, kind, and API version of the resource.

The specificity of the ResourceClaim means it is most useful when you must guarantee which service instance the application workload uses. For example, if the application must connect to the exact same database instance while it advances through development, test, and production

environments. If you do not need this guarantee VMware recommends that you use the ClassClaim API instead.

Using a ClassClaim

A ClassClaim targets a ClusterInstanceClass in the Kubernetes cluster. To target this class, the ClassClaim only requires the name of the ClusterInstanceClass.

The ClusterInstanceClass can represent any set of service instances and therefore each time you create a new ClassClaim, you can claim any of the service instances represented by that ClusterInstanceClass. After a ClassClaim has claimed a service instance, it never looks for another. This is true even if the ClassClaim's `spec` is updated, or the ClusterInstanceClass is updated. Therefore, the ClassClaim is performing a **point-in-time** lookup at its creation, using the ClusterInstanceClass for that lookup.

The loose coupling between the ClassClaim and the service instances means that a ClassClaim is best in situations where:

- You must inject different service instances into the application workload at different points in its advancement from development to production environments. For more information, see Abstracting Service Implementations Behind A Class Across Clusters.
- The ClassClaim, and also any workload referencing it, must be promoted from one environment to the next without changing their specification.

The ClassClaim is the only type of claim that you can use to dynamically provision service instances.

Tutorials

In this section:

For apps teams:

- Working with Bitnami Services

For ops teams:

- Set up dynamic provisioning of service instances
- Integrating cloud services into Tanzu Application Platform
- Using direct secret references
- Abstracting service implementations behind a class across clusters

Set up dynamic provisioning of service instances

In this Services Toolkit tutorial you learn how service operators can set up a new, self-serve, and customized service for Tanzu Application Platform (commonly known as TAP). The example uses VMware RabbitMQ for Kubernetes, but the steps and learnings can apply to almost any other service.

About this tutorial

Target user role: Service Operator
Complexity: Advanced
Estimated time: 60 minutes
Topics covered: Dynamic Provisioning, Crossplane, VMware RabbitMQ for Kubernetes operator
Learning outcomes: Ability to offer new, on-demand, and customized services in your Tanzu Application Platform clusters

Prerequisites

- Access to a Tanzu Application Platform cluster v1.5.0 or later.
- Basic familiarity with Crossplane, particularly the concepts of Composition and CompositeResourceDefinitions.

Scenario

The tutorial is centered around the following hypothetical, but somewhat realistic, real-world scenario.

You work at BigCorp and are tasked to provide an on-demand, self-serve RabbitMQ service for BigCorp's development teams who are working with Tanzu Application Platform. You have already reviewed the RabbitMQ offering that is available with Bitnami Services, but have discovered that while it is an excellent service for testing and for quickly getting started, it is not quite suitable for BigCorp's stringent and specific needs.

In particular, you must comply with BigCorp's auditing and logging policy, and want to enforce that every RabbitMQ cluster in use on the platform adheres to that policy. At the same time, you don't want to be a blocker for the application teams and want to offer them self-serve access to RabbitMQ whenever they need it, without incurring any untoward delays. You have heard great things about Tanzu Application Platform's dynamic provisioning capability, and are now looking to make use of it to help you complete your task.

In this tutorial you will learn how to:

- Install the RabbitMQ Cluster Kubernetes operator
- Create a `CompositeResourceDefinition`
- Create a `Composition`
- Create a provisioner-based class
- Understand and create the necessary RBAC permissions
- Create a claim for the class to test it all out
- Understand how all the pieces fit together to power the dynamic provisioning capability in Tanzu Application Platform

Concepts

The following diagram provides an overview of the elements of dynamic provisioning and how they fit together.

The following is a high-level overview of how the system works:

1. The service operator creates a `CompositeResourceDefinition` and a `Composition`, which together define the configuration of the service instances that will be dynamically provisioned.
2. The service operator creates a class pointing to the `CompositeResourceDefinition`. This informs application development teams that the service is available.
3. The service operator applies necessary Role-Based Access Control (RBAC) to permit the system to create the necessary resources, and to authorize application development teams to create claims for the class.
4. The application developer creates a claim referring to the class, optionally passing through parameters to override any default configuration where permissible.
5. The system creates a `CompositeResource`, merging information provided in the claim with default configuration specified by the system and configuration defined in the `Composition`.
6. Crossplane reconciles the `CompositeResource` into a service instance and writes credentials for the instance into a `Secret`.
7. The `Secret` is written back to the application developer's namespace, so that application workloads can use it.

As you follow this tutorial, it will address the parts of this diagram in more detail.

Procedure

The following steps show how to configure dynamic provisioning for a service.

Step 1: Install the operator

When adding any new service to Tanzu Application Platform, ensure that there are a suitable set of APIs available in the cluster from which to construct the service instances. Usually, this involves installing one or more Kubernetes Operators into the cluster.

Given the aim of this tutorial is to set up a new RabbitMQ service, install the RabbitMQ Cluster Operator for Kubernetes.

Note

> The steps in this tutorial use the open source version of the operator. For most real-world deployments, VMware recommends using the official, supported version provided by VMware. For more information, see VMware RabbitMQ for Kubernetes.

Use `kapp` to install the operator by running:

```
kapp -y deploy --app rmq-operator --file https://github.com/rabbitmq/cluster-operator/releases/latest/download/cluster-operator.yml
```

This causes a new API Group/Version of `rabbitmq.com/v1beta1` and Kind named `RabbitmqCluster` to become available in the cluster. You can now use this API to create RabbitMQ cluster instances as part of the dynamic provisioning setup.

Step 2: Creating a `CompositeResourceDefinition`

Tanzu Application Platform's dynamic provisioning capability relies on Crossplane. You can find the specific integration point at `.spec.provisioner.crossplane.compositeResourceDefinition` in Tanzu Application Platform's `ClusterInstanceClass` API.

As the name suggests, this field is looking for a `CompositeResourceDefinition`, which you create in this step of the procedure. The `CompositeResourceDefinition` (XRD) defines the shape of a new, custom API type that encompasses the specific set of requirements laid out by the scenario in this tutorial.

Create a file named `xrabbitmqclusters.messaging.bigcorp.org.xrd.yaml` and copy in the following contents.

```
# xrabbitmqclusters.messaging.bigcorp.org.xrd.yaml

---
apiVersion: apiextensions.crossplane.io/v1
kind: CompositeResourceDefinition
metadata:
  name: xrabbitmqclusters.messaging.bigcorp.org
spec:
  connectionSecretKeys:
  - host
  - password
  - port
  - provider
  - type
  - username
  group: messaging.bigcorp.org
  names:
    kind: XRabbitmqCluster
    plural: xrabbitmqclusters
  versions:
  - name: v1alpha1
    referenceable: true
    schema:
      openAPIV3Schema:
        properties:
          spec:
            description: The OpenAPIV3Schema of this Composite Resource Definition.
            properties:
              replicas:
                description: The desired number of replicas forming the cluster
                type: integer
              storageGB:
                description: The desired storage capacity of a single replica, in GB.
```

```
                type: integer
            type: object
        type: object
    served: true
```

Then use kubectl to apply the file to the Tanzu Application Platform cluster.

```
kubectl apply -f xrabbitmqclusters.messaging.bigcorp.org.xrd.yaml
```

For a detailed explanation of `CompositeResourceDefinition` see, the Crossplane documentation.

The following is a condensed explanation of the most relevant pieces of the `CompositeResourceDefinition` configuration, provided in this section, as it relates to dynamic provisioning in Tanzu Application Platform.

The example in this tutorial does **not** specify `.spec.claimNames` in the XRD. Tanzu Application Platform's dynamic provisioning capability makes use of Crossplane's cluster-scoped Composite Resources, rather than the namespace-scoped Claims ("Claims" here not to be confused with Tanzu Application Platform's own concept of claims). As such, this configuration is not required, although it does not cause any adverse effects if you add it.

Next, see the `.spec.connectionKeys` field. This field detects the keys that will exist in the `Secret` resulting from the dynamic provisioning request. You likely want this `Secret` to conform with the Service Binding Specification for Kubernetes, as this, in part, is what allows for automatic configuration of the service instance by Tanzu Application Platform's application workloads. This is assuming that the application is using a binding-aware library such as Spring Cloud Bindings. Specific key name requirements vary by service type, however all must provide the `type` key.

Finally, see the `.spec.properties` section in the schema for `v1alpha1`. This is where you, as the service operator, can set which configuration options you want to expose to application development teams. In the example in this section, there are two configuration options: `replicas` and `storageGB`. By adding these properties to the specification, you are handing over control of these specific configuration options to the development teams. For example, you might want to add `storageGB` if the development teams have more knowledge about how much storage their apps require than you do. By adding `storageGB` you can allow them to decide for themselves how much storage they require.

You can choose to add as many or as few configuration options here as you like. You can also choose to set default values. In highly regulated environments, you might not want to allow for any configuration by developers at all.

In the scenario at the beginning of this tutorial, it says that you must comply with the auditing and logging policy. You do not specify any configuration related to auditing or logging in the XRD in this step. This is intentional as in this scenario there are strict auditing and logging requirements and cannot permit developers to override those. In the next step you learn how to ensure that those requirements get enforced on the resulting RabbitMQ clusters.

To verify the status of the XRD you created, run:

```
kubectl get xrds
```

If successful, the `xrabbitmqclusters.messaging.bigcorp.org` is listed with `ESTABLISHED=True`.

You might see some other XRDs listed as well. These are the `*.bitnami.*.tanzu.vmware.com` XRDs. These are part of the `bitnami.services.tanzu.vmware.com` package with Tanzu Application Platform and serve as the basis of the Bitnami Services. You can ignore these other XRDs for now, but if you want to see how they are used in practice, see Claim services on Tanzu Application Platform and Consume services on Tanzu Application Platform in the Tanzu Application Platform getting started guide.

As a result of creating the XRD, a new API Group/Version of `messaging.bigcorp.org/v1alpha1` and Kind named `XRabbitmqCluster` become available in the cluster. If you inspect this API further, notice that the `replicas` and `storageGB` properties configured in the XRD are present in the specification of `XRabbitmqCluster`.

```
kubectl explain --api-version=messaging.bigcorp.org/v1alpha1 xrabbitmqclusters.spec
```

You will also notice that Crossplane has injected some other fields into the specification as well, but you can mostly ignore these for now.

Step 3: Creating a Crossplane `Composition`

You do most of the configuration for dynamic provisioning during the creation of the `Composition`.

For a more detailed explanation about the `Composition`, see the Crossplane documentation.

The following are the basics you must know to start to create a `Composition` for use in Tanzu Application Platform.

Create a file named `xrabbitmqclusters.messaging.bigcorp.org.composition.yaml` and copy in the following contents.

```
# xrabbitmqclusters.messaging.bigcorp.org.composition.yaml

---
apiVersion: apiextensions.crossplane.io/v1
kind: Composition
metadata:
  name: xrabbitmqclusters.messaging.bigcorp.org
spec:
  compositeTypeRef:
    apiVersion: messaging.bigcorp.org/v1alpha1
    kind: XRabbitmqCluster
  resources:
  - base:
      apiVersion: kubernetes.crossplane.io/v1alpha2
      kind: Object
      spec:
        forProvider:
          manifest:
            apiVersion: rabbitmq.com/v1beta1
            kind: RabbitmqCluster
            metadata:
              namespace: rmq-clusters
            spec:
              terminationGracePeriodSeconds: 0
              replicas: 1
              persistence:
                storage: 1Gi
              resources:
                requests:
                  cpu: 200m
                  memory: 1Gi
                limits:
                  cpu: 300m
                  memory: 1Gi
              rabbitmq:
                envConfig: |
                  RABBITMQ_LOGS=""
                additionalConfig: |
                  log.console = true
                  log.console.level = debug
                  log.console.formatter = json
                  log.console.formatter.json.field_map = verbosity:v time msg domain f
```

```
ile line pid level:-
                  log.console.formatter.json.verbosity_map = debug:7 info:6 notice:5 w
arning:4 error:3 critical:2 alert:1 emergency:0
                  log.console.formatter.time_format = epoch_usecs
        connectionDetails:
        - apiVersion: v1
          kind: Secret
          namespace: rmq-clusters
          fieldPath: data.provider
          toConnectionSecretKey: provider
        - apiVersion: v1
          kind: Secret

      - fromFieldPath: metadata.name
        toFieldPath: spec.connectionDetails[4].name
        transforms:
        - string:
            fmt: '%s-default-user'
            type: Format
          type: string
        type: FromCompositeFieldPath
      - fromFieldPath: metadata.name
        toFieldPath: spec.connectionDetails[5].name
        transforms:
        - string:
            fmt: '%s-default-user'
            type: Format
          type: string
        type: FromCompositeFieldPath
    readinessChecks:
      - type: MatchString
        fieldPath: status.atProvider.manifest.status.conditions[1].status # ClusterAva
ilable
        matchString: "True"
```

Use kubectl to apply the file to the Tanzu Application Platform cluster.

```
kubectl apply -f xrabbitmqclusters.messaging.bigcorp.org.composition.yaml
```

About `.spec.compositeTypeRef`

The `.spec.compositeTypeRef` is configured to refer to `XRabbitmqCluster` on the `messaging.bigcorp.org/v1alpha1` API group and version.

```
...
spec:
  compositeTypeRef:
    apiVersion: messaging.bigcorp.org/v1alpha1
    kind: XRabbitmqCluster
...
```

This is the API that was created when you applied the XRD in Step 2: Creating a `CompositeResourceDefinition`. By configuring `.spec.compositeTypeRef` to refer to this API, you are instructing Crossplane to use the configuration contained within this `Composition` to compose subsequent managed resources whenever it observes that a new `XRabbitmqCluster` resource is created in the cluster. Tanzu Application Platform's dynamic provisioning system creates the `XRabbitmqCluster` resources automatically. To visualize how these pieces fit together, see the diagram in the Concepts section.

About `.spec.resources`

The `.spec.resources` section is where you specify the managed resources to be created. Managed resources are tied to Crossplane's `Providers`, with each `Provider` defining a set of managed resources which can then be used in compositions. Tanzu Application Platform includes two `Providers` with the Crossplane package: provider-helm and provider-kubernetes. This makes a `Release` managed resource available, which is used to manage Helm releases, and makes an `Object` managed resource available, which used to manage arbitrary Kubernetes resources. You can install and use any other `Provider`. To find the latest providers, see the Upbound Marketplace. The more providers you install, the more managed resources you can choose from in your compositions.

The `Object` managed resource

The overarching goal is to compose whatever resources are necessary to create functioning, usable service instances and to surface the credentials and connectivity information required to connect to those instances in a known and repeatable way. This tutorial uses the `RabbitmqCluster` resource, which presents one single API to use to create fully functioning RabbitMQ clusters, credentials for which get stored in `Secrets` in the cluster.

However, `RabbitmqCluster` is not a Crossplane managed resource so you cannot refer to this resource directly under `.spec.resources`. To work around this, use `provider-kubernetes` and its corresponding `Object` managed resource. `Object` enables you to wrap any arbitrary Kubernetes resource, such as `RabbitmqCluster`, into a Crossplane managed resource and to then use them like any other managed resource inside `Compositions`.

```
...
spec:
  resources:
  - base:
      apiVersion: kubernetes.crossplane.io/v1alpha2
      kind: Object
      spec:
        forProvider:
          manifest:
            apiVersion: rabbitmq.com/v1beta1
            kind: RabbitmqCluster
            metadata:
              namespace: rmq-clusters
            spec:
              terminationGracePeriodSeconds: 0
              replicas: 1
              persistence:
                storage: 1Gi
```

```
              resources:
                requests:
                  cpu: 200m
                  memory: 1Gi
                limits:
                  cpu: 300m
                  memory: 1Gi
              rabbitmq:
                envConfig: |
                  RABBITMQ_LOGS=""
                additionalConfig: |
                  log.console = true
                  log.console.level = debug
                  log.console.formatter = json
                  log.console.formatter.json.field_map = verbosity:v time msg domain f
ile line pid level:-
                  log.console.formatter.json.verbosity_map = debug:7 info:6 notice:5 w
arning:4 error:3 critical:2 alert:1 emergency:0
                  log.console.formatter.time_format = epoch_usecs
...
```

The `Object` managed resource is where you configure `RabbitmqCluster` resources. This is the place in which you can now fine-tune the configuration of the RabbitMQ Clusters to your needs.

Recall from the hypothetical scenario that you are particularly concerned about your company's logging policy. The configuration in the `Object` translates that hypothetical policy into default configuration on the `RabbitmqCluster` resource by specifying `.spec.rabbitmq.additionalConfig` for the resource. This was taken from one of the examples in the RabbitMQ Cluster Operator GitHub repository. You can configure the resource however you want and to whatever requirements necessary.

The `patches` section

The `Object` also sets default values for the number of replicas and the amount of persistent storage for new `RabbitmqClusters` to one replica and 1 Gi. However, you want to allow these two values to be configurable by the application development teams as specified in Step 2: Creating a `CompositeResourceDefinition`. You can configure this using patches.

```
...
patches:
  - fromFieldPath: metadata.name
    toFieldPath: spec.forProvider.manifest.metadata.name
    type: FromCompositeFieldPath
...
```

The first thing to note is that all the patches are of type `FromCompositeFieldPath`, which allows you to take values defined on the composite resource (`XRabbitmqCluster` in this case) and to pass them through to the underlying managed resource (an `Object` wrapping `RabbitmqCluster` in this case). The first patch sets the name of the `RabbitmqCluster` to the same name as the name of the composite resource `XRabbitmqCluster`, which were created using `generateName`, thereby ensuring a unique name for each dynamically provisioned `RabbitmqCluster` instance.

```
...
patches:
...
  - fromFieldPath: spec.replicas
    toFieldPath: spec.forProvider.manifest.spec.replicas
    type: FromCompositeFieldPath
  - fromFieldPath: spec.storageGB
    toFieldPath: spec.forProvider.manifest.spec.persistence.storage
    transforms:
```

```
    - string:
        fmt: '%dGi'
        type: Format
      type: string
    type: FromCompositeFieldPath
...
```

The second and third patches pass through configuration for the number of replicas and amount of persistent storage, which overrides the default values already configured.

The remaining patches all do the same thing, which is to patch in the name of the `Secret` for the fields in the `connectionDetails` section.

```
...
- fromFieldPath: metadata.name
  toFieldPath: spec.connectionDetails[0].name
  transforms:
  - string:
      fmt: '%s-default-user'
      type: Format
    type: string
  type: FromCompositeFieldPath
...
```

When creating a `RabbitmqCluster` resource using the RabbitMQ Cluster Kubernetes operator, the operator creates a `Secret` containing credentials and connectivity information used to connect to the cluster. That `Secret` is named `x-default-user`, where `x` is the name of the `RabbitmqCluster` resource. Because the name of the `RabbitmqCluster` cannot be known upfront, you must use patches to ensure that the `connectionDetails` section refers to the correctly-named `Secret`.

The `connectionDetails` sections are where you configure which keys and values to expose in the resulting `Secret`. You must specify the same set of keys as defined in the original XRD.

The `readinessChecks` section

Configuring readiness checks helps to keep consumers of dynamic provisioning, that is, the application teams, informed about when the resulting service instances are ready for application workloads to use.

```
...
readinessChecks:
  - type: MatchString
    fieldPath: status.atProvider.manifest.status.conditions[1].status # ClusterAvailab
le
    matchString: "True"
```

Where possible it is simplest to use the `Ready` condition to verify readiness. However, the `RabbitmqCluster` API doesn't expose a simple `Ready` condition, so you must configure the ready check on `ClusterAvailable` instead.

Check the namespace

One final important decision is the name of the namespace in which to create the dynamically provisioned `RabbitmqCluster` resources. This tutorial uses the `rmq-clusters` namespace.

```
...
spec:
  resources:
  - base:
      apiVersion: kubernetes.crossplane.io/v1alpha2
```

```
      kind: Object
      spec:
        forProvider:
          manifest:
            apiVersion: rabbitmq.com/v1beta1
            kind: RabbitmqCluster
            metadata:
              namespace: rmq-clusters
...
```

To make sure that the `rmq-clusters` namespace exists.

```
kubectl create namespace rmq-clusters
```

This configuration says that all dynamically provisioned `RabbitmqCluster` resources must be placed in the same `rmq-clusters` namespace. If you want to place each new cluster into a separate namespace, you must create an additional `Object` managed resource to wrap the creation of a `Namespace` and to apply patches to the resources accordingly. For this tutorial you only require one namespace.

Step 4: Creating a provisioner-based class

The creation of the XRD and the Composition brings to an end the Crossplane-centric part of this tutorial. What remains is to integrate all that you configured into Tanzu Application Platform's classes and claims model so that application teams can more easily make use of it. The first step here is to create a provisioner-based class and to point it at the XRD you created.

Create a file named `bigcorp-rabbitmq.class.yaml` and copy in the following contents.

```
# bigcorp-rabbitmq.class.yaml

---
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ClusterInstanceClass
metadata:
  name: bigcorp-rabbitmq
spec:
  description:
    short: On-demand RabbitMQ clusters precision engineered to meet the needs of BigCo
rp!
  provisioner:
    crossplane:
      compositeResourceDefinition: xrabbitmqclusters.messaging.bigcorp.org
```

Then use kubectl to apply the file to the Tanzu Application Platform cluster.

```
kubectl apply -f bigcorp-rabbitmq.class.yaml
```

This is referred to as a provisioner-based class due to the configuration of `.spec.provisioner`. For more information, see ClusterInstanceClass.

By creating this class you are informing application teams that the service is available. Application teams can discover it by using the `tanzu service class list` command. They can also use `tanzu service class get bigcorp-rabbitmq`, which provides detailed information about the class, including details of the `replicas` and `storageGB` parameters that you configured earlier.

Step 5: Configure supporting RBAC

There are two parts of RBAC to consider when you set up a new service for dynamic provisioning in Tanzu Application Platform. The first relates to granting permissions to the providers used in the compositions. The `Composition` created earlier uses `Object` managed resources ultimately to create

`RabbitmqCluster` resources. Therefore, you must grant `provider-kubernetes` permission to create `RabbitmqCluster` resources. You can do this by using an aggregating `ClusterRole` as follows.

Create a file named `provider-kubernetes-rmqcluster-read-writer.rbac.yaml` and copy in the following contents.

```
# provider-kubernetes-rmqcluster-read-writer.rbac.yaml

---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: rmqcluster-read-writer
  labels:
    services.tanzu.vmware.com/aggregate-to-provider-kubernetes: "true"
rules:
- apiGroups:
  - rabbitmq.com
  resources:
  - rabbitmqclusters
  verbs:
  - "*"
```

Then use kubectl to apply the file to the Tanzu Application Platform cluster.

```
kubectl apply -f provider-kubernetes-rmqcluster-read-writer.rbac.yaml
```

While not necessary here, a corresponding label `services.tanzu.vmware.com/aggregate-to-provider-helm: "true"` exists for aggregating RBAC permissions to `provider-helm` as well.

The second element of RBAC detects who is authorized to use the new service. This is an important piece of configuration. You are configuring an on-demand service and making it available to application teams. Without any other supporting policy in place, application teams can create as many `RabbitmqClusters` as they like. This is of course the whole point of an on-demand service, but you must be conscious of resource use, and might want to control who can create new service instances on-demand.

You can grant authorization by using standard Kubernetes RBAC resources. Dynamic provisioning uses a custom RBAC verb, `claim`, which you can apply to classes to permit claiming from classes.

Create a file named `app-operator-claim-class-bigcorp-rabbitmq.rbac.yaml` and copy in the following contents.

```
# app-operator-claim-class-bigcorp-rabbitmq.rbac.yaml

---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: app-operator-claim-class-bigcorp-rabbitmq
  labels:
    apps.tanzu.vmware.com/aggregate-to-app-operator-cluster-access: "true"
rules:
- apiGroups:
  - services.apps.tanzu.vmware.com
  resources:
  - clusterinstanceclasses
  resourceNames:
  - bigcorp-rabbitmq
  verbs:
  - claim
```

Then use kubectl to apply the file to the Tanzu Application Platform cluster.

```
kubectl apply -f app-operator-claim-class-bigcorp-rabbitmq.rbac.yaml
```

This `ClusterRole` grants anyone holding the `app-operator` Tanzu Application Platform user role the ability to claim from the `bigcorp-rabbitmq` class.

Step 6: Verify your configuration

To test your configuration, create a claim for the class and thereby trigger the dynamic provisioning of a new RabbitMQ cluster. This step is typically performed by the application operator, rather than the service operator, but it is important that you to confirm that everything is configured correctly.

Create a file named `bigcorp-rmq-1.claim.yaml` and copy in the following contents.

```
# bigcorp-rmq-1.claim.yaml

---
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ClassClaim
metadata:
  name: bigcorp-rmq-1
spec:
  classRef:
    name: bigcorp-rabbitmq
  parameters:
    storageGB: 2
    replicas: 3
```

Then use kubectl to apply the file to the Tanzu Application Platform cluster.

```
kubectl apply -f bigcorp-rmq-1.claim.yaml
```

After the RabbitMQ service is provisioned, the claim status reports `Ready=True`.

```
kubectl get classclaim bigcorp-rmq-1
```

Working with Bitnami Services

For the tutorial about working with Bitnami Services, see Working with Bitnami Services.

Integrating cloud services into Tanzu Application Platform

In this Services Toolkit tutorial you learn how service operators can integrate the cloud services of their choice into Tanzu Application Platform (commonly known as TAP).

There are a multitude of cloud-based services available on the market for consumers today. AWS, Azure, and GCP all provide support for a wide range of fully-managed, performant and on-demand services ranging from databases, to message queues, to storage solutions and beyond. In this tutorial you will learn how to integrate any one of these services into Tanzu Application Platform, so that you can offer it for apps teams to consume in a simple and effective way.

This tutorial is written at a slightly higher level than the other tutorials in this documentation. This is because it is not feasible to write detailed, step-by-step documentation for integrating every cloud-based service into Tanzu Application Platform. Each service brings a different set of considerations and concerns.

Instead, this tutorial guides you through the general approach to integrating cloud-based services into Tanzu Application Platform. While specific configurations change between services, the overall process remains the same through a consistent set of steps. The aim is to give you enough

understanding so that you can integrate any cloud-based service you want into Tanzu Application Platform.

For a more specific and low-level procedure, see Configure dynamic provisioning of AWS RDS service instances, which provides each step in detail for AWS RDS integration. It might be useful to read through that guide even if you want to integrate with one of the other cloud providers.

In addition, for Tanzu Application Platform v1.7 or later, you can instead use the AWS Services package, which provides a more streamlined approach for integrating services from AWS into Tanzu Application Platform.

About this tutorial

Target user role: Service Operator
Complexity: Advanced
Estimated time: 30 minutes
Topics covered: Dynamic Provisioning, Cloud-based Services, AWS, Azure, GCP, Crossplane
Learning outcomes: An understanding of the steps involved in integrating cloud-based services into Tanzu Application Platform

Concepts

The following is a high-level workflow outlining what is required to integrate a cloud-based service into Tanzu Application Platform.

1. **Install Provider and create ProviderConfig:**
    - Follow the official Upbound documentation to install the Provider and create a ProviderConfig.
2. **Create CompositeResourceDefinition:**
    - Create a CompositeResourceDefinition to define the shape of a new API type representing the service.
    - Choose which (if any) configuration parameters to expose to apps teams.
3. **Create Composition:**
    - Create a Composition using managed resources supplied by the Provider.
    - You can compose as many or as few managed resources as required to generate a service instance that application workloads can connect to and use over the network.
    - (Optional but recommended) Configure the connection secret to adhere to the Service Binding Specification for Kubernetes.
4. **Create provisioner-based ClusterInstanceClass:**
    - Create a provisioner-based ClusterInstanceClass pointing to the CompositeResourceDefinition created earlier.
5. **Create required RBAC:**
    - Create RBAC using the `claim` verb pointing to the provisioner-based ClusterInstanceClass to permit claiming from the class.
6. **Create ClassClaim:**
    - Create a ClassClaim pointing to the provisioner-based ClusterInstanceClass to begin a dynamic provisioning request.
    - Wait for the ClassClaim to report `READY=True`.

Procedure

This tutorial provides the steps required to integrate cloud services, and includes tips and references to example configurations where appropriate.

Step 1: Install a Provider

Install a suitable Crossplane `Provider` for your cloud of choice. Upbound provides support for the three main cloud providers:

- provider-aws
- provider-azure
- provider-gcp

Note

These cloud-based Providers often install many hundreds of additional CRDs onto the cluster, which can have a negative impact on cluster performance. For more information, see Cluster performance degradation due to large number of CRDs.

Choose the Provider you want, and then follow Upbound's official documentation to install the `Provider` and to create a corresponding `ProviderConfig`.

Important

The official documentation for the `Provider` includes a step to "Install Universal Crossplane". You can skip this step because Crossplane is already installed as part of Tanzu Application Platform.

The documentation also assumes Crossplane is installed in the `upbound-system` namespace. However, when working with Crossplane on Tanzu Application Platform, it is installed to the `crossplane-system` namespace by default. Ensure that you use the correct namespace when you create the `Secret` and the `ProviderConfig` with credentials for the `Provider`.

Step 2: Create a CompositeResourceDefinition

Create a `CompositeResourceDefinition`, which defines the shape of a new API type which is used to create the cloud-based resources.

For help creating the `CompositeResourceDefinition`, see the Crossplane documentation, or see Create a CompositeResourceDefinition in *Configure dynamic provisioning of AWS RDS service instances*.

Step 3: Create a Composition

This step is likely to be the most time-consuming. The `Composition` is where you define the configuration for the resources that make up the service instances for app teams to claim. Configure the necessary resources for usable service instances that users can connect to and use over the network.

To get started with creating a `Composition`, first read through Configuring Composition in the Upbound documentation.

You can also see the following `Composition` examples:

- For AWS RDS, see Define composite resource types (AWS).
- For Azure Flexible Server, see Define Composite Resource Types (Azure).
- For GCP Cloud SQL, see Define Composite Resource Types (GCP).

Step 4: Create a provisioner-based ClusterInstanceClass

Create a provisioner-based `ClusterInstanceClass` which is configured to refer to the `CompositeResourceDefinition` created earlier. For example:

```
---
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ClusterInstanceClass
metadata:
  name: cloud-service-foo
spec:
  description:
    short: FooDB by cloud provider Foo!
  provisioner:
    crossplane:
      compositeResourceDefinition: NAME-OF-THE-COMPOSITE-RESOURCE-DEFINITION
```

For a real-world example, see Make the service discoverable in *Configure dynamic provisioning of AWS RDS service instances*.

Step 5: Configure RBAC

Create an Role-Based Access Control (RBAC) rule using the `claim` verb pointing to the `ClusterInstanceClass` you created. For example:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: app-operator-claim-foo-db
  labels:
    apps.tanzu.vmware.com/aggregate-to-app-operator-cluster-access: "true"
rules:
- apiGroups:
  - "services.apps.tanzu.vmware.com"
  resources:
  - clusterinstanceclasses
  resourceNames:
  - cloud-service-foo
  verbs:
  - claim
```

For a real-world example, see Configure RBAC in *Configure dynamic provisioning of AWS RDS service instances*.

Step 6: Verify your integration

To test your integration, create a `ClassClaim` that points to the `ClusterInstanceClass` you created. For example:

```
---
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ClassClaim
metadata:
  name: claim-1
spec:
  classRef:
    name: cloud-service-foo
```

```
  parameters:
    key: value
```

Verify that the `ClassClaim` eventually transitions into a `READY=True` state. If it doesn't, debug the `ClassClaim` using kubectl. For how to do this, see Troubleshoot Services Toolkit.

Abstracting service implementations behind a class across clusters

In this Services Toolkit tutorial you learn how service operators can configure a class that allows for claims to resolve to different backing implementations of a service, such as PostgreSQL, depending on which cluster the class is claimed in.

This sort of setup allows the configurations of workloads and class claims to remain unchanged as they are promoted through environments, whilst also enabling service operators to change the implementations of the backing services without further configuration.

About this tutorial

Target user role: Service Operator
Complexity: Medium
Estimated time: 60 minutes
Topics covered: Classes, Claims, Claim-by-Class, Multi-Cluster
Learning outcomes: Ability to abstract the implementation (for example, helm, tanzu data service, cloud) of a service (for example, RabbitMQ) across multiple clusters

Prerequisites

- Access to three separate Tanzu Application Platform clusters v1.5.0 or later. This tutorial refers to them as `iterate`, `run-test`, and `run-production`, but you can use different names if required.

Scenario

The tutorial is centered around the following hypothetical, but somewhat realistic, real-world scenario.

You work at BigCorp as a service operator. BigCorp uses three separate Tanzu Application Platform clusters: `iterate`, `run-test`, and `run-production`. Application workloads begin on the `iterate` cluster, before being promoted to the `run-test` cluster, and then finally to the `run-production` cluster. The application development team have asked you for a PostgreSQL service they can use with their workloads, which must be available on all three clusters.

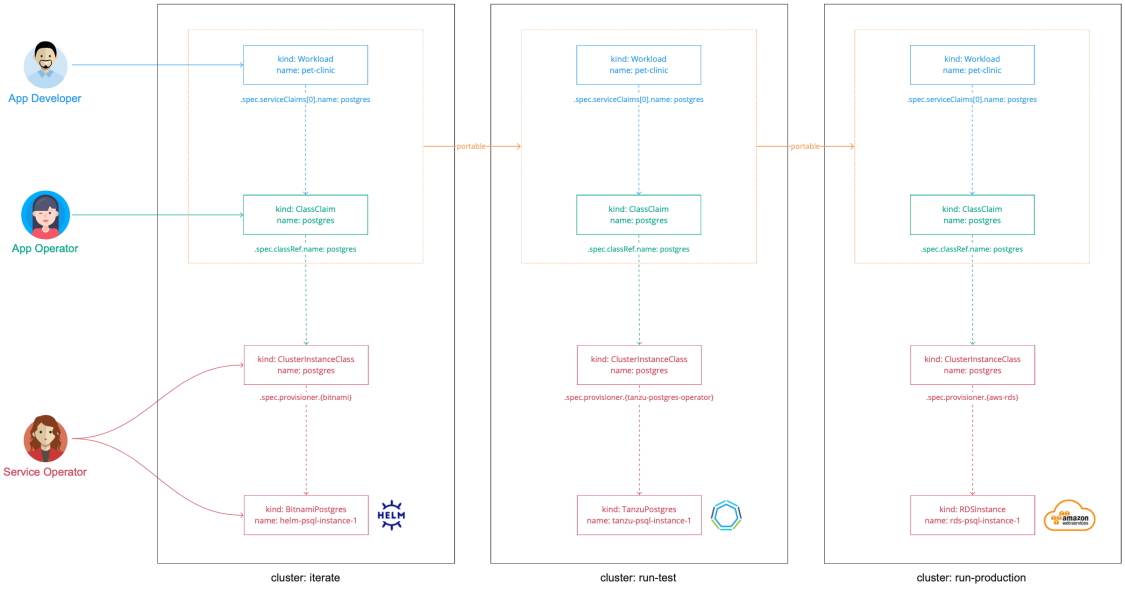
You are aware that the service level objectives (SLOs) for each cluster are different and want to tailor the implementation of the PostgreSQL service to each of the clusters accordingly. The `iterate` cluster has low level SLOs, so you want to offer an unmanaged PostgreSQL service backed by simple Helm chart. The `run-test` cluster has more robust requirements, so want to offer a PostgreSQL service backed by VMware SQL with Postgres for Kubernetes. The `run-production` cluster is critically important, so you want to use a fully managed, cloud-based PostgreSQL implementation there.

You want to ensure that the differing implementations are completely opaque to development teams. They do not need to know about the inner workings of the services, and must be able to keep their workloads and class claims the same as they are promoted across clusters. You have

heard great things about Tanzu Application Platform's claims and classes abstractions and want to make use of them to help you complete your task.

Concepts

This section provides a high-level overview of the elements you will use during this tutorial and how they all fit together.



In this diagram:

- There are three clusters: `iterate`, `run-test`, and `run-production`.
- In each cluster, the service operator creates a `ClusterInstanceClass` called postgres.
  - In the `iterate` cluster, this is a provisioner-based class that uses Bitnami Services to provision Helm instances of PostgreSQL.
  - In the `run-test` cluster, this is a provisioner-based class that uses VMware SQL with Postgres for Kubernetes to provision instances of PostgreSQL.
  - In the `run-production` cluster, this is a provisioner-based class that uses Amazon RDS to provision instances running in Amazon AWS RDS.
- The app operator creates a `ClassClaim`. This is applied with a consuming workload.
  - When it is applied in `iterate` it resolves to a Helm chart instance.
  - When it is promoted to `run-test` it resolves to a VMware PostgreSQL instance.
  - When it is promoted to `run-production` it resolves to an Amazon AWS RDS instance.
- The definition of the `ClassClaim` remains identical across the clusters, which is easier for the application development team.

Important

The backing service implementations and environment layouts used in this scenario are arbitrary. They are not recommendations or requirements.

Although this tutorial uses provisioner-based classes on all three clusters, you can also use a combination of provisioner-based and pool-based classes across the clusters. You might want to do this in cases where, for example, you want to allow for dynamic provisioning of service instances in

the `iterate` cluster, but want to be more considered about the approach in the `run-production` cluster where you might want to ensure that workloads only ever connect to one specific service instance. You can achieve this by using a provisioner-based class on the `iterate` cluster, and an identically named pool-based class on the `run-production` cluster that is configured to only ever select from a pool that consists of one service instance.

Procedure

The following steps explain how to set up a class that allows for claims to resolve to differing implementations of PostgreSQL depending on the cluster it is in.

Step 1: Set up the run-test cluster

Configure the `run-test` cluster for dynamic provisioning of VMware PostgreSQL service instances. To do that, see Configure dynamic provisioning of VMware SQL with Postgres for Kubernetes service instances and complete the steps in the following sections only:

1. Install the Tanzu VMware Postgres Operator
2. Set up the namespace
3. Create a CompositeResourceDefinition
4. Create a Composition
5. Configure RBAC

You do not have to do any other sections in that topic.

Step 2: Set up the run-production cluster

Configure the `run-production` cluster for dynamic provisioning of AWS RDS PostgreSQL service instances. To do that, see Configure Dynamic Provisioning of AWS RDS Service Instances and complete the steps in the following sections only:

1. Install the AWS Provider for Crossplane
2. Create a CompositeResourceDefinition
3. Create a Composition
4. Configure RBAC

You do not have to do any other sections in that topic.

Step 3: Create the class

The `ClusterInstanceClass` acts as the abstraction fronting the differing service implementations across the different clusters. You must create a class with the same name on all three of the clusters, but the configuration of the class varies slightly on each. The `ClassClaim` refers to classes by name. The fact that the class name remains consistent is what allows for the `ClassClaim`, which the application development teams create, to remain unchanged as they are promoted across the clusters.

Create a file named `postgres.class.iterate-cluster.yaml` and copy in the following contents.

```
# postgres.class.iterate-cluster.yaml

---
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ClusterInstanceClass
metadata:
  name: bigcorp-postgresql
```

```
spec:
  description:
    short: PostgreSQL by BigCorp
  provisioner:
    crossplane:
      compositeResourceDefinition: xpostgresqlinstances.bitnami.database.tanzu.vmware.
com
```

This class refers to the `xpostgresqlinstances.bitnami.database.tanzu.vmware.com` CompositeResourceDefinition. This is installed as part of the Bitnami Services package and powers the PostgreSQL service.

You are reusing the underlying CompositeResourceDefinition here from a different class using the class name you want.

Use kubectl to apply the file to the `iterate` cluster.

```
kubectl apply -f postgres.class.iterate-cluster.yaml
```

Create a file named `postgres.class.run-test-cluster.yaml` and copy in the following contents.

```
# postgres.class.run-test-cluster.yaml

---
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ClusterInstanceClass
metadata:
  name: bigcorp-postgresql
spec:
  description:
    short: PostgreSQL by BigCorp
  provisioner:
    crossplane:
      compositeResourceDefinition: xpostgresqlinstances.database.tanzu.example.org
```

This class is almost identical to the previous one, however this one refers instead to the `xpostgresqlinstances.database.tanzu.example.org` CompositeResourceDefinition.

Use kubectl to apply the file to the `run-test` cluster.

```
kubectl apply -f postgres.class.run-test-cluster.yaml
```

Create a file named `postgres.class.run-production-cluster.yaml` and copy in the following contents.

```
# postgres.class.run-production-cluster.yaml

---
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ClusterInstanceClass
metadata:
  name: bigcorp-postgresql
spec:
  description:
    short: PostgreSQL by BigCorp
  provisioner:
    crossplane:
      compositeResourceDefinition: xpostgresqlinstances.database.rds.example.org
```

Again, this class is almost identical to the previous two, but this time refers to the `xpostgresqlinstances.database.rds.example.org` CompositeResourceDefinition.

Use kubectl to apply the file to the `run-production` cluster.

```
kubectl apply -f postgres.class.run-production-cluster.yaml
```

Step 4: Create and promote the workload and class claim

After configuring the clusters and classes, switch roles from service operator to application operator and developer to create the workload and class claim YAML and promote it through the three clusters.

Create a file named `app-with-postgres.yaml` and copy in the following contents.

```
# app-with-postgres.yaml

---
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ClassClaim
metadata:
  name: postgres
  namespace: default
spec:
  classRef:
    name: bigcorp-postgresql

---
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: pet-clinic
  namespace: default
  labels:
    apps.tanzu.vmware.com/workload-type: web
    app.kubernetes.io/part-of: pet-clinic
spec:
  params:
  - name: annotations
    value:
      autoscaling.knative.dev/minScale: "1"
  env:
  - name: SPRING_PROFILES_ACTIVE
    value: postgres
  serviceClaims:
  - name: db
    ref:
      apiVersion: services.apps.tanzu.vmware.com/v1alpha1
      kind: ClassClaim
      name: postgres
  source:
    git:
      url: https://github.com/sample-accelerators/spring-petclinic
      ref:
        branch: main
        tag: tap-1.2
```

Then use kubectl to apply the file to the `iterate` cluster.

```
kubectl apply -f app-with-postgres.yaml
```

Wait for the workload to become ready and then inspect the cluster to see that the workload is bound to a Helm-based PostgreSQL service instance. Target the `iterate` cluster then run `helm list -A` to confirm.

Next, apply the exact same `app-with-postgres.yaml` to the `run-test` cluster. When it is ready, confirm that the workload is bound to a Tanzu-based PostgreSQL service instance. Target the `run-test` cluster then run `kubectl get postgres -n tanzu-psql-service-instances` to confirm.

Finally, apply the exact same `app-with-postgres.yaml` to the `run-production` cluster. When it is ready, confirm that the workload is bound to a RDS-based PostgreSQL service instance. Target the `run-production` cluster then run `kubectl get RDSInstance -A` to confirm.

Using direct secret references

In this Services Toolkit tutorial you learn how developers can use direct references to Kubernetes `Secret` resources to connect their application workloads to almost any backing service.

This includes backing services that:

- Run external to Tanzu Application Platform
- Do not adhere to ProvisionedService in the Service Binding Specification for Kubernetes in GitHub.

If you are familiar with Cloud Foundry and Tanzu Application Service, this capability is similar to the concept of user-provided service instances. For more information about user-provided service instances in Cloud Foundry, see the Cloud Foundry documentation.

This tutorial demonstrates a procedure to bind a new application on Tanzu Application Platform to an existing PostgreSQL database that exists in Azure. However, the steps are applicable to any backing service that you want to connect to.

About this tutorial

Target user role: Service Operator and Application Operator
Complexity: Easy
Estimated time: 10 minutes
Topics covered: Service Binding, Direct Secret References
Learning outcomes: Ability to bind workloads to almost any backing service using direct secret references

Prerequisites

Before you can follow this tutorial, you must have:

- Access to a Tanzu Application Platform cluster v1.5.0 or later.
- An Azure PostgreSQL database to connect to.
- Configured networking between the workload and the service endpoint and you must have the credentials for the backing service. Whether this requires extra steps depends on your Kubernetes distribution and the backing service you want to connect your Tanzu Application Platform workloads to.

Create a binding-compatible secret

1. Create a file named `external-azure-db-binding-compatible.yaml` and enter a Kubernetes secret resource similar to the following example:

```
# external-azure-db-binding-compatible.yaml
---
apiVersion: v1
kind: Secret
metadata:
  name: external-azure-db-binding-compatible
type: Opaque
stringData:
```

```
  type: postgresql
  provider: azure
  host: EXAMPLE.DATABASE.AZURE.COM
  port: "5432"
  database: "EXAMPLE-DB-NAME"
  username: "USER@EXAMPLE"
  password: "PASSWORD"
```

Substitute in the values as required.

When using direct secret references, the `Secret` values must abide by the Well-known Secret Entries specifications as defined by the Service Binding Specification for Kubernetes. If you plan to bind this secret to a Spring-based application workload and want to take advantage of the auto-wiring feature, this secret must also contain the properties required by Spring Cloud Bindings.

2. Apply the YAML file by running:

```
kubectl apply -f external-azure-db-binding-compatible.yaml
```

If you are using a multicluster Tanzu Application Platform topology, apply the YAML file to all Run clusters.

3. In a file named `stk-secret-reader.yaml`, grant sufficient Role-Based Access Control (RBAC) permissions to permit Services Toolkit to read the secrets specified by the class:

```
# stk-secret-reader.yaml
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: stk-secret-reader
  labels:
    servicebinding.io/controller: "true"
rules:
- apiGroups:
  - ""
  resources:
  - secrets
  verbs:
  - get
  - list
  - watch
```

4. Apply your changes by running:

```
kubectl apply -f stk-secret-reader.yaml
```

If you are using a multicluster Tanzu Application Platform topology, apply the YAML file to all Run clusters.

5. Create a claim for the newly created secret by running:

```
tanzu service resource-claim create external-azure-db-claim \
  --resource-name external-azure-db-binding-compatible \
  --resource-kind Secret \
  --resource-api-version v1
```

If you are using a multicluster Tanzu Application Platform topology, create the claim on the Build cluster.

6. Obtain the claim reference of the claim by running:

```
tanzu service resource-claim list -o wide
```

If you are using a multicluster Tanzu Application Platform topology, obtain the claim reference on the Build cluster.

Expected output:

```
NAME                     READY  REASON  CLAIM REF
external-azure-db-claim  True           services.apps.tanzu.vmware.com/v1alpha
1:ResourceClaim:external-azure-db-claim
```

From the output, record the value of `CLAIM REF`.

7. Create an application workload by running a command similar to the following example:

```
tanzu apps workload create WORKLOAD-NAME \
  --git-repo https://github.com/sample-accelerators/spring-petclinic \
  --git-branch main \
  --git-tag tap-1.2 \
  --type web \
  --label app.kubernetes.io/part-of=spring-petclinic \
  --annotation autoscaling.knative.dev/minScale=1 \
  --env SPRING_PROFILES_ACTIVE=postgres \
  --service-ref db=REFERENCE
```

Where:

- `WORKLOAD-NAME` is the name of the application workload. For example, `pet-clinic`.
- `REFERENCE` is the value of the `CLAIM REF` for the newly created claim in the output of the last step.

If you are using a multicluster Tanzu Application Platform topology, create the application workload on the Build cluster.

Services Toolkit how-to guides

This section contains how-to guides for Services Toolkit.

In this section:

- Authorize users and groups to claim from provisioner-based classes
- Configure dynamic provisioning of AWS RDS service instances
- Configure dynamic provisioning of VMware SQL with Postgres for Kubernetes service instances
- Configure private registry and VMware Tanzu Application Catalog integration for Bitnami Services
- Troubleshoot Services Toolkit

Authorize users and groups to claim from provisioner-based classes

This Services Toolkit topic for service operators explains how you configure access control so that the required users and groups have authorization to claim from provisioner-based classes.

By default, only users with `cluster-admin` privileges are authorized to create claims for provisioner-based classes. This is because creating claims for provisioner-based classes creates new service

instances, all of which consume resources and might incur monetary cost. As such, you might want to configure some form of access control.

There is one exception to this rule, which is that by default, users with the `app-operator` user role are authorized to create claims for the provisioner-based classes that are part of the Bitnami Services package. For how-to deactivate this default behavior, see Revoke default authorization for claiming from the Bitnami Services classes later in this topic.

Access control is implemented through standard Kubernetes Role-Based Access Control (RBAC) with the use of the custom verb `claim`. You must create a rule in a `ClusterRole` which specifies the `claim` verb for one or more `clusterinstanceclasses`, and then bind the `ClusterRole` to the roles that you want to authorize to create claims for classes with a `ClusterRoleBinding`. This approach is particularly effective when paired with Tanzu Application Platform's aggregated user roles. For more information about user roles in Tanzu Application Platform, see Role descriptions.

Authorize all users with the app-operator user role to claim from any namespace

Create a `ClusterRole` with a rule that specifies the `claim` verb for one or more `ClusterInstanceClass` resources and apply the relevant label.

For example:

```
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: app-operator-claim-class-bigcorp-rabbitmq
  labels:
    apps.tanzu.vmware.com/aggregate-to-app-operator-cluster-access: "true"
rules:
- apiGroups:
  - services.apps.tanzu.vmware.com
  resources:
  - clusterinstanceclasses
  resourceNames:
  - bigcorp-rabbitmq
  verbs:
  - claim
```

This example specifies a `ClusterRole` that permits claiming from a class named `bigcorp-rabbitmq`. The example also includes the `apps.tanzu.vmware.com/aggregate-to-app-operator-cluster-access: "true"` label, which causes this `ClusterRole` to aggregate to Tanzu Application Platform's app-operator user role at the cluster scope.

The result is that any user who has the `app-operator` role is now authorized to claim from the `bigcorp-rabbitmq` class. By default, the `app-operator` user role is authorized to create claims for the provisioner-based class.

Authorize a user to claim from a specific namespace

Create a `ClusterRole` with a rule that specifies the `claim` verb for one or more `ClusterInstanceClass` resource and a corresponding `RoleBinding` to bind it to a user.

For example:

```
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
```

```
  name: claim-class-bigcorp-rabbitmq
rules:
- apiGroups:
  - services.apps.tanzu.vmware.com
  resources:
  - clusterinstanceclasses
  resourceNames:
  - bigcorp-rabbitmq
  verbs:
  - claim

---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: alice-claim-class-bigcorp-rabbitmq
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: claim-class-bigcorp-rabbitmq
subjects:
- kind: User
  name: "alice@example.com"
  apiGroup: rbac.authorization.k8s.io
```

This example specifies a `ClusterRole` that permits claiming from a class named `bigcorp-rabbitmq`. The YAML also creates a `ClusterRoleBinding`that binds the user `alice@example.com` to the `ClusterRole`.

The result is that `alice@example.com` is now authorized to claim from `bigcorp-rabbitmq` class.

The user `alice@example.com` still needs permission to create `ClassClaims` in namespaces that they want to consume the services from.

The following example gives `alice@example.com` permission to get, create, update, or delete `ClassClaims` in the `apps` namespace:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: Role
metadata:
   name: create-class-claim-example
   namespace: apps
rules:
  - apiGroups:
    - services.apps.tanzu.vmware.com
    resources:
    - classclaims
    verbs:
    - get
    - create
    - update
    - delete
---
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: rbac-role-binding-role-binding
  namespace: apps
subjects:
  - kind: User
    name: "alice@example.com"
    apiGroup: rbac.authorization.k8s.io
roleRef:
  kind: Role
```

```
  name: create-class-claim-example
  apiGroup: rbac.authorization.k8s.io
```

Revoke default authorization for claiming from the Bitnami Services classes

By default, users with the `app-operator` user role are authorized to create claims for the provisioner-based classes which are part of the Bitnami Services package.

To revoke this authorization:

1. Add the following to your `tap-values.yaml` file:

   ```
   bitnami_services:
     globals:
       create_clusterroles: false
   ```

2. Update Tanzu Application Platform by running:

   ```
   tanzu package installed update tap -p tap.tanzu.vmware.com --values-file tap-va
   lues.yaml -n tap-install
   ```

The result is that any user who has the `app-operator` role is now not authorized to create claims for any of the Bitnami services in any namespace on the cluster.

Configure dynamic provisioning of AWS RDS service instances

This Services Toolkit topic for service operators explains how you set up dynamic provisioning. This enables app development teams to self-serve AWS RDS service instances that are customized.

If you are not already familiar with dynamic provisioning in Tanzu Application Platform, following the tutorial Set up dynamic provisioning of service instances might help you to understand the steps presented in this topic.

In Tanzu Application Platform v1.7 or later, consider using the AWS Services package, rather than using this topic. Both provide the same outcome, which is the availability of an AWS RDS service in the platform. However, the AWS Services package provides a more streamlined and user-friendly approach for integrating AWS RDS into Tanzu Application Platform.

Prerequisites

Before you configure dynamic provisioning, you must have:

- Access to a Tanzu Application Platform cluster v1.6.1 or later.
- The Tanzu services CLI plug-in v0.7.0 or later.
- Access to AWS.

Configure dynamic provisioning

To configure dynamic provisioning for AWS RDS service instances, you must:

1. Install the AWS Provider for Crossplane
2. Create a CompositeResourceDefinition
3. Create a Composition

4. Make the service discoverable
5. Configure RBAC
6. Verify your configuration

Install the AWS Provider for Crossplane

The first step is to install the AWS `Provider` for Crossplane.

The following variants of AWS `Provider` are available:

- crossplane-contrib/provider-aws
- upbound/provider-aws
- upbound/provider-family-aws

VMware recommends that you use the upbound/provider-family-aws. This variant is both fully supported by Upbound and also gives you more control when installing APIs. This helps to improve performance issues often associated with the more monolithic upbound/provider-aws. For more information about how Crossplane is resolving the Provider CRD scaling problem, see the Crossplane Blog.

You must install both the top-level family Provider and the `provider-aws-rds` Provider. To do so:

1. Create a file named `provider-family-aws.yaml` and copy in the following contents, which configures both Providers:

```
# provider-family-aws.yaml

---
# The AWS "family" Provider - manages the ProviderConfig for all other Provider
s in the same family.
# Does not have to be created explicitly, if not created explicitly it will be
installed by the first Provider created
# in the family.
apiVersion: pkg.crossplane.io/v1
kind: Provider
metadata:
  name: upbound-provider-family-aws
spec:
  package: xpkg.upbound.io/upbound/provider-family-aws:v0.36.0
  controllerConfigRef:
    name: upbound-provider-family-aws
---
# The AWS RDS Provider - just one of the many Providers in the AWS family.
# You can add as few or as many additional Providers in the same family as you
wish.
apiVersion: pkg.crossplane.io/v1
kind: Provider
metadata:
  name: upbound-provider-aws-rds
spec:
  package: xpkg.upbound.io/upbound/provider-aws-rds:v0.36.0
  controllerConfigRef:
    name: upbound-provider-family-aws
---
# The ControllerConfig applies settings to a Provider Pod.
# With family Providers each Provider is a unique Pod running in the cluster.
apiVersion: pkg.crossplane.io/v1alpha1
kind: ControllerConfig
metadata:
  name: upbound-provider-family-aws
```

2. Apply the file to the Tanzu Application Platform cluster by running:

```
kubectl apply -f provider-family-aws.yaml
```

3. Verify that both Providers are installed by running:

   ```
   kubectl get providers
   ```

   From the output, confirm that `INSTALLED=True` and `HEALTHY=TRUE`.

4. Create a `ProviderConfig` for the Providers. For instructions, see the sections *Create a Kubernetes secret for AWS* and *Create a ProviderConfig* in the Upbound documentation.

Important

The Upbound documentation assumes Crossplane is installed in the `upbound-system` namespace. However, when working with Crossplane on Tanzu Application Platform, it is installed to the `crossplane-system` namespace. Ensure that you use the correct namespace when you create the `Secret` with credentials for the `Provider`. **Note** Depending on the setup of your AWS account, you might also need to include `aws_session_token` in the `Secret`.

Create a CompositeResourceDefinition

To create the CompositeResourceDefinition (XRD):

1. Create a file named `xpostgresqlinstances.database.rds.example.org.xrd.yaml` and copy in the following contents:

```
# xpostgresqlinstances.database.rds.example.org.xrd.yaml

---
apiVersion: apiextensions.crossplane.io/v1
kind: CompositeResourceDefinition
metadata:
  name: xpostgresqlinstances.database.rds.example.org
spec:
  claimNames:
    kind: PostgreSQLInstance
    plural: postgresqlinstances
  connectionSecretKeys:
  - type
  - provider
  - host
  - port
  - database
  - username
  - password
  group: database.rds.example.org
  names:
    kind: XPostgreSQLInstance
    plural: xpostgresqlinstances
  versions:
  - name: v1alpha1
    referenceable: true
    schema:
      openAPIV3Schema:
        properties:
          spec:
            properties:
              storageGB:
                type: integer
```

```
                default: 20
            type: object
        type: object
    served: true
```

This XRD configures the parameter `storageGB`. This gives application teams the option to choose a suitable amount of storage for the AWS RDS service instance when they create a claim. You can choose to expose as many or as few parameters to application teams as you like.

2. Apply the file to the Tanzu Application Platform cluster by running:

```
kubectl apply -f xpostgresqlinstances.database.rds.example.org.xrd.yaml
```

Create a Composition

To create the composition:

1. Create a file named `xpostgresqlinstances.database.rds.example.org.composition.yaml` and copy in the following contents:

```
# xpostgresqlinstances.database.rds.example.org.composition.yaml

---
apiVersion: apiextensions.crossplane.io/v1
kind: Composition
metadata:
  labels:
    provider: "aws"
    vpc: "default"
  name: xpostgresqlinstances.database.rds.example.org
spec:
  compositeTypeRef:
    apiVersion: database.rds.example.org/v1alpha1
    kind: XPostgreSQLInstance
  publishConnectionDetailsWithStoreConfigRef:
    name: default
  resources:
  - base:
      apiVersion: rds.aws.upbound.io/v1beta1
      kind: Instance
      spec:
        forProvider:
          # NOTE: configure this section to your specific requirements
          instanceClass: db.t3.micro
          autoGeneratePassword: true
          passwordSecretRef:
            key: password
            namespace: crossplane-system
          engine: postgres
          engineVersion: "13.8"                    # <---- Refer to https://doc
s.aws.amazon.com/AmazonRDS/latest/PostgreSQLReleaseNotes/postgresql-release-cal
endar.html for latest
          name: postgres
          username: masteruser
          publiclyAccessible: true                 # <---- DANGER
          region: us-east-1
          skipFinalSnapshot: true
        writeConnectionSecretToRef:
          namespace: crossplane-system
    connectionDetails:
    - name: type
      value: postgresql
    - name: provider
```

```
      value: aws
    - name: database
      value: postgres
    - fromConnectionSecretKey: username
    - fromConnectionSecretKey: password
    - name: host
      fromConnectionSecretKey: endpoint
    - fromConnectionSecretKey: port
    name: instance
    patches:
    - fromFieldPath: metadata.uid
      toFieldPath: spec.forProvider.passwordSecretRef.name
      transforms:
      - string:
          fmt: '%s-postgresql-pw'
          type: Format
        type: string
      type: FromCompositeFieldPath
    - fromFieldPath: metadata.uid
      toFieldPath: spec.writeConnectionSecretToRef.name
      transforms:
      - string:
          fmt: '%s-postgresql'
          type: Format
        type: string
      type: FromCompositeFieldPath
    - fromFieldPath: spec.storageGB
      toFieldPath: spec.forProvider.allocatedStorage
      type: FromCompositeFieldPath
```

This Composition configures all RDS PostgreSQL instances as follows:

- All instances are placed in the `us-east-1` region.
- All instances use the default Virtual Private Cloud (VPC) for the respective AWS account.
- All instances are publicly accessible over the Internet.

2. If you want to keep the instances publicly accessible over the Internet and use the default VPC, add an inbound rule for TCP on port 5432 to the security group of the default VPC to allow connection to the instances.
3. If you do not want the instances to be publicly accessible over the Internet, edit the Composition as required. Specific requirements vary, but this might include composing a combination of VPCs, Subnets, SubnetGroups, Routes, SecurityGroups, and SecurityGroupRules. Refer to Compositions that are available online for inspiration and guidance.

   For example, see `getting-started-with-aws-with-vpc` in the Upbound documentation. This example defines a Composition that creates a separate VPC for each RDS PostgreSQL instance and automatically configures inbound rules. If you want to follow this example, you might need to install additional Providers from the AWS Provider Family, such as upbound/provider-aws-ec2.
4. Make any other configuration changes to the Composition so that it meets your specific requirements.
5. Apply the file to the Tanzu Application Platform cluster by running:

   ```
   kubectl apply -f xpostgresqlinstances.database.rds.example.org.composition.yaml
   ```

Make the service discoverable

To make the service discoverable to application teams:

1. Create a file named `rds.class.yaml` and copy in the following contents:

```
# rds.class.yaml

---
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ClusterInstanceClass
metadata:
  name: aws-rds-psql
spec:
  description:
    short: Amazon AWS RDS PostgreSQL
  provisioner:
    crossplane:
      compositeResourceDefinition: xpostgresqlinstances.database.rds.example.or
g
```

2. Apply the file to the Tanzu Application Platform cluster by running:

```
kubectl apply -f rds.class.yaml
```

Configure RBAC

To configure Role-Based Access Control (RBAC) to authorize users with the app-operator role to claim from the class:

1. Create a file named `app-operator-claim-aws-rds-psql.rbac.yaml` and copy in the following contents:

```
# app-operator-claim-aws-rds-psql.rbac.yaml

apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: app-operator-claim-aws-rds-psql
  labels:
    apps.tanzu.vmware.com/aggregate-to-app-operator-cluster-access: "true"
rules:
- apiGroups:
  - "services.apps.tanzu.vmware.com"
  resources:
  - clusterinstanceclasses
  resourceNames:
  - aws-rds-psql
  verbs:
  - claim
```

2. Apply the file to the Tanzu Application Platform cluster by running:

```
kubectl apply -f app-operator-claim-aws-rds-psql.rbac.yaml
```

Verify your configuration

To verify your configuration, create a claim for an AWS RDS service instance by running:

```
tanzu service class-claim create rds-psql-1 --class aws-rds-psql -p storageGB=30
```

Note

Whether application workloads can establish network connectivity to the resulting RDS database depends on a number of factors. This includes specifics about the environment you're working in and the configuration in the `Composition` file. At a minimum, you can configure a `securityGroup` to permit inbound traffic. There might be other requirements as well.

Configure dynamic provisioning of VMware SQL with Postgres for Kubernetes service instances

This Services Toolkit topic for service operators explains how you set up dynamic provisioning. This enables app development teams to create self-serve VMware SQL with Postgres for Kubernetes service instances that are customized to meet their needs.

If you are not already familiar with dynamic provisioning in Tanzu Application Platform, following the tutorial Set up dynamic provisioning of service instances. might be help you understand the steps presented in this topic.

Prerequisites

Before you configure dynamic provisioning, you must have:

- Access to a Tanzu Application Platform cluster v1.5.0 or later.
- The Tanzu services CLI plug-in v0.6.0 or later.

Configure dynamic provisioning

To configure dynamic provisioning for VMware SQL with Postgres for Kubernetes services instances, you must:

1. Install the VMware Postgres Operator
2. Set up the namespace
3. Create a CompositeResourceDefinition
4. Create a Composition
5. Make the service discoverable
6. Configure RBAC
7. Verify your configuration

Install the VMware Postgres Operator

Install the VMware Postgres Operator by following the steps in Installing a VMware Postgres Operator.

Set up the namespace

This topic configures dynamic provisioning to provision all PostgreSQL service instances into the same namespace. This namespace is named `tanzu-psql-service-instances`.

To set up the namespace:

1. Ensure that the namespace exists by running the following:

```
kubectl create namespace tanzu-psql-service-instances
```

2. The VMware Postgres Operator also requires that a secret holding registry credentials exists in the same namespace that the service instances will be created in. Ensure that the secret exists in the namespace by running:

```
kubectl create secret --namespace=tanzu-psql-service-instances docker-registry
regsecret \
  --docker-server=https://registry.tanzu.vmware.com \
  --docker-username=`USERNAME` \
  --docker-password=`PASSWORD`
```

   Where:

   - `USERNAME` is your registry username.
   - `PASSWORD` is your registry password.

Note

You must update the `--docker-server` value if you relocated images as part of the installation of the operator.

Create a CompositeResourceDefinition

To create the CompositeResourceDefinition (XRD):

1. Create a file named `xpostgresqlinstances.database.tanzu.example.org.xrd.yaml` and copy in the following contents:

```
# xpostgresqlinstances.database.tanzu.example.org.xrd.yaml

---
apiVersion: apiextensions.crossplane.io/v1
kind: CompositeResourceDefinition
metadata:
  name: xpostgresqlinstances.database.tanzu.example.org
spec:
  connectionSecretKeys:
  - provider
  - type
  - database
  - host
  - password
  - port
  - uri
  - username
  group: database.tanzu.example.org
  names:
    kind: XPostgreSQLInstance
    plural: xpostgresqlinstances
  versions:
  - name: v1alpha1
    referenceable: true
    schema:
      openAPIV3Schema:
        properties:
          spec:
            properties:
              storageGB:
                type: integer
                default: 20
            type: object
```

```
        type: object
    served: true
```

This XRD configures the parameter `storageGB`. This gives application teams the option to choose a suitable amount of storage for the Tanzu Postgres service instance when they create a claim. You can choose to expose as many or as few parameters to application teams as you like.

2. Apply the file to the Tanzu Application Platform cluster by running:

```
kubectl apply -f xpostgresqlinstances.database.tanzu.example.org.xrd.yaml
```

Create a Composition

To create the Composition:

1. Create a file named `xpostgresqlinstances.database.tanzu.example.org.composition.yaml` and copy in the following contents:

```
# xpostgresqlinstances.database.tanzu.example.org.composition.yaml

---
apiVersion: apiextensions.crossplane.io/v1
kind: Composition
metadata:
  name: xpostgresqlinstances.database.tanzu.example.org
spec:
  compositeTypeRef:
    apiVersion: database.tanzu.example.org/v1alpha1
    kind: XPostgreSQLInstance
  publishConnectionDetailsWithStoreConfigRef:
    name: default
  resources:
  - base:
      apiVersion: kubernetes.crossplane.io/v1alpha2
      kind: Object
      spec:
        forProvider:
          manifest:
            apiVersion: sql.tanzu.vmware.com/v1
            kind: Postgres
            metadata:
              name: PATCHED
              namespace: tanzu-psql-service-instances
            spec:
              storageSize: 2G
        connectionDetails:
        - apiVersion: v1
          kind: Secret
          namespace: tanzu-psql-service-instances
          fieldPath: data.provider
          toConnectionSecretKey: provider
        - apiVersion: v1
          kind: Secret
          namespace: tanzu-psql-service-instances
          fieldPath: data.type
          toConnectionSecretKey: type
        - apiVersion: v1
          kind: Secret
          namespace: tanzu-psql-service-instances
          fieldPath: data.host
          toConnectionSecretKey: host
        - apiVersion: v1
          kind: Secret
```

```
        namespace: tanzu-psql-service-instances
        fieldPath: data.port
        toConnectionSecretKey: port
      - apiVersion: v1
        kind: Secret
        namespace: tanzu-psql-service-instances
        fieldPath: data.username
        toConnectionSecretKey: username
      - apiVersion: v1
        kind: Secret
        namespace: tanzu-psql-service-instances
        fieldPath: data.password
        toConnectionSecretKey: password
      - apiVersion: v1
        kind: Secret
        namespace: tanzu-psql-service-instances
        fieldPath: data.database
        toConnectionSecretKey: database
      - apiVersion: v1
        kind: Secret
        namespace: tanzu-psql-service-instances
        fieldPath: data.uri
        toConnectionSecretKey: uri
      writeConnectionSecretToRef:
        namespace: tanzu-psql-service-instances
  connectionDetails:
  - fromConnectionSecretKey: provider
  - fromConnectionSecretKey: type
  - fromConnectionSecretKey: host
  - fromConnectionSecretKey: port
  - fromConnectionSecretKey: username
  - fromConnectionSecretKey: password
  - fromConnectionSecretKey: database
  - fromConnectionSecretKey: uri
  patches:
    - fromFieldPath: metadata.name
      toFieldPath: spec.forProvider.manifest.metadata.name
      type: FromCompositeFieldPath
    - fromFieldPath: spec.storageSize
      toFieldPath: spec.forProvider.manifest.spec.persistence.storage
      transforms:
      - string:
          fmt: '%dG'
          type: Format
        type: string
      type: FromCompositeFieldPath
    - fromFieldPath: metadata.name
      toFieldPath: spec.writeConnectionSecretToRef.name
      transforms:
      - string:
          fmt: '%s-psql'
          type: Format
        type: string
      type: FromCompositeFieldPath
    - fromFieldPath: metadata.name
      toFieldPath: spec.connectionDetails[0].name
      transforms:
      - string:
          fmt: '%s-app-user-db-secret'
          type: Format
        type: string
      type: FromCompositeFieldPath
    - fromFieldPath: metadata.name
      toFieldPath: spec.connectionDetails[1].name
      transforms:
      - string:
```

```
            fmt: '%s-app-user-db-secret'
            type: Format
          type: string
        type: FromCompositeFieldPath
      - fromFieldPath: metadata.name
        toFieldPath: spec.connectionDetails[2].name
        transforms:
        - string:
            fmt: '%s-app-user-db-secret'
            type: Format
          type: string
        type: FromCompositeFieldPath
      - fromFieldPath: metadata.name
        toFieldPath: spec.connectionDetails[3].name
        transforms:
        - string:
            fmt: '%s-app-user-db-secret'
            type: Format
          type: string
        type: FromCompositeFieldPath
      - fromFieldPath: metadata.name
        toFieldPath: spec.connectionDetails[4].name
        transforms:
        - string:
            fmt: '%s-app-user-db-secret'
            type: Format
          type: string
        type: FromCompositeFieldPath
      - fromFieldPath: metadata.name
        toFieldPath: spec.connectionDetails[5].name
        transforms:
        - string:
            fmt: '%s-app-user-db-secret'
            type: Format
          type: string
        type: FromCompositeFieldPath
      - fromFieldPath: metadata.name
        toFieldPath: spec.connectionDetails[6].name
        transforms:
        - string:
            fmt: '%s-app-user-db-secret'
            type: Format
          type: string
        type: FromCompositeFieldPath
      - fromFieldPath: metadata.name
        toFieldPath: spec.connectionDetails[7].name
        transforms:
        - string:
            fmt: '%s-app-user-db-secret'
            type: Format
          type: string
        type: FromCompositeFieldPath
    readinessChecks:
      - type: MatchString
        fieldPath: status.atProvider.manifest.status.currentState
        matchString: "Running"
```

2. Configure the Composition you just copied to your specific requirements.
3. Apply the file to the Tanzu Application Platform cluster by running:

```
kubectl apply -f xpostgresqlinstances.database.tanzu.example.org.composition.ya
ml
```

Make the service discoverable

To make the service discoverable to application teams:

1. Create a file named `tanzu-psql.class.yaml` and copy in the following contents:

```
# tanzu-psql.class.yaml

---
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ClusterInstanceClass
metadata:
  name: tanzu-psql
spec:
  description:
    short: VMware SQL with Postgres
  provisioner:
    crossplane:
      compositeResourceDefinition: xpostgresqlinstances.database.tanzu.example.
org
```

2. Apply the file to the Tanzu Application Platform cluster by running:

```
kubectl apply -f tanzu-psql.class.yaml
```

Configure RBAC

To configure access control with RBAC:

1. Create a file named `provider-kubernetes-tanzu-postgres-read-writer.rbac.yaml` and copy in the following contents:

```
# provider-kubernetes-tanzu-postgres-read-writer.rbac.yaml

---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: tanzu-postgres-read-writer
  labels:
    services.tanzu.vmware.com/aggregate-to-provider-kubernetes: "true"
rules:
- apiGroups:
  - sql.tanzu.vmware.com
  resources:
  - postgres
  verbs:
  - "*"
```

2. Apply the file to the Tanzu Application Platform cluster by running:

```
kubectl apply -f provider-kubernetes-tanzu-postgres-read-writer.rbac.yaml
```

3. Create a file named `app-operator-claim-tanzu-psql.rbac.yaml` and copy in the following contents:

```
# app-operator-claim-tanzu-psql.rbac.yaml

apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: app-operator-claim-tanzu-psql
  labels:
    apps.tanzu.vmware.com/aggregate-to-app-operator-cluster-access: "true"
rules:
```

```
- apiGroups:
  - "services.apps.tanzu.vmware.com"
  resources:
  - clusterinstanceclasses
  resourceNames:
  - tanzu-psql
  verbs:
  - claim
```

4. Apply the file to the Tanzu Application Platform cluster by running:

```
kubectl apply -f app-operator-claim-tanzu-psql.rbac.yaml
```

Verify your configuration

To verify your configuration, create a claim for a PostgreSQL service instance by running:

```
tanzu service class-claim create tanzu-psql-1 --class tanzu-psql -p storageGB=5
```

Troubleshoot Services Toolkit

This topic explains how you can troubleshoot issues related to working with services on Tanzu Application Platform (commonly known as TAP).

For the limitations of services on Tanzu Application Platform, see Services Toolkit limitations.

Debug `ClassClaim` and provisioner-based `ClusterInstanceClass`

This section provides guidance on how to debug issues related to using `ClassClaim` and provisioner-based `ClusterInstanceClass`. The approach starts by inspecting a `ClassClaim` and tracing back through the chain of resources that are created when fulfilling the `ClassClaim`.

Prerequisites

To follow the steps in this section, you must have kubectl access to the cluster.

Step 1: Inspect the `ClassClaim`, `ClusterInstanceClass`, and `CompositeResourceDefinition`

1. Inspect the status of `ClassClaim` by running:

   ```
   kubectl describe classclaim claim-name -n NAMESPACE
   ```

   Where `NAMESPACE` is your namespace.

   From the output, check the following:

   - Check the status conditions for information that can lead you to the cause of the issue.
   - Check `.spec.classRef.name` and record the value.

2. Inspect the status of the `ClusterInstanceClass` by running:

   ```
   kubectl describe clusterinstanceclass CLASS-NAME
   ```

   Where `CLASS-NAME` is the value of `.spec.classRef.name` you retrieved in the previous step.

From the output, check the following:

- Check the status conditions for information that can lead you to the cause of the issue.
- Check that the `Ready` condition has status `"True"`.
- Check `.spec.provisioner.crossplane` and record the value.

3. Inspect the status of the `CompositeResourceDefinition` by running:

```
kubectl describe xrd XRD-NAME
```

Where `XRD-NAME` is the value of `.spec.provisioner.crossplane` you retrieved in the previous step.

From the output, check the following:

- Check the status conditions for information that can lead you to the cause of the issue.
- Check that the `Established` condition has status `"True"`.
- Check events for any errors or warnings that can lead you to the cause of the issue.
- If both the `ClusterInstanceClass` reports `Ready="True"` and the `CompositeResourceDefinition` reports `Established="True"`, move on to the next section.

Step 2: Inspect the Composite Resource, the Managed Resources and the underlying resources

1. Check `.status.provisionedResourceRef` by running:

```
kubectl describe classclaim claim-name -n NAMESPACE
```

Where `NAMESPACE` is your namespace.

From the output, check the following:

- Check `.status.provisionedResourceRef`, and record the values of `kind`, `apiVersion`, and `name`.

2. Inspect the status of the Composite Resource by running:

```
kubectl describe KIND.API-GROUP NAME
```

Where:

- `KIND` is the value of `kind` you retrieved in the previous step.
- `API-GROUP` is the value of `apiVersion` you retrieved in the previous step without the `/<version>` part.
- `NAME` is the value of `name` you retrieved in the previous step.

From the output, check the following:

- Check the status conditions for information that can lead you to the cause of the issue.
- Check if there was an issue creating the Managed Resources from which this Composite Resource is composed. Refer to `.spec.resourceRefs` in the output and for each:

        - Use the values of `kind`, `apiVersion`, and `name` to inspect the status of the Managed Resource.
        - Check the status conditions for information that can lead you to the cause of the issue.
    - Check events for any errors or warnings that can lead you to the cause of the issue.
    - If all Managed Resources appear healthy, move on to the next section.

Step 3: Inspect the events log

Inspect the events log by running:

```
kubectl get events -A
```

From the output, check the following:

- Check for any errors or warnings that can lead you to the cause of the issue.
- If there are no errors or warnings, move on to the next section.

Step 4: Inspect the secret

1. Check `.status.resourceRef` by running:

   ```
   kubectl get classclaim claim-name -n NAMESPACE -o yaml
   ```

   Where `NAMESPACE` is your namespace.

   From the output, check the following:

   - Check `.status.resourceRef` and record the values `kind`, `apiVersion`, `name`, and `namespace`

2. Inspect the claimed resource, which is likely a secret, by running:

   ```
   kubectl get secret NAME -n NAMESPACE -o yaml
   ```

   Where:

   - `NAME` is the `name` you retrieved in the previous step.
   - `NAMESPACE` is the `namespace` you retrieved in the previous step.

   If the secret is there and has data, then something else must be causing the issue.

Step 5: Contact support

If you have followed the steps in this section and are still unable to discover the cause of the issue, contact VMware Support for further guidance and help to resolve the issue.

Unexpected error if `additionalProperties` is `true` in a CompositeResourceDefinition

Symptom:

When creating a `CompositeResourceDefinition`, if you set `additionalProperties: true` in the `openAPIV3Schema` section, an error occurs during the validation step of the creation of any `ClassClaim` that refers to a class that refers to the `CompositeResourceDefinitions`.

The error appears as follows:

```
json: cannot unmarshal bool into Go struct field JSONSchemaProps.AdditionalProperties
of type apiextensions.JSONSchemaPropsOrBool
```

Solution:

Rather than setting `additionalProperties: true`, you can set `additionalProperties: {}`. This has the same effect, but does not cause unexpected errors.

Cannot claim from clusterinstanceclass when creating a `ClassClaim`

Symptom:

Users who were previously able to create a `ClassClaim` now get an admission error similar to:

```
user 'alice@example.com' cannot 'claim' from clusterinstanceclass 'bigcorp-rabbitmq'
```

This occurs even if users were granted the `claim` permission on `ClusterInstanceClasses` through either:

- A `Role` and a `RoleBinding`
- A `ClusterRole` and a `RoleBinding`

Explanation:

You now need the cluster-level `claim` permission, granted through a `ClusterRole` and `ClusterRoleBinding`. Namespace-scoped permissions are no longer enough. This is to protect against unexpected access to resources in other namespaces.

This change was introduced with Services Toolkit v0.12.0 in Tanzu Application Platform v1.7.0. For more information about this change, see The claim verb for ClusterInstanceClass.

Solution:

To allow users to create `ClassClaims` again, you must:

1. Move from a `Role` to a `ClusterRole` for granting users permission to claim a `ClusterInstanceClass`.
2. Move from a `RoleBinding` to a `ClusterRoleBinding` for binding this permission to a user.

For more information, see Authorize users and groups to claim from provisioner-based classes.

Services Toolkit reference

This section provides reference documentation for Services Toolkit.

In this section:

- API documentation
- Tanzu Service CLI plug-in reference
- Services Toolkit terminology and user roles
- Services Toolkit limitations

Services Toolkit API documentation

This section of the documentation provides detailed information about Services Toolkit's APIs.

- ClusterInstanceClass and ClassClaim

- ResourceClaim and ResourceClaimPolicy
- InstanceQuery
- RBAC

ClusterInstanceClass and ClassClaim

This topic provides Services Toolkit API documentation for `ClusterInstanceClass` and `ClassClaim`.

ClusterInstanceClass

You can configure `ClusterInstanceClass` to one of two variants - either pool-based or provisioner-based.

- Claims for pool-based classes are fulfilled by identifying service instances using the configuration in `.spec.pool`.
- Claims for provisioner-based classes are fulfilled by provisioning new service instances using the configuration in `.spec.provisioner`.

A class can either be a pool-based class or a provisioner-based class, but never both.

The following snippet outlines the `ClusterInstanceClass` YAML:

```
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ClusterInstanceClass

metadata:
  # A name for the class. The class name is used by consumers (application operators
  # and developers) when creating claims.
  name: mysql-unmanaged

spec:
  # Provide information about the class in the description.
  description:
    # A short description for the class. Aim to provide just enough information
    # to help consumers (application operators and developers) to understand
    # what's on offer by the class.
    short: MySQL by Bitnami

  # (Optional) Configure a provisioner-based class.
  # Must specify one of either `provisioner` or `pool`.
  provisioner:
    # Configure provisioning using Crossplane (https://www.crossplane.io/).
    crossplane:
      # CompositeResourceDefinition refers to the name of a Composite Resource Definit
ion (XRD).
      # For example, "xpostgresqlinstances.database.example.org".
      compositeResourceDefinition: xmysqlinstances.bitnami.database.tanzu.vmware.com

      # (Optional) The compositionSelector allows you to match a Composition by
      # labels rather than naming one explicitly. It is used to set the compositionRef
      # if none is specified explicitly.
      compositionSelector:
        matchLabels:
          provider: bitnami
          type: mysql

      # (Optional) CompositionRef specifies which Composition this XR will use to
      # compose resources when it is created, updated, or deleted.
      # This can be omitted and is set automatically if the XRD has a default or
      # enforced composition reference, or if the below composition selector is set.
      compositionRef:
```

```
        name: composition-name

      # (Optional) CompositionUpdatePolicy specifies how existing XRs should be
      # updated to new revisions of their underlying composition.
      # One of either 'Automatic' or 'Manual'; default=Automatic.
      compositionUpdatePolicy: Manual

  # (Optional) Configure a pool-based class.
  # Must specify one of either `provisioner` or `pool`.
  pool:
    # (Optional) Group specifies the API group for the resources belonging to this cla
ss.
    group:

    # Kind specifies the API Kind for the resources belonging to this class.
    kind:

    # (Optional) FieldSelector specifies a set of fields that MUST match certain condi
tions.
    # See https://kubernetes.io/docs/concepts/overview/working-with-objects/field-sele
ctors/.
    fieldSelector:

    # (Optional) LabelSelector specifies a set of labels that MUST match.
    # See https://kubernetes.io/docs/concepts/overview/working-with-objects/labels/#la
bel-selectors.
    labelSelector:

# status is populated by the controller
status:
  # Conditions for the class.
  conditions:
    # The condition type. Currently only 'Ready'.
    - type: Ready
      # status can be either 'True' or 'False'.
      status: "True"
      # reason provides a reason for status: "False" for additional context.
      # One of 'PooledResourceNotFound', 'CompositeResourceDefinitionNotFound',
      # 'CompositeResourceDefinitionNotValid', or 'CompositeResourceDefinitionNotRead
y'.
      # Not set if status: "True".
      reason:

  # (Optional) claimParameters contains the OpenAPIV3Schema used to configure
  # claims for this class.
  # Not set on pool-based classes.
  claimParameters:
    openAPIV3Schema:
      description: The OpenAPIV3Schema of this Composite Resource Definition.
      properties:
        storageGB:
          default: 1
          description: The desired storage capacity of the database, in Gigabytes.
          type: integer
      type: object

  # instanceType holds information about the resource selected by this class.
  # If using the Crossplane provisioner, this refers to the CompositeResource (XR)
  # defined by the CompositeResourceDefinition (XRD) referred to in the class.
  instanceType:
    # (Optional) Group specifies the API group.
    group: bitnami.database.tanzu.vmware.com
    # Kind specifies the API Kind.
    kind: XMySQLInstance
    # Version specifies the API version.
    version: v1alpha1
```

```
  # Populated based on metadata.generation when controller observes a change to
  # the resource. If this value is out of date, other status fields do not
  # reflect latest state.
  observedGeneration: 1
```

ClassClaim

`ClassClaim` refers to a `ClusterInstanceClass` from which service instances are then either selected (for pool-based classes) or provisioned (for provisioner-based classes) to fulfill the claim. `ClassClaim` adheres to Provisioned Service as defined by the Service Binding Specification for Kubernetes.You can bind a `ClassClaim` to an application workload by using a reference in the workload's `.spec.serviceClaims` configuration.

The following snippet outlines the `ClassClaims` YAML:

```
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ClassClaim

metadata:
  # The name for the claim.
  name: mysql-claim-1
  # The namespace in which to create the claim.
  namespace: my-apps

spec:
  # classRef holds a reference to a ClusterInstanceClass.
  classRef:
    # The name of the class from which to claim a service instance.
    # For information about the permissions users must have to claim from the class,
    # see the note below this snippet.
    name: mysql-unmanaged

  # (Optional) parameters are key-value pairs that are configuration inputs to the
  # instance obtained from the referenced ClusterInstanceClass. These parameters
  # only take effect when referring to a provisioner-based class.
  parameters:
    key: value

status:
  # Conditions for the claim.
  conditions:
    # The condition type. Can be one of 'Ready', 'ClassMatched', 'Validated', or
    # 'ResourceClaimCreated'. All condition types are initialized for all claims.
    # The Ready condition reports status: "True" once all other condition types are he
althy.
    - type: Ready
      # status can be either 'True' or 'False'.
      status: "True"
      # reason provides a reason for status: "False" for additional context.
      # One of 'UnableToFetchClass', 'ClassDoesNotExist', 'ClassNotReady',
      # 'UnableToQueryClaimableInstances', 'NoClaimableInstances',
      # 'UnableToCreateResourceClaim', 'UnableToCreateClaimableInstance', 'ResourceRea
dy',
      # 'ResourceNotReady', 'ResourceReadyUnsupported', or 'ReasonParametersInvalid'.
      # Not set if status: "True".
      reason:

  # binding holds a reference to a secret, in the same namespace, which contains
  # credentials for accessing the claimed service instance.
  binding:
    # The name of the `Secret`. The presence of the .status.binding.name field
    # marks this resource as a Provisioned Service.
    name: 770845b6-02f0-4c1b-8d0c-3dae81bad35c
```

```
  # provisionedResourceRef contains a reference to the provisioned resource.
  # Only set if the claim refers to a provisioner-based class.
  provisionedResourceRef:
    # The API Group/Version of the provisioned resource in the GROUP/VERSION format.
    apiVersion: bitnami.database.tanzu.vmware.com/v1alpha1
    # The API kind of the provisioned resource.
    kind: XMysqlInstance
    # The name of the provisioned resource.
    name: mysql-1-57dr7

  # resourceRef contains a reference to the claimed resource.
  resourceRef:
    # The API Group/Version of the claimed resource in the GROUP/VERSION format.
    apiVersion: v1
    # The API kind of the claimed resource.
    kind: Secret
    # The name of the claimed resource.
    name: 770845b6-02f0-4c1b-8d0c-3dae81bad35c
    # The namespace of the claimed resource.
    namespace: my-apps

  # Populated based on metadata.generation when controller observes a change to
  # the resource. If this value is out of date, other status fields do not reflect
  # latest state.
  observedGeneration: 1
```

Note

If you refer to a provisioner-based class in `spec.classref.name`, you must have sufficient RBAC permission to claim from the class. For more information, see Authorize users and groups to claim from provisioner-based classes.

ResourceClaim and ResourceClaimPolicy

This topic provides Services Toolkit API documentation for `ResourceClaim` and `ResourceClaimPolicy`.

ResourceClaim

`ResourceClaim` is used to claim a specific Kubernetes resource by using a reference. `ResourceClaim` adheres to Provisioned Service as defined by the Service Binding Specification for Kubernetes. you can bind a `ResourceClaim` to an application workload by using a reference in the workload's `.spec.serviceClaims` configuration.

A `ResourceClaim` is exclusive by nature. This means that after a `ResourceClaim` has claimed a resource, no other `ResourceClaim` can claim that same resource.

```
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ResourceClaim

metadata:
  # The name for the claim.
  name: claim-1
  # The namespace in which to create the claim.
  namespace: my-apps
  # Internal finalizers applied by the resource claim controller to ensure
  # resources are cleaned up.
  finalizers:
  - resourceclaims.services.apps.tanzu.vmware.com/finalizer
```

```
  - resourceclaims.services.apps.tanzu.vmware.com/lease-finalizer

spec:
  # ref is a reference to the resource to be claimed.
  ref:
    # The API Group/Version of the resource to claim in the GROUP/VERSION format.
    apiVersion: v1
    # The API Kind of the resource to claim.
    kind: Secret
    # The name of the resource to claim.
    name: 770845b6-02f0-4c1b-8d0c-3dae81bad35c
    # (Optional) The namespace of the resource to claim. If the resource exists
    # in a different namespace to the namespace of the claim, then you must configure
    # a corresponding ResourceClaimPolicy to permit claiming of the resource.
    namespace: service-instances

status:
  # Conditions for the claim.
  conditions:
    # The condition type. Can be one of 'Ready', 'ResourceMatched' or 'ResourceMatche
d'.
    # All condition types are initialized for all claims.
    # The Ready condition reports status: "True" once all other condition types are he
althy.
    - type: Ready
      # status can be either 'True' or 'False'.
      status: "True"
      # reason provides a reason for status: "False" for additional context.
      # One of 'ResourceNotFound', 'BindingNotCopyable', 'UnableToSetExclusiveClaim',
      # 'ResourceNonBindable', 'NoMatchingResourceClaimPolicy',
      # 'UnableToTrackReferencedResource', 'ResourceAlreadyClaimed',
      # 'UpdatedResourceReference', or 'ClaimMarkedForDeletion'.
      # Not set if status: "True".
      reason:

  # binding holds a reference to a secret in the same namespace which contains
  # credentials for accessing the claimed service instance.
  binding:
    # The name of the secret. The presence of the .status.binding.name field marks
    # this resource as a Provisioned Service.
    name: 770845b6-02f0-4c1b-8d0c-3dae81bad35c

  # claimedResourceRef holds a reference to the claimed resource.
  claimedResourceRef:
    # The API Group/Version of the claimed resource in the GROUP/VERSION format.
    apiVersion: v1
    # The API kind of the claimed resource.
    kind: Secret
    # The name of the claimed resource.
    name: 770845b6-02f0-4c1b-8d0c-3dae81bad35c
    # The namespace of the claimed resource.
    namespace: service-instances

  # Populated based on metadata.generation when controller observes a change to
  # the resource. If this value is out of date, other status fields do not
  # reflect latest state.
  observedGeneration: 1
```

ResourceClaimPolicy

`ResourceClaimPolicy` provides a mechanism to either permit or deny the claiming of resources across namespaces.

```
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ResourceClaimPolicy

metadata:
  # The name for the policy.
  name: default-ns-can-claim-secret-1
  # The namespace for the policy.
  # ResourceClaimPolicy resources must exist in the same namespace as the resources
  # they are permitting to be claimed.
  namespace: x-namespace-1

spec:
  # consumingNamespaces specifies the source namespace(s) to permit the claiming
  # of the resources from.
  # Use '*' to configure all namespaces.
  consumingNamespaces:
  - default

  # The API group of the resource to permit the claiming of.
  group: rabbitmq.com
  # The API kind of the resource to permit the claiming of.
  kind: RabbitmqCluster
  # (Optional) selector is a labelSelector to match resources to permit the claiming o
f.
  selector:
    matchLabels:
      "key": "value"
```

InstanceQuery

This topic provides Services Toolkit API documentation for `InstanceQuery`.

InstanceQuery

`InstanceQuery` is a create-only API that, given a pool-based `ClusterInstanceClass`, returns the intersection of the set of service instances represented by that class and the claimable service instances for the namespace of the `InstanceQuery`.

```
apiVersion: claimable.services.apps.tanzu.vmware.com/v1alpha1
kind: InstanceQuery

metadata:
  # An arbitrary name for the query.
  name: test
  # The namespace from which to run the query. The resulting list of instances is
  # specific to the namespace of the query itself.
  namespace: my-apps

spec:
  # The name of the class to query for claimable instances. Must refer to a
  # pool-based class and not a provisioner-based class.
  class: pooled-class-1
  # (Optional) A limit on the maximum number of instances to return.
  # The default is 50.
  limit: 1

status:
  # A list of service instances that you can claim by using ResourceClaims created
  # in the same namespace as the query.
  instances:
    # The API group/version of the claimable instance in the format GROUP/VERSION.
  - apiVersion: v1
```

```
    # The API kind of the claimable instance.
    kind: Secret
    # The name of the claimable instance.
    name: my-secret-two
    # The namespace of the claimable instance.
    namespace: default
```

RBAC

This topic provides API documentation for Role-Based Access Control (RBAC) relating to Services Toolkit's APIs.

Aggregation labels

This section describes the following Aggregation labels:

- servicebinding.io/controller: "true"
- services.tanzu.vmware.com/aggregate-to-provider-kubernetes: "true"
- services.tanzu.vmware.com/aggregate-to-provider-helm: "true"

servicebinding.io/controller: "true"

Use this label to grant the Services Toolkit and service bindings controllers permission to get, list, and watch resources to be claimed and bound in the cluster.

For example, the following `ClusterRole` grants the controllers permission to get, list, and watch `RabbitmqCluster` resources. You cannot create `ClassClaims` or `ResourceClaims` unless the controllers have at least these permissions for each resource type being claimed.

```
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: resource-claims-rmq-role
  labels:
    servicebinding.io/controller: "true"
rules:
- apiGroups:
  - rabbitmq.com
  resources:
  - rabbitmqclusters
  verbs:
  - get
  - list
  - watch
```

services.tanzu.vmware.com/aggregate-to-provider-kubernetes: "true"

Use this label to aggregate RBAC rules to `provider-kubernetes`, which is a Crossplane `Provider` installed by default as part of the Crossplane package in Tanzu Application Platform. You must grant relevant RBAC permissions for each API Group/Kind used during the creation of `Compositions` as part of setting up dynamic provisioning.

For example, the following `ClusterRole` grants `provider-kubernetes` full control over `rabbitmqclusters` on the `rabbitmq.com` API Group. This allows you to compose `rabbitmqclusters` in `Compositions`. For a full example, see Setup Dynamic Provisioning of Service Instances.

```
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: rmqcluster-read-writer
  labels:
    services.tanzu.vmware.com/aggregate-to-provider-kubernetes: "true"
rules:
- apiGroups:
  - rabbitmq.com
  resources:
  - rabbitmqclusters
  verbs:
  - "*"
```

services.tanzu.vmware.com/aggregate-to-provider-helm: “true”

Use this label to aggregate RBAC rules to `provider-helm`, which is a Crossplane `Provider` installed by default as part of the Crossplane package in Tanzu Application Platform. You must grant relevant RBAC permissions for each API Group/Kind used during the creation of Helm releases when using the `Release` managed resource as part of `Compositions`.

For example, the following `ClusterRole` grants `provider-helm` full control over `rabbitmqclusters` on the `rabbitmq.com` API Group. This allows you to compose Helm `Releases` which themselves eventually deploy `rabbitmqclusters` in your `Compositions`.

```
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: rmqcluster-read-writer
  labels:
    services.tanzu.vmware.com/aggregate-to-provider-helm: "true"
rules:
- apiGroups:
  - rabbitmq.com
  resources:
  - rabbitmqclusters
  verbs:
  - "*"
```

The claim verb for ClusterInstanceClass

Services Toolkit supports using the `claim` verb for RBAC rules that apply to a `ClusterInstanceClass`. You can use this with relevant aggregating labels or `ClusterRoleBindings` as a form of access control to specify who can claim from which `ClusterInstanceClass`.

For example:

```
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: app-operator-claim-class-bigcorp-rabbitmq
  labels:
    # (Optional) Aggregates this ClusterRole to Tanzu Application Platform's
    # app-operator user role at the cluster scope. You can choose to aggregate
    # this to any of the other standard user roles as well.
    apps.tanzu.vmware.com/aggregate-to-app-operator-cluster-access: "true"
rules:
# Permits claiming from the 'bigcorp-rabbitmq' class
```

```
- apiGroups:
  - services.apps.tanzu.vmware.com
  resources:
  - clusterinstanceclasses
  resourceNames:
  - bigcorp-rabbitmq
  verbs:
  - claim
```

As of Services Toolkit v0.12.0 in Tanzu Application Platform v1.7.0, you must grant the permission to `claim` from a `ClusterInstanceClass` at the cluster level. You now must use a `ClusterRole` and `ClusterRoleBinding`. Namespace-scoped permissions, such as using a `Role` and `RoleBinding` or `ClusterRole` and `RoleBinding`, are not sufficient. If you used `Roles` and `RoleBindings`, or `ClusterRoles` and `RoleBindings` to grant `claim` permissions in specific namespaces only, this change might affect you. For more information, see Authorize users and groups to claim from provisioner-based classes.

Previously, Services Toolkit allowed you to `claim` from a `ClusterInstanceClass` with only namespace-level permissions. However, this allowed users with only namespace-level permissions to obtain or indirectly deploy resources into namespaces that they do not have access to according to the RBAC permissions.

Tanzu Service CLI plug-in command reference

The Tanzu Service CLI plug-in command reference has moved to the Tanzu CLI Command Reference documentation.

Services Toolkit terminology and user roles

This topic provides descriptions of the terms and user roles used in the Services Toolkit documentation.

Terminology

The following terms are used in the Services Toolkit documentation.

Service

Service is broad, high-level term that describes something used in either the development of, or running of application workloads. Often, but not exclusively, synonymous with the concept of a backing service as defined by the Twelve Factor App:

“… any service the app consumes over the network as part of its normal operation”

For example:

- A PostgreSQL service (implemented as a Kubernetes Operator provided by Tanzu Data Services)
- A PostgreSQL service (implemented as a process running on an Application Developer’s laptop)
- Object storage (implemented as SaaS running on AWS)
- AppSSO

Service resource

A service resource is a Kubernetes resource that provides some of the functions related to a Service.

For example:

- A Kubernetes resource with API Kind `PostgreSQL`
- A Kubernetes resource with API Kind `FirewallRule`
- A Kubernetes resource with API Kind `RabbitmqUser`
- A Kubernetes resource with API Kind `ClientRegistration` that provides access to an App SSO service
- A Kubernetes resource with API Kind `Secret` containing credentials and connectivity information for a Service that may or may not be running on the cluster itself.

Provisioned service

A provisioned service is any service resource that defines a `.status.binding.name` which points to a secret in the same namespace that contains credentials and connectivity information for the resource.

This term is defined in the Service Binding Specification for Kubernetes. For the full definition, see the Service Binding Specification in GitHub.

Service binding

A service binding is a mechanism in which service instance credentials and other related connectivity information are automatically communicated to application workloads.

For example:

- The Service binding concept implemented through the `ServiceBinding` service resource provided by servicebinding in GitHub.

Service instance

A service instance is an abstraction over one or a group of interrelated service resources that together provide the functions for a particular service.

One of the service resources that make up an instance must either adhere to the definition of provisioned service, or be a secret conforming to the service binding specification for Kubernetes. This guarantees that you can claim a service and subsequently bind service instances to application workloads.

You make service instances discoverable through service instance classes.

For example:

- The `RabbitmqCluster` service resource provided by the RabbitMQ Cluster Kubernetes operator. This service resource adheres to provisioned service. Therefore, you can consider any `RabbitmqCluster` resource on a Kubernetes cluster to be a service instance.
- A logical grouping of the following service resources form a single AWS RDS service instance:
    - An AWS RDS `DBInstance`
    - An AWS RDS `DBSubnetGroup`
    - A Carvel `SecretTemplate` configured to produce a secret conforming to the Service Binding Specification for Kubernetes
    - A `Role`, `RoleBinding`, and `ServiceAccount`
- A Kubernetes `Secret` conforming to the Service Binding Specification for Kubernetes containing credentials for a Service running external to the cluster.

Service instance class

A service instance class is more commonly called a class. Service instance classes provide a way to describe categories of service instances.

A service instance class enables service instances belonging to the class to be discovered. They come in one of two varieties: pool-based or provisioner-based.

- Claims for pool-based classes are fulfilled by selecting a service instance from a pool.
- Claims for provisioner-based classes are fulfilled by provisioning new service instances.

Different classes might map to different services or to different configurations of the same service.

For example:

- A `ClusterInstanceClass` named “rabbitmq-dev” pointing to all `RabbitmqCluster` service resources configured with `.spec.replicas=1` identified by label `class: rmq-dev`.
- A `ClusterInstanceClass` named “rabbitmq-prod” pointing to all `RabbitmqCluster` service resources configured with `.spec.replicas=3` identified by label `class: rmq-prod`.
- A `ClusterInstanceClass` named “aws-rds-postgresql” pointing to secrets that conform with the Binding Specification and identified by label `class: aws-rds`.
- A `ClusterInstanceClass` named “mysql-on-demand” which provisions MySQL service instances.

Claim

A claim is a mechanism in which requests for service instances can be declared and fulfilled without requiring detailed knowledge of the service instances themselves.

Claims come in one of two varieties - resource claim and class claim:

- Resource claims refer to a specific service instance.
- Class claims refer to a class from which a service instance is then either selected (pool-based) or provisioned (provisioner-based).

For example:

- A resource claim pointing to a `RabbitmqCluster` service instance named `rmq-1` in the namespace `service-instances`.
- A class claim pointing to a class named `on-demand-rabbitmq`.

Claimable service instance

A claimable service instance is any service instance that you are permitted to claim using a resource claim from a namespace, taking into consideration:

- Location (namespace) of the service instance in relation to the location of the resource claim.
- Any matching resource claim policies.
- Exclusivity of resource claims, that is, you can only claim an instance once.

For example:

- A `RabbitmqCluster` service resource located in the same namespace as a resource claim and that has not already been claimed by another resource claim is a claimable service instance.
- A `RabbitmqCluster` service resource located in a different namespace to a resource claim, for which a matching resource claim policy exists, and has not already been claimed by

another resource claim is a claimable service instance.

- A `RabbitmqCluster` service resource located in the same namespace as a resource claim that has already been claimed is not a claimable service instance due to the exclusive nature of Resource Claims.

Dynamic provisioning

Dynamic provisioning is a capability of Services Toolkit in which class claims that refer to provisioner-based classes are fulfilled automatically through the provisioning of new service instances.

Service resource life cycle API

A service resource life cycle API is any Kubernetes API that you can use to manage the life cycle—create, read, update and delete (CRUD)—of a service resource.

For example:

- `rabbitmqclusters.rabbitmq.com/v1beta1`

Service cluster

A service cluster is applicable within the context of Service API Projection and Service Resource Replication. It is a Kubernetes cluster that has Service Resource Lifecycle APIs installed and a corresponding controller managing their life cycle.

Workload cluster

A workload cluster is applicable within the context of Service API Projection and Service Resource Replication. It is a Kubernetes cluster that has developer-created applications running on it.

User roles

Services Toolkit caters to the following user roles.

These user roles are not user personas. It is possible, and even expected, that one person can be associated with many user roles at any given time. The user roles align to Tanzu Application Platform's user roles. Services Toolkit is primarily responsible for defining the service operator role. For more information about the user roles, see Role descriptions.

The user roles listed in this section consist of a short description and the tasks required. For detailed information about the corresponding Role-Based Access Control (RBAC) associated with each role, see Detailed role permissions breakdown.

Application developer (AD)

The application developer role encompasses both app-editor and app-viewer roles as defined by Tanzu Application Platform. For more information about the app-editor and app-viewer roles, see Role descriptions.

Application developers do the following:

- Bind and unbind application workloads to and from resource claims.
- Get, list, and watch ResourceClaims.
- get, list, and watch ClusterInstanceClasses associated with ResourceClaims.

Application operator (AO)

Encompasses the app-operator role as defined by Tanzu Application Platform. For more information about the app-operator role, see Role descriptions.

Application operators do the following:

- Discover and learn about service instance classes available on a cluster.
- Discover claimable service instances associated with service instance classes.
- Life cycle management (CRUD) of resource claims.

Service operator (SO)

Service operators do the following:

- Life cycle management (CRUD) of service instances.
- Life cycle management (CRUD) of service instance classes.
- Life cycle management (CRUD) of resource claim policies.
- Identify pending resource claims and, if appropriate, help to fulfil such claims through a combination of the previous tasks.
- Setup and configure dynamic provisioning.

Services Toolkit limitations

This topic tells you about the limitations related to working with services on Tanzu Application Platform (commonly known as TAP).

Cannot claim and bind to the same service instance from across multiple namespaces

Two or more workloads located in two or more distinct namespaces cannot claim and bind to the same service instance. This is due to the mutually exclusive nature of claims. After a claim has claimed a service instance, no other claim can then claim that same service instance.

This limitation does not exist for two or more workloads located in the same namespace. In this case, the workloads can all still all bind to one claim. This is not possible across the namespace divide.

Overview of Source Controller

Tanzu Source Controller provides a standard interface for artifact acquisition and extends the function of Flux CD Source Controller.

Tanzu Source Controller supports the following two resource types:

- ImageRepository [Deprecated]
- MavenArtifact

An `ImageRepository` resource can resolve the source from the contents of an image in an image registry. This enables app developers to create and update workloads from local source code or a code repository.

A `MavenArtifact` resource can resolve a binary artifact from a Maven repository. This functionality enables the supply chain to support artifacts produced externally.

Note

Fetching `RELEASE` version from GitHub packages is not currently supported. The `metadata.xml` in GitHub packages does not have the `release` tag that contains the released version number. For more information, see Maven-metadata.xml is corrupted on upload to registry on GitHub.

Overview of Source Controller

Tanzu Source Controller provides a standard interface for artifact acquisition and extends the function of Flux CD Source Controller.

Tanzu Source Controller supports the following two resource types:

- ImageRepository [Deprecated]
- MavenArtifact

An `ImageRepository` resource can resolve the source from the contents of an image in an image registry. This enables app developers to create and update workloads from local source code or a code repository.

A `MavenArtifact` resource can resolve a binary artifact from a Maven repository. This functionality enables the supply chain to support artifacts produced externally.

Note

Fetching `RELEASE` version from GitHub packages is not currently supported. The `metadata.xml` in GitHub packages does not have the `release` tag that contains the released version number. For more information, see Maven-metadata.xml is corrupted on upload to registry on GitHub.

Install Source Controller

This topic tells you how to install Source Controller from the Tanzu Application Platform (commonly known as TAP) package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install Source Controller. For more information about profiles, see Components and installation profiles.

Prerequisites

Before installing Source Controller:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- Install cert-manager on the cluster. For more information, see Install cert-manager.

Install

To install Source Controller:

1. List version information for the package by running:

```
tanzu package available list controller.source.apps.tanzu.vmware.com --namespac
e tap-install
```

For example:

```
$ tanzu package available list controller.source.apps.tanzu.vmware.com --namesp
ace tap-install
- Retrieving package versions for controller.source.apps.tanzu.vmware.com...
  NAME                                     VERSION  RELEASED-AT
  controller.source.apps.tanzu.vmware.com  0.3.1    2022-01-23 19:00:00 -0500 -
05
  controller.source.apps.tanzu.vmware.com  0.3.2    2022-02-21 19:00:00 -0500 -
05
  controller.source.apps.tanzu.vmware.com  0.3.3    2022-03-03 19:00:00 -0500 -
05
  controller.source.apps.tanzu.vmware.com  0.4.1    2022-06-09 19:00:00 -0500 -
05
  controller.source.apps.tanzu.vmware.com  0.9.0    2024-03-19 00:00:00 -0500 -
05
```

2. (Optional) Gather the values schema:

```
tanzu package available get controller.source.apps.tanzu.vmware.com/VERSION-NUM
BER --values-schema --namespace tap-install
```

Where `VERSION-NUMBER` is the version of the package listed in step 1 above.

For example:

```
tanzu package available get controller.source.apps.tanzu.vmware.com/0.9.0-buil
d.2 --values-schema --namespace tap-install

  KEY               DEFAULT  TYPE    DESCRIPTION
  resources                           Optional: Tanzu Source Controller resource
limit configuration
  aws_iam_role_arn  ""       string  Optional: Arn role that has access to pull
images from ECR container registry
  ca_cert_data      ""       string  Optional: PEM Encoded certificate data for
image registries with private CA.
```

3. (Optional) Create a file named `source-controller-values.yaml` to override the default installation settings. You can configure the following fields:

    - `ca_cert_data`: Enables Source Controller to connect to image registries that use self-signed or private certificate authorities. If a certificate error `x509: certificate signed by unknown authority` occurs, use this option to trust additional certificate authorities.

      To provide a custom certificate, add the PEM-encoded CA certificate data to `source-controller-values.yaml`. For example:

      ```
      ca_cert_data: |
          -----BEGIN CERTIFICATE-----
          MIICpTCCAYUCBgkqhkiG9w0BBQ0wMzAbBgkqhkiG9w0BBQwwDgQIYg9x6gkCAggA
          ...
          9TlA7A4FFpQqbhAuAVH6KQ8WMZIrVxJSQ03c9lKVkI62wQ==
          -----END CERTIFICATE-----
      ```

    - `aws_iam_role_arn`: Annotates the Source Controller service with an AWS Identity and Access Management (IAM) role. This allows Source Controller to pull images from Amazon Elastic Container Registry (ECR).

To add the AWS IAM role Amazon Resource Name (ARN) to the Source Controller service, add the ARN to `source-controller-values.yaml`. For example:

```
aws_iam_role_arn: "eks.amazonaws.com/role-arn: arn:aws:iam::112233445566:
role/source-controller-manager"
```

- `resources`: Allows you to update the default resource configuration for the Source Controller. By default, the Source Controller resource configuration is set as follows:

  ```
  resources:
    limits:
      cpu: 100m
      memory: 512Mi
    requests:
      cpu: 100m
      memory: 20Mi
  ```

  To update the default resource configuration, add the configuration you require to `source-controller-values.yaml`. For example:

  ```
  resources:
    limits:
      cpu: 100m
      memory: 1Gi
  ```

4. Install the package by running:

   ```
   tanzu package install source-controller \
     --package controller.source.apps.tanzu.vmware.com \
     --version VERSION-NUMBER \
     --namespace tap-install \
     --values-file VALUES-FILE
   ```

   Where:

   - `VERSION-NUMBER` is the version of the package listed in step 1 above.
   - `VALUES-FILE` is the path to the file created in step 3.

   For example:

   ```
   $ tanzu package install source-controller
       --package controller.source.apps.tanzu.vmware.com
       --version 0.9.0-build.2
       --namespace tap-install
       --values-file source-controller-values.yaml

   4:33:18PM: Creating service account 'source-controller-tap-install-sa'
   4:33:18PM: Creating cluster admin role 'source-controller-tap-install-cluster-r
   ole'
   4:33:18PM: Creating cluster role binding 'source-controller-tap-install-cluster
   -rolebinding'
   4:33:18PM: Creating secret 'source-controller-tap-install-values'
   4:33:18PM: Creating overlay secrets
   4:33:18PM: Creating package install resource
   4:33:18PM: Waiting for PackageInstall reconciliation for 'source-controller'
   4:33:18PM: Fetch started (2s ago)
   4:33:20PM: Fetching

      | Succeeded
4:33:45PM: Deploy succeeded
```

5. Verify the package installation by running:

   ```
   tanzu package installed get source-controller -n tap-install
   ```

   For example:

   ```
   tanzu package installed get source-controller -n tap-install
   NAMESPACE:          tap-install
   NAME:               source-controller
   PACKAGE-NAME:       controller.source.apps.tanzu.vmware.com
   PACKAGE-VERSION:    0.9.0-build.2
   STATUS:             Reconcile succeeded
   CONDITIONS:         - status: "True"
     type: ReconcileSucceeded
   ```

   Verify that `STATUS` is `Reconcile succeeded`:

   ```
   kubectl get pods -n source-system
   ```

   For example:

   ```
   $ kubectl get pods -n source-system
   NAME                                        READY   STATUS    RESTARTS   AGE
   source-controller-manager-f68dc7bb6-4lrn6   1/1     Running   0          100s
   ```

   Verify that `STATUS` is `Running`.

Troubleshoot Source Controller

This topic gives you guidance about how to troubleshoot issues with Source Controller.

Collecting Logs from Source Controller Manager

To retrieve Pod logs from the `controller-manager`, run the following command in the `source-system` namespace:

```
kubectl logs -n source-system -l control-plane=controller-manager
```

For example:

```
kubectl logs -n source-system -l control-plane=controller-manager
2021-11-18T17:59:43.152Z        INFO    controller.imagerepository      Starting Event

Source Controller reference

This topic provides reference documentation for Source Controller.

ImageRepository [Deprecated]

```
---
apiVersion: source.apps.tanzu.vmware.com/v1alpha1
kind: ImageRepository
spec:
  image: registry.example/image/repository:tag
  # optional fields
  interval: 5m
  imagePullSecrets: []
  serviceAccountName: default
```

`ImageRepository` resolves source code defined in an Open Container Initiative (OCI) image repository, exposing the resulting source artifact at a URL defined by `.status.artifact.url`.

The interval determines how often to check tagged images for changes. Setting this value too high will result in delays in discovering new sources, while setting it too low may trigger a registry's rate limits.

Repository credentials can be defined as image pull secrets. You can reference them either directly from the resources at `.spec.imagePullSecrets` or attach them to a service account referenced at `.spec.serviceAccountName`. The default service account name `"default"` is used if not otherwise specified. The default credential helpers for the registry are also used, for example, pulling from Google Container Registry (GCR) on a Google Kubernetes Engine (GKE) cluster.

MavenArtifact

```
---
apiVersion: source.apps.tanzu.vmware.com/v1alpha1
kind: MavenArtifact
metadata:
  name: mavenartifact-sample
spec:
  artifact:
    groupId: org.springframework.boot
    artifactId: spring-boot
    version: "2.7.0"
  repository:
    url: https://repo1.maven.org/maven2
  interval: 5m0s
  timeout: 1m0s
```

`MavenArtifact` resolves artifact from a Maven repository, exposing the resulting artifact at a URL defined by `.status.artifact.url`.

The `interval` determines how often to check artifact for changes. Setting this value too high results in delays in discovering new sources, while setting it too low may trigger a repository's rate limits.

Repository credentials may be defined as secrets referenced from the resources at `.spec.repository.secretRef`. Secrets referenced by `spec.repository.secretRef` is parsed as follows:

```
---
apiVersion: v1
kind: Secret
metadata:
  name: auth-secret
type: Opaque
data:
  username: <BASE64>
  password: <BASE64>
  caFile:   <BASE64>   // PEM Encoded certificate data for Custom CA
  certFile: <BASE64>   // PEM-encoded client certificate
  keyFile:  <BASE64>   // Private Key
```

Maven supports a broad set of `version` syntax. Source Controller supports a strict subset of Maven's version syntax in order to ensure compatibility and avoid user confusion. The subset of supported syntax may grow over time, but will never expand past the syntax defined directly by Maven. This behavior means that we can use `mvn` as a reference implementation for artifact resolution.

Version support implemented in the following order:

1. Pinned version - an exact match of a version in2 `maven-metadata.xml (versioning/versions/version)`.
2. `RELEASE` - metaversion defined in `maven-metadata.xml (versioning/release)`.
3. `*-SNAPSHOT` - the newest artifact for a snapshot version.
4. `LATEST` - metaversion defined in `maven-metadata.xml (versioning/latest)`.
5. Version ranges - https://maven.apache.org/enforcer/enforcer-rules/versionRanges.html. Support is planned for a future release.

Note

Pinned versions should be immutable, all other versions are dynamic and can change at any time. The `.spec.interval` defines how frequently to check for updated artifacts.

Overview of Spring Boot conventions

This topic tells you about the Spring Boot conventions component.

Spring Boot conventions enriches Spring Boot application deployments in a Tanzu Application Platform supply chain by mutating the `PodSpec` and adding or editing some security checks, probes, and other features to provide a production-ready application.

Spring Boot conventions also sets the relevant Application Live View labels automatically on the `PodSpec` so that Application Live View is enabled by default for a Spring Boot application.

Spring Boot conventions comprises many conventions applied to any Spring Boot application that is submitted to the supply chain in which the convention controller is configured. The conventions include:

- Setting liveness/readiness actuator probes
- Enabling the automatic configuration of actuators on the platform and workload levels
- Setting Prometheus annotations when `micrometer-registry-prometheus` dependency exists on the classpath
- Setting `JAVA_TOOL_OPTIONS` and Application Live View labels for a Spring Boot application

Important

Spring Boot conventions supports Spring Boot and Spring Cloud Gateway applications. Application Live View conventions supports only Steeltoe applications. For more information about Application Live View conventions, see Application Live View convention server.

Overview of Spring Boot conventions

This topic tells you about the Spring Boot conventions component.

Spring Boot conventions enriches Spring Boot application deployments in a Tanzu Application Platform supply chain by mutating the `PodSpec` and adding or editing some security checks, probes, and other features to provide a production-ready application.

Spring Boot conventions also sets the relevant Application Live View labels automatically on the `PodSpec` so that Application Live View is enabled by default for a Spring Boot application.

- Setting liveness/readiness actuator probes
- Enabling the automatic configuration of actuators on the platform and workload levels
- Setting Prometheus annotations when `micrometer-registry-prometheus` dependency exists on the classpath
- Setting `JAVA_TOOL_OPTIONS` and Application Live View labels for a Spring Boot application

Important

Spring Boot conventions supports Spring Boot and Spring Cloud Gateway applications. Application Live View conventions supports only Steeltoe applications. For more information about Application Live View conventions, see Application Live View convention server.

Install Spring Boot conventions

This topic tells you how to install Spring Boot conventions from the Tanzu Application Platform package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install Spring Boot conventions. For more information about profiles, see Components and installation profiles.

Prerequisites

Before installing Spring Boot conventions:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- Install Supply Chain Choreographer.

Install Spring Boot conventions

To install Spring Boot conventions:

1. Get the exact name and version information for the Spring Boot conventions package to install by running:

   ```
   tanzu package available list spring-boot-conventions.tanzu.vmware.com --namespa
   ce tap-install
   ```

   For example:

   ```
   $ tanzu package available list spring-boot-conventions.tanzu.vmware.com --names
   pace tap-install
   / Retrieving package versions for spring-boot-conventions.tanzu.vmware.com...
   NAME                                        VERSION           RELEASED-AT
   ...
   spring-boot-conventions.tanzu.vmware.com    1.9.0     2024-03-22T00:00:00Z
   ...
   ```

2. (Optional) Change the default installation settings by running:

   ```
   tanzu package available get spring-boot-conventions.tanzu.vmware.com/VERSION-NU
   MBER \
   --values-schema --namespace tap-install
   ```

   Where `VERSION-NUMBER` is the version of the package listed. For example: `1.9.1`.

   For example:

   ```
   $ tanzu package available get spring-boot-conventions.tanzu.vmware.com/1.8.0-bu
   ild.1 --values-schema --namespace tap-install
        KEY                                          DEFAULT             TYPE
   DESCRIPTION
        autoConfigureActuators                       false               boolean
   Enable or disable the automatic configuration of actuators on the TAP platform
   level
        kubernetes_distribution                                          string
   Kubernetes distribution that this package is being installed on. Accepted

   values: [''',''openshift'']
        kubernetes_version                                               string
   Optional: The Kubernetes Version. Valid values are '1.24.*', or ''
        livenessProbe.terminationGracePeriodSeconds                      number
   configure a grace period for the kubelet to wait  between triggering a shut dow
   n

   of the failed container, and then forcing the container runtime to stop that
   ```

```
container
     livenessProbe.timeoutSeconds                1                   number
Number of seconds after which the probe times out
     livenessProbe.failureThreshold                                  number
After a probe fails failureThreshold times in a row, Kubernetes considers that

the overall check has failed
     livenessProbe.initialDelaySeconds           0                   number
Number of seconds after the container has started before liveness probes are

initiated
     livenessProbe.periodSeconds                 10                  number
How often (in seconds) to perform the probe
     livenessProbe.successThreshold              1                   number
Minimum consecutive successes for the probe to be considered successful after

having failed
     readinessProbe.initialDelaySeconds            0                 number
Number of seconds after the container has started before readiness probes are

initiated
     readinessProbe.periodSeconds                  10                number
How often (in seconds) to perform the probe
     readinessProbe.successThreshold               1                 number
Minimum consecutive successes for the probe to be considered successful after

having failed
     readinessProbe.terminationGracePeriodSeconds                    number
configure a grace period for the kubelet to wait between triggering a shut down

of the failed container, and then forcing the container runtime to stop that

container
     readinessProbe.timeoutSeconds                 1                 number
Number of seconds after which the probe times out
     readinessProbe.failureThreshold                                 number
After a probe fails failureThreshold times in a row, Kubernetes considers that

the overall check has failed
     startupProbe.periodSeconds                    10                number
How often (in seconds) to perform the probe
     startupProbe.successThreshold                 1                 number
Minimum consecutive successes for the probe to be considered successful after

having failed
     startupProbe.terminationGracePeriodSeconds                      number
configure a grace period for the kubelet to wait between triggering a shut down

of the failed container, and then forcing the container runtime to stop that

container
     startupProbe.timeoutSeconds                   1                 number
Number of seconds after which the probe times out
     startupProbe.failureThreshold                                   number
After a probe fails failureThreshold times in a row, Kubernetes considers that

the overall check has failed
     startupProbe.initialDelaySeconds              0                 number
Number of seconds after the container has started before probes are initiated
```

For more information about configuring probes in Spring Boot conventions, see Configure liveness, readiness, and startup probes for Spring Boot applications (alpha)

3. Install the package by running:

```
tanzu package install spring-boot-conventions \
 --package spring-boot-conventions.tanzu.vmware.com \
 --version VERSION-NUMBER \
 --namespace tap-install
```

Where `VERSION-NUMBER` is the version of the package you listed earlier.

4. Verify you installed the package by running:

```
tanzu package installed get spring-boot-conventions --namespace tap-install
```

For example:

```
tanzu package installed get spring-boot-conventions -n tap-install
| Retrieving installation details for spring-boot-conventions...
NAME:                    spring-boot-conventions
PACKAGE-NAME:            spring-boot-conventions.tanzu.vmware.com
PACKAGE-VERSION:         1.9.1
STATUS:                  Reconcile succeeded
CONDITIONS:              [{ReconcileSucceeded True  }]
USEFUL-ERROR-MESSAGE:
```

Verify that `STATUS` is `Reconcile succeeded`

Configure and access Spring Boot actuators in Tanzu Application Platform

This topic tells you how the Spring Boot conventions in Tanzu Application Platform configure Spring Boot actuators automatically. With this feature, users can activate or deactivate the automatic configuration of actuators on Tanzu Application Platform and on individual workloads.

Workload-level configuration

Developers can add a label to their workloads to activate or deactivate the automatic configuration of actuators. By default, all existing and future accelerator projects are configured to activate automatic configuration on the workload level.

To activate or deactivate the automatic configuration of actuators at the workload level:

- To activate automatic configuration of actuators, set the following label to `true` in your workload YAML:

  `apps.tanzu.vmware.com/auto-configure-actuators: "true"`

  If the preceding label is set to `true`, the Spring Boot actuator convention sets the following actuator configuration:

  - The `JAVA_TOOL_OPTIONS` property is set as `-Dmanagement.server.port="8081"`.
  - The `JAVA_TOOL_OPTIONS` property is set as `-Dmanagement.endpoints.web.base-path="/actuator"`.
  - Annotation on the PodIntent is set as `boot.spring.io/actuator: http://:8081/actuator`.

  In addition to these settings, Application Live View is activated with the following actuator configuration:

  - Label on the PodIntent is set as `tanzu.app.live.view.application.actuator: actuator`.

    - Label on the PodIntent is set as `tanzu.app.live.view.application.actuator.port: 8081`.

- To deactivate automatic configuration of actuators, set the following label to `false` in your workload YAML:

  `apps.tanzu.vmware.com/auto-configure-actuators: "false"`

  If the preceding label is set to `false`, the Spring Boot actuator convention does not set any `JAVA_TOOL_OPTIONS` and does not set the annotation `boot.spring.io/actuator`.

  Application Live View is activated and configured with default values for Spring Boot web applications, assuming that some actuators are activated on the default port. On activating Application Live View, the following actuator settings are set:

    - The `JAVA_TOOL_OPTIONS` property is set as `-Dserver.port="8080"`.
    - Label on the PodIntent is set as `tanzu.app.live.view.application.actuator: actuator`.
    - Label on the PodIntent is set as `tanzu.app.live.view.application.actuator.port: 8080`.

The Application Live View GUI renders the pages with accessible information based on whether the actuator endpoints are accessible for an application.

By default, as an additional security measure, Spring Boot conventions does not expose all the actuator data over HTTP by exposing all the actuator endpoints. In addition, the information exposed by the health endpoint is not set to `always` by default.

If the automatic configuration of actuators is set to `true` either at the workload level or platform level, the Spring Boot convention then sets the runtime environment properties `management.endpoints.web.exposure.include="*"` and `management.endpoint.health.show-details=true` on to the PodSpec to expose all the actuator endpoints and detailed health information. You do not need to add these properties manually in `application.properties` or `application.yml`.

Platform-level configuration

In contrast to activating or deactivating the automatic configuration of actuators on the level of individual workloads, you can set a global setting for the platform instead. This setting is taken into account ONLY when there is no specific `auto-configure-actuators` setting on the individual workload.

To activate or deactivate the automatic configuration of actuators at a global level:

- To activate the automatic configuration, when you install Spring Boot conventions, provide an entry in the `values.yaml` file. For example:

  ```
  springboot_conventions:
    autoConfigureActuators: true
  ```

- To deactivate the automatic configuration, you can provide the following entry:

  ```
  springboot_conventions:
    autoConfigureActuators: false
  ```

Note

The default values for both platform level and workload level configuration is false.

To run Application Live View with Spring Boot apps, the Spring Boot convention recognizes PodIntents and adds the following metadata labels:

- `tanzu.app.live.view: "true"`: Activates the connector to observe application pod
- `tanzu.app.live.view.application.name: APPLICATION-NAME`: Identifies the app name to be used internally by Application Live View
- `tanzu.app.live.view.application.actuator.port: ACTUATOR-PORT`: Identifies the port on the pod at which the actuators are available for Application Live View
- `tanzu.app.live.view.application.flavours: spring-boot`: Exposes the framework flavor of the app

To run Application Live View with Spring Cloud Gateway apps, Spring Boot conventions recognizes PodIntents and adds the following metadata labels:

- `tanzu.app.live.view: "true"`: Activates the connector to observe application pod
- `tanzu.app.live.view.application.name: APPLICATION-NAME`: Identifies the app name to be used internally by Application Live View
- `tanzu.app.live.view.application.actuator.port: ACTUATOR-PORT`: Identifies the port on the pod at which the actuators are available for Application Live View
- `tanzu.app.live.view.application.flavours: spring-boot,spring-cloud-gateway`: Exposes the framework flavors of the app

Configure liveness, readiness, and startup probes for Spring Boot applications (alpha)

This topic tells you how to override the liveness, readiness, and startup probes' settings for Spring Boot apps in Tanzu Application Platform. You can override the Kubernetes default probe settings in `spring-boot-conventions` for containers on Tanzu Application Platform.

Caution

This feature is in alpha testing. It is intended for evaluation and test purposes only.

Overview of the probes

Kubernetes provides built-in mechanisms for checking the health and readiness of your Spring Boot apps. By default, Kubernetes uses specific endpoints provided by Spring Boot Actuator for liveness and readiness checks. However, you might need to customize these probes to align them with your app's specific requirements.

Probe	Function
Liveness	Indicates whether the app is running and responsive. If the probe fails, Kubernetes might restart the container.
Readiness	Indicates whether the app is ready to serve requests. If the probe fails, Kubernetes won't route traffic to the container.
Startup	Indicates when the app has completed its initialization and is ready to handle traffic. This is especially useful for apps with a slow startup process.

For more information about the probes, see the Kubernetes documentation.

Override the default configurations of the probes

To override the default settings and customize the probes at a cluster level:

1. List the schema for the `spring-boot-conventions` package by running:

```
tanzu package available get spring-boot-conventions.tanzu.vmware.com/VERSION-NU
MBER \
--values-schema --namespace tap-install
```

Where `VERSION-NUMBER` is the version of the package listed. For example: `1.8.0-build.1`.

For example:

```
$ tanzu package available get spring-boot-conventions.tanzu.vmware.com/1.8.0-bu
ild.1 --values-schema --namespace tap-install
    KEY                                          DEFAULT             TYPE     D
ESCRIPTION
    autoConfigureActuators                       false               boolean  E
nable or disable the automatic configuration of actuators on the TAP platform l
evel
    kubernetes_distribution                                          string   K
ubernetes distribution that this package is being installed on. Accepted

values: [''''],''openshift'']
    kubernetes_version                                               string   O
ptional: The Kubernetes Version. Valid values are '1.24.*', or ''
    livenessProbe.terminationGracePeriodSeconds                      number   c
onfigure a grace period for the kubelet to wait  between triggering a shut down

of the failed container, and then forcing the container runtime to stop that

container
    livenessProbe.timeoutSeconds                 1                   number   N

    livenessProbe.failureThreshold                                   number   A
fter a probe fails failureThreshold times in a row, Kubernetes considers that

the overall check has failed
    livenessProbe.initialDelaySeconds            0                   number   N
umber of seconds after the container has started before liveness probes are

initiated
    livenessProbe.periodSeconds                  10                  number   H
ow often (in seconds) to perform the probe
    livenessProbe.successThreshold               1                   number   M
inimum consecutive successes for the probe to be considered successful after

having failed
    readinessProbe.initialDelaySeconds             0                 number   N
umber of seconds after the container has started before readiness probes are

initiated
    readinessProbe.periodSeconds                   10                number   H
ow often (in seconds) to perform the probe
    readinessProbe.successThreshold                1                 number   M
inimum consecutive successes for the probe to be considered successful after

having failed
    readinessProbe.terminationGracePeriodSeconds                     number   c
onfigure a grace period for the kubelet to wait between triggering a shut down

of the failed container, and then forcing the container runtime to stop that

container
    readinessProbe.timeoutSeconds                  1                 number   N
umber of seconds after which the probe times out
    readinessProbe.failureThreshold                                  number   A
```

```
fter a probe fails failureThreshold times in a row, Kubernetes considers that

the overall check has failed
    startupProbe.periodSeconds                      10                number   H
ow often (in seconds) to perform the probe
    startupProbe.successThreshold                   1                 number   M
inimum consecutive successes for the probe to be considered successful after

having failed
    startupProbe.terminationGracePeriodSeconds                        number   c
onfigure a grace period for the kubelet to wait between triggering a shut down

of the failed container, and then forcing the container runtime to stop that

container
    startupProbe.timeoutSeconds                     1                 number   N
umber of seconds after which the probe times out
    startupProbe.failureThreshold                                     number   A
fter a probe fails failureThreshold times in a row, Kubernetes considers that

the overall check has failed
    startupProbe.initialDelaySeconds                0                 number   N
umber of seconds after the container has started before probes are initiated
```

2. When you install Spring Boot conventions, provide an entry in the `values.yaml` file to override the configuration.

   For example:

   ```
   springboot_conventions:
     autoConfigureActuators: true
     livenessProbe:
       initialDelaySeconds: 11
       periodSeconds: 12
       timeoutSeconds: 13
       terminationGracePeriodSeconds: 14
     readinessProbe:
       initialDelaySeconds: 15
       periodSeconds: 12
       successThreshold: 3
       failureThreshold: 4
   ```

3. Install the package by running:

   ```
   tanzu package install spring-boot-conventions \
    --package spring-boot-conventions.tanzu.vmware.com \
    --version VERSION-NUMBER \
    --namespace tap-install \
    --values-file values.yaml
   ```

   Where `VERSION-NUMBER` is the version of the package to install. For example: `1.8.0-build.1`.

4. Verify that you installed the package by running:

   ```
   tanzu package installed get spring-boot-conventions --namespace tap-install
   ```

   For example:

   ```
   $ tanzu package installed get spring-boot-conventions -n tap-install
   | Retrieving installation details for spring-boot-conventions...
   NAME:                    spring-boot-conventions
   PACKAGE-NAME:            spring-boot-conventions.tanzu.vmware.com
   PACKAGE-VERSION:         1.8.0-build.1
   STATUS:                  Reconcile succeeded
   ```

```
CONDITIONS:              [{ReconcileSucceeded True  }]
USEFUL-ERROR-MESSAGE:
```

Verify that `STATUS` is `Reconcile succeeded`

The Spring Boot convention applies the probe and timeout settings at the cluster level to all Spring Boot and Spring Native workloads.

5. Verify the `PodIntent` of your workload by ensuring that `spec.containers.livenessProbe` shows the overridden configuration values propagated through the Spring Boot conventions:

```
kubectl get podintents.conventions.carto.run tanzu-java-web-app -o yaml

spec:
 containers:
 - env:
   - name: JAVA_TOOL_OPTIONS
     value: -Dmanagement.endpoint.health.probes.add-additional-paths="true" -Dm
anagement.endpoint.health.show-details="always"
       -Dmanagement.endpoints.web.base-path="/actuator" -Dmanagement.endpoints.
web.exposure.include="*"
       -Dmanagement.health.probes.enabled="true" -Dmanagement.server.port="808
1"
       -Dserver.port="8080" -Dserver.shutdown.grace-period="24s"
   image: dev.registry.tanzu.vmware.com/app-live-view/test/tanzu-java-web-app-d
efault@sha256:fa822a6585eb1287a817a956f16d77dd391624462a626bf37bbf0f9e89ff7562
   livenessProbe:
     httpGet:
       path: /livez
       port: 8080
       scheme: HTTP
     initialDelaySeconds: 11
     periodSeconds: 12
     terminationGracePeriodSeconds: 14
     timeoutSeconds: 13
   name: workload
   ports:
   - containerPort: 8080
     protocol: TCP
   readinessProbe:
     failureThreshold: 4
     httpGet:
       path: /readyz
       port: 8080
       scheme: HTTP
     initialDelaySeconds: 15
     periodSeconds: 12
     successThreshold: 3
   resources: {}
   securityContext:
     runAsUser: 1000
   startupProbe:
     httpGet:
       path: /startupz
       port: 8080
       scheme: HTTP
```

Setting additional paths for the probes

The Spring Boot convention automatically sets `management.endpoint.health.probes.add-additional-paths` to `true` if the Spring Boot application is v2.6.0 or later. For any versions earlier than v2.6.0, `management.endpoint.health.probes.add-additional-paths` is not supported.

The `spring-boot-actuator-probes` convention in Spring Boot conventions sets the liveness, readiness, and startup probe endpoints to `/livez`, `/readyz`, and `readyz` respectively. These endpoints act as additional endpoint paths on the actuator probes.

For example, when you run `https://tanzu-java-web-app.default.apps.20.22.106.199.nip.io/actuator/health/livez` to monitor the liveness probe, you can view the health of the application. This helps you evaluate whether an application that is running in a container is in a healthy state.

Similarly, when running `https://tanzu-java-web-app.default.apps.20.22.106.199.nip.io/actuator/health/readyz` to view the readiness probe and the startup probe, you can evaluate whether the application is ready to receive traffic and whether the application has started up properly.

Enable Application Live View for Spring Boot applications

To run Application Live View for Spring Boot apps, Spring Boot conventions recognizes PodIntents and automatically adds the following metadata labels:

- `tanzu.app.live.view: "true"`: Enables the connector to observe application pod
- `tanzu.app.live.view.application.name: APPLICATION-NAME`: Identifies the app name to be used internally by Application Live View
- `tanzu.app.live.view.application.actuator.port: ACTUATOR-PORT`: Identifies the port on the pod at which the actuators are available for Application Live View
- `tanzu.app.live.view.application.flavours: spring-boot`: Exposes the framework flavor of the app

To run Application Live View for Spring Cloud Gateway apps, Spring Boot conventions recognizes PodIntents and adds the following metadata labels:

- `tanzu.app.live.view: "true"`: Enables the connector to observe application pod
- `tanzu.app.live.view.application.name: APPLICATION-NAME`: Identifies the app name to be used internally by Application Live View
- `tanzu.app.live.view.application.actuator.port: ACTUATOR-PORT`: Identifies the port on the pod at which the actuators are available for Application Live View
- `tanzu.app.live.view.application.flavours: spring-boot,spring-cloud-gateway`: Exposes the framework flavors of the app

These metadata labels allow Application Live View to identify pods that are enabled for Application Live View. The metadata labels also tell the Application Live View connector what kind of app it is and on which port the actuators are accessible for Application Live View. For more information, see Configuring and accessing Spring Boot actuators in Tanzu Application Platform.

Verify the applied labels and annotations

To verify the applied labels and annotations, run:

```
kubectl get podintents.conventions.carto.run WORKLOAD-NAME -o yaml
```

Where `WORKLOAD-NAME` is the name of the deployed workload. For example: `tanzu-java-web-app`.

Expected output of Spring Boot workload:

```
apiVersion: conventions.carto.run/v1alpha1
kind: PodIntent
metadata:

Enable Spring Native apps for Application Live View

This topic tells you how to run Spring Native workloads within Tanzu Application Platform (commonly known as TAP).

This topic describes how the Spring Boot convention server enhances Tanzu `PodIntents` with metadata. This metadata can include labels, annotations, or properties required to run native workloads in Tanzu Application Platform.

The metadata enables Application Live View to discover and register the app instances so that Application Live View can access the actuator data from those workloads.

Configure a Spring Native application

To make Application Live View interact with a Spring Native app within Tanzu Application Platform:

1. Add the `spring-boot-starter-actuator` module dependency for Maven in `pom.xml` as follows:

```
<dependency>
 <groupId>org.springframework.boot</groupId>
 <artifactId>spring-boot-starter-actuator</artifactId>
</dependency>
```

2. Add a native profile that includes the `native-maven-plugin` for the build phase in `pom.xml`, as follows:

```
<profiles>
 <profile>
     <id>native</id>
     <build>
       <plugins>
           <plugin>
             <groupId>org.graalvm.buildtools</groupId>
               <artifactId>native-maven-plugin</artifactId>
             </plugin>
         </plugins>
     </build>
 </profile>
</profiles>
```

Important

For Maven-based projects, you must add the `org.graalvm.buildtools` build plug-in and configure it to run when the native profile is active.

3. Add the following configuration in `pom.xml` to generate `build-info.properties` in your Spring Boot application. Application Live View uses this information to display the Spring Boot version that the app uses.

```
<plugin>
<groupId>org.springframework.boot</groupId>
<artifactId>spring-boot-maven-plugin</artifactId>
<executions>
 <execution>
   <goals>
     <goal>build-info</goal>
   </goals>
   <configuration>
     <additionalProperties>
       <spring.boot.version>${project.parent.version}</spring.boot.version>
     </additionalProperties>
   </configuration>
 </execution>
</executions>
</plugin>
```

Create a native workload

Create a workload for the Spring Native application similar to the following example:

```
$ tanzu apps workload create spring-cloud-serverless \
--git-repo https://github.com/vudayani-vmw/spring-cloud-serverless --git-branch main \
--type web --label apps.tanzu.vmware.com/auto-configure-actuators=true \
--label app.kubernetes.io/part-of=spring-cloud-serverless --yes \
```

```
--annotation autoscaling.knative.dev/min-scale=1 \
--build-env "BP_JVM_VERSION=17" --build-env "BP_NATIVE_IMAGE=true" \
--build-env "BP_MAVEN_BUILD_ARGUMENTS= -Pnative -Dmaven.test.skip=true \
--no-transfer-progress package \
-Dspring-boot.aot.jvmArguments='-Dmanagement.endpoint.health.probes.add-additional-pat
hs='true' \
-Dmanagement.endpoint.health.show-details='always' \
-Dmanagement.endpoints.web.base-path='/actuator' \
-Dmanagement.endpoints.web.exposure.include='*' \
-Dmanagement.health.probes.enabled='true' \
-Dmanagement.server.port=8081 -Dserver.port=8080' "
```

Where:

- The required build arguments, such as `BP_JVM_VERSION`, `BP_NATIVE_IMAGE`, and `BP_MAVEN_BUILD_ARGUMENTS`, are configured to build a native executable file as shown in the example. The build environment variables are required to enable a native build profile and native image-building.
- The override configuration options at runtime provide AOT (Ahead-Of-Time) configuration to the build process by using the `spring-boot.aot.jvmArguments` option. For Gradle builds, the `spring-boot.aot.jvmArguments` is set as part of the `BP_GRADLE_ADDITIONAL_BUILD_ARGUMENTS` build environment variable.

These build environment parameters do not directly set the runtime values. The build environment parameters, provided as part of `spring-boot.aot.jvmArguments`, are only used as build-time signals. These signals indicate to generate code that allows configuration options to be set at runtime.

Configure at runtime

There are two methods to override the configuration at runtime. You can, by default, let Spring Boot conventions configure automatically, or you can use environment variables to configure manually.

Configure automatically (default)
Automatic configuration by Spring Boot conventions is the default method. Spring Boot conventions add the necessary environment variables and labels to the workload `PodSpec` based on the `apps.tanzu.vmware.com/auto-configure-actuators` flag. When the `apps.tanzu.vmware.com/auto-configure-actuators` is set to `true`, Spring Boot conventions adds the following environment variables to the native workload `PodSpec`:

```
Spec:
  Containers:
    Env:
      Name:   MANAGEMENT_SERVER_PORT
      Value:  8081
      Name:   MANAGEMENT_ENDPOINT_HEALTH_PROBES_ADD_ADDITIONAL_PATHS
      Value:  true
      Name:   MANAGEMENT_ENDPOINT_HEALTH_SHOW_DETAILS
      Value:  always
      Name:   MANAGEMENT_ENDPOINTS_WEB_BASE_PATH
      Value:  /actuator
      Name:   MANAGEMENT_ENDPOINTS_WEB_EXPOSURE_INCLUDE
      Value:  *
      Name:   MANAGEMENT_HEALTH_PROBES_ENABLED
      Value:  true
      Name:   SERVER_PORT
      Value:  8080
      Name:   SERVER_SHUTDOWN_GRACE_PERIOD
      Value:  24s
```

Configure manually

You can manually override runtime configuration settings by providing environment variables. To customize the configuration, set the relevant environment variables in accordance with your requirements. The following example overrides `MANAGEMENT_SERVER_PORT` as `8088`, and it overrides `SERVER_PORT` as `8082`.

```
tanzu apps workload create spring-cloud-serverless \
--git-repo https://github.com/vudayani-vmw/spring-cloud-serverless --git-branch main
--type web \
--label tanzu.app.live.view.application.flavours=spring-boot_spring-native \
--label apps.tanzu.vmware.com/auto-configure-actuators=true --label \
app.kubernetes.io/part-of=spring-cloud-serverless --label apps.tanzu.vmware.com/has-
tests=true \
--yes --annotation autoscaling.knative.dev/min-scale=1 --build-env "BP_JVM_VERSION=1
7" \
--build-env "BP_NATIVE_IMAGE=true" --build-env "BP_MAVEN_BUILD_ARGUMENTS= -Pnative \
-Dmaven.test.skip=true --no-transfer-progress package \
-Dspring-boot.aot.jvmArguments='-Dmanagement.endpoint.health.probes.add-additional-p
aths='true' \
-Dmanagement.endpoint.health.show-details='always' -Dmanagement.endpoints.web.base-p
ath='/actuator' \
-Dmanagement.endpoints.web.exposure.include='*' -Dmanagement.health.probes.enabled
='true' \
-Dmanagement.server.port=8081 -Dserver.port=8080' " --env MANAGEMENT_SERVER_PORT=808
8 \
--env SERVER_PORT=8082
```

The resulting `PodSpec` is:

```
Spec:
  Containers:
    Env:
      Name:   MANAGEMENT_SERVER_PORT
      Value:  8088
      Name:   SERVER_PORT
      Value:  8082
      Name:   MANAGEMENT_ENDPOINT_HEALTH_PROBES_ADD_ADDITIONAL_PATHS
      Value:  true
      Name:   MANAGEMENT_ENDPOINT_HEALTH_SHOW_DETAILS
      Value:  always
      Name:   MANAGEMENT_ENDPOINTS_WEB_BASE_PATH
      Value:  /actuator
      Name:   MANAGEMENT_ENDPOINTS_WEB_EXPOSURE_INCLUDE
      Value:  *
      Name:   MANAGEMENT_HEALTH_PROBES_ENABLED
      Value:  true
      Name:   SERVER_SHUTDOWN_GRACE_PERIOD
      Value:  24s
```

Spring Boot conventions also set the Application Live View labels on the `PodSpec` to enable Application Live View.

Verify the applied labels and annotations

Verify the applied labels and annotations by running:

```
kubectl get podintents.conventions.carto.run WORKLOAD-NAME -o yaml
```

Where `WORKLOAD-NAME` is the name of the deployed workload. For example, `spring-cloud-serverless`.

Expected output of the Spring Boot workload:

```
...
Labels:       app.kubernetes.io/component=intent
              app.kubernetes.io/part-of=spring-cloud-serverless
              apps.tanzu.vmware.com/auto-configure-actuators=true
              apps.tanzu.vmware.com/has-tests=true
              apps.tanzu.vmware.com/workload-type=web
              carto.run/cluster-template-name=convention-template
              carto.run/resource-name=config-provider
              carto.run/supply-chain-name=source-to-url
              carto.run/template-kind=ClusterConfigTemplate
              carto.run/template-lifecycle=mutable
              carto.run/workload-name=spring-cloud-serverless
              carto.run/workload-namespace=default
              tanzu.app.live.view.application.flavours=spring-boot_spring-native
...
```

Enable Prometheus scraping for Spring Boot applications on workloads

This topic tells you how to enable Prometheus to get metrics for your Spring Boot applications on Tanzu Application Platform (commonly known as TAP) workloads.

About Prometheus scraping for Spring Boot applications

Spring Boot conventions recognizes PodIntents and automatically adds Prometheus annotations on the Tanzu Application Platform workload PodSpec. This means that you do not need to manually add the annotations in your workload YAML. The pods with these Prometheus annotations are considered for scraping of metrics.

The following annotations are added:

- `prometheus.io/scrape: "true"`: Enables the Prometheus scrape feature. This identifies which pods to scrape for metrics.
- `prometheus.io/path: "/actuator/prometheus"`: Sets the Prometheus scrape path to the endpoint where Prometheus exposes metrics.
- `prometheus.io/port: "8080"`: Sets the Prometheus port to the default server port of a Spring Boot application. This ensures that the right port is used for the scrape job for each pod.

Note

If any of these annotations are added manually, the manual annotation setting takes precedence over the automatic setting.

Spring Boot conventions allows you to activate or deactivate the automatic configuration of actuators on Tanzu Application Platform and on individual workloads. If the label `apps.tanzu.vmware.com/auto-configure-actuators` on the workload is set to `true`, Spring Boot conventions activates automatic configuration of actuators. The default label setting on the workload is `apps.tanzu.vmware.com/auto-configure-actuators: "false"`.

If `apps.tanzu.vmware.com/auto-configure-actuators` label is set to `true` on the workload YAML, then the management server port is also switched to 8081 and Spring Boot conventions uses that port to access the actuators instead of the default app port. Therefore, the Prometheus port is also

set to 8081 automatically on the PodSpec so that the metrics can be scraped using that port. All the other native Prometheus annotations remain the same as the `false` case.

For more information, see Configuring and accessing Spring Boot actuators in Tanzu Application Platform.

Enable Prometheus to scrape metrics

To enable Prometheus to scrape metrics from HTTP endpoints of a Spring Boot application, add the Micrometer registry dependency for Prometheus support in the POM dependencies section:

```
<dependency>
   <groupId>io.micrometer</groupId>
   <artifactId>micrometer-registry-prometheus</artifactId>
</dependency>
```

Verify the applied annotations

To verify the applied labels and annotations, run:

```
kubectl get podintents.conventions.carto.run WORKLOAD-NAME -o yaml
```

Where `WORKLOAD-NAME` is the name of the deployed workload. For example: `tanzu-java-web-app`.

Example output

Example output for a Spring Boot workload PodIntent:

```

List of Spring Boot conventions

This topic tells you about what the conventions do and how to apply them.

When submitting the following pod `Pod Intent` on each convention, the output can change depending on the applied convention.

Before any Spring Boot conventions are applied, the pod intent looks similar to this YAML:

```
apiVersion: conventions.carto.run/v1alpha1
kind: PodIntent
metadata:
  name: spring-sample
spec:
  template:
    spec:
      containers:
      - name: workload
        image: springio/petclinic
```

Most of the Spring Boot conventions either edit or add properties to the environment variable `JAVA_TOOL_OPTIONS`. You can override those conventions by providing the `JAVA_TOOL_OPTIONS` value you want through the Tanzu CLI or `workload.yaml`.

When a `JAVA_TOOL_OPTIONS` property already exists for a workload, the convention uses the existing value rather than the value that the convention applies by default. The property value that you provide is used for the pod specification mutation.

Set a `JAVA_TOOL_OPTIONS` property for a workload

Do one of the following actions to set `JAVA_TOOL_OPTIONS` property and values:

Use the Tanzu CLI apps plug-in
When creating or updating a workload, set a `JAVA_TOOL_OPTIONS` property using the `--env` flag by running:

```
tanzu apps workload create APP-NAME --env JAVA_TOOL_OPTIONS="-DPROPERTY-NAME=VALUE"
```

For example, to set the management port to `8080` rather than the spring-boot-actuator-convention default port `8081`, run:

```
tanzu apps workload create APP-NAME --env JAVA_TOOL_OPTIONS="-Dmanagement.server.por
t=8080"
```

Use workload.yaml

Follow these steps:

1. Provide one or more values for the `JAVA_TOOL_OPTIONS` property in the `workload.yaml`. For example:

```
apiVersion: carto.run/v1alpha1
kind: Workload
...
spec:
env:
- name: JAVA_TOOL_OPTIONS
  value: -Dmanagement.server.port=8082
source:
...
```

2. Apply the `workload.yaml` file by running the command:

```
tanzu apps workload create -f workload.yaml
```

Spring Boot convention

If the `spring-boot` dependency is in the metadata within the `SBOM` file under `dependencies`, the Spring Boot convention is applied to the `PodTemplateSpec` object.

The Spring Boot convention adds a label (`conventions.carto.run/framework: spring-boot`) to the `PodTemplateSpec` that describes the framework associated with the workload, and adds an annotation (`boot.spring.io/version: VERSION-NO`) that describes the Spring Boot version of the dependency.

The label and annotation are added for informational purposes only.

Example of PodIntent after applying the convention:

```
apiVersion: conventions.carto.run/v1alpha1
kind: PodIntent
metadata:
 annotations:
   kubectl.kubernetes.io/last-applied-configuration: |
     {"apiVersion":"conventions.carto.run/v1alpha1","kind":"PodIntent","metadata":{"an
notations":{},"name":"spring-sample","namespace":"default"},"spec":{"template":{"spe
c":{"containers":[{"image":"springio/petclinic","name":"workload"}]}}}}

...

status:
 conditions:
 - lastTransitionTime: "..." # This status indicates that all worked as expected
   status: "True"
   type: ConventionsApplied
 - lastTransitionTime: "..."
   status: "True"
   type: Ready
 observedGeneration: 1
 template:
   metadata:
     annotations:
       boot.spring.io/version: 2.3.3.RELEASE
       conventions.carto.run/applied-conventions: |-
         spring-boot-convention/spring-boot
     labels:
       conventions.carto.run/framework: spring-boot
```

```
  spec:
    containers:
    - image: index.docker.io/springio/petclinic@sha256:...
      name: workload
      resources: {}
```

Spring boot graceful shut down convention

If any of the following dependencies are in the metadata within the `SBOM` file under `dependencies`, the Spring Boot graceful shut down convention is applied to the `PodTemplateSpec` object:

- `spring-boot-starter-tomcat`
- `spring-boot-starter-jetty`
- `spring-boot-starter-reactor-netty`
- `spring-boot-starter-undertow`
- `tomcat-embed-core`

The Graceful Shutdown convention `spring-boot-graceful-shutdown` adds a property in the environment variable `JAVA_TOOL_OPTIONS` with the key `server.shutdown.grace-period`. The key value is calculated to be 80% of the value set in `.target.Spec.TerminationGracePeriodSeconds`. The default value for `.target.Spec.TerminationGracePeriodSeconds` is 30 seconds.

Example of PodIntent after applying the convention:

```
apiVersion: conventions.carto.run/v1alpha1
kind: PodIntent
metadata:
  annotations:
    kubectl.kubernetes.io/last-applied-configuration: |
      {"apiVersion":"conventions.carto.run/v1alpha1","kind":"PodIntent","metadata":{"a
nnotations":{},"name":"spring-sample","namespace":"default"},"spec":{"template":{"spe
c":{"containers":[{"image":"springio/petclinic","name":"workload"}]}}}}

...

status:
  conditions:
  - lastTransitionTime: "..." # This status indicates that all worked as expected
    status: "True"
    type: ConventionsApplied
  - lastTransitionTime: "..."
    status: "True"
    type: Ready
  observedGeneration: 1
  template:
    metadata:
      annotations:
        boot.spring.io/version: 2.3.3.RELEASE
        conventions.carto.run/applied-conventions: |-
          spring-boot-convention/spring-boot
          spring-boot-convention/spring-boot-graceful-shutdown
      labels:
        conventions.carto.run/framework: spring-boot
    spec:
      containers:
      - env:
        - name: JAVA_TOOL_OPTIONS
          value: -Dserver.shutdown.grace-period="24s"
        image: index.docker.io/springio/petclinic@sha256:...
        name: workload
        resources: {}
```

Spring Boot web convention

If any of the following dependencies are in the metadata within the `SBOM` file under `dependencies`, the Spring Boot web convention is applied to the `PodTemplateSpec` object:

- spring-boot
- spring-boot-web

The web convention `spring-boot-web` obtains the `server.port` property from the `JAVA_TOOL_OPTIONS` environment variable and sets it as a port in the `PodTemplateSpec`. If `JAVA_TOOL_OPTIONS` environment variable does not contain a `server.port` property or value, the convention adds the property and sets the value to `8080`, which is the Spring Boot default.

Example of PodIntent after applying the convention:

```
apiVersion: conventions.carto.run/v1alpha1
kind: PodIntent
metadata:
  annotations:
    kubectl.kubernetes.io/last-applied-configuration: |
      {"apiVersion":"conventions.carto.run/v1alpha1","kind":"PodIntent","metadata":{"a
nnotations":{},"name":"spring-sample","namespace":"default"},"spec":{"template":{"spe
c":{"containers":[{"image":"springio/petclinic","name":"workload"}]}}}}

...

status:
  conditions:
  - lastTransitionTime: "..." # This status indicates that all worked as expected
    status: "True"
    type: ConventionsApplied
  - lastTransitionTime: "..."
    status: "True"
    type: Ready
  observedGeneration: 1
  template:
    metadata:
      annotations:
        boot.spring.io/version: 2.3.3.RELEASE
        conventions.carto.run/applied-conventions: |-
          spring-boot-convention/spring-boot
          spring-boot-convention/spring-boot-web
      labels:
        conventions.carto.run/framework: spring-boot
    spec:
      containers:
      - env:
        - name: JAVA_TOOL_OPTIONS
          value: -Dserver.port="8080"
        image: index.docker.io/springio/petclinic@sha256:...
        name: workload
        ports:
        - containerPort: 8080
          protocol: TCP
        resources: {}
```

Spring Boot Actuator convention

If the `spring-boot-actuator` dependency is in the metadata within the `SBOM` file under `dependencies`, the Spring Boot actuator convention is applied to the `PodTemplateSpec` object.

The Spring Boot Actuator convention does the following actions:

If the workload-level or platform-level automatic configuration of actuators is enabled:

1. Sets the management port in the `JAVA_TOOL_OPTIONS` environment variable to `8081`.
2. Sets the base path in the `JAVA_TOOL_OPTIONS` environment variable to `/actuator`.
3. Adds an annotation, `boot.spring.io/actuator`, to where the actuator is accessed.

The management port is set to port `8081` for security reasons. Although you can prevent public access to the actuator endpoints that are exposed on the management port when it is set to the default `8080`, the threat of exposure through internal access remains. The best practice for security is to set the management port to something other than `8080`.

However, if a management port number value is provided using the `-Dmanagement.server.port` property in `JAVA_TOOL_OPTIONS`, the Spring Boot actuator convention uses that value rather than its default `8081` as the management port.

You can access the management context of a Spring Boot application by creating a service pointing to port `8081` and base path `/actuator`.

Important

To override the management port setting applied by this convention, see How to set a JAVA_TOOL_OPTIONS property for a workload earlier in this topic. Any alternative methods for setting the management port are overwritten. For example, if you configure the management port using `application.properties/yml` or `config server`, the Spring Boot Actuator convention overrides your configuration.

If the workload-level or platform-level automatic configuration of actuators is deactivated, the Spring Boot actuator convention does not set any `JAVA_TOOLS_OPTIONS` and does not set the annotation `boot.spring.io/actuator`.

Example of PodIntent after applying the convention:

```
apiVersion: conventions.carto.run/v1alpha1
kind: PodIntent
metadata:
 annotations:
   kubectl.kubernetes.io/last-applied-configuration: |
     {"apiVersion":"conventions.carto.run/v1alpha1","kind":"PodIntent","metadata":{"an
notations":{},"name":"spring-sample","namespace":"default"},"spec":{"template":{"spe
c":{"containers":[{"image":"springio/petclinic","name":"workload"}]}}}}

...

status:
 conditions:
 - lastTransitionTime: "..." # This status indicates that all worked as expected
   status: "True"
   type: ConventionsApplied
 - lastTransitionTime: "..."
   status: "True"
   type: Ready
 observedGeneration: 1
 template:
   metadata:
     annotations:
       boot.spring.io/actuator: http://:8081/actuator
       boot.spring.io/version: 2.3.3.RELEASE
       conventions.carto.run/applied-conventions: |-
         spring-boot-convention/spring-boot
         spring-boot-convention/spring-boot-web
```

```
        spring-boot-convention/spring-boot-actuator
    labels:
      conventions.carto.run/framework: spring-boot
  spec:
    containers:
    - env:
      - name: JAVA_TOOL_OPTIONS
        value: Dmanagement.endpoints.web.base-path="/actuator" -Dmanagement.server.po
rt="8081" -Dserver.port="8080"
      image: index.docker.io/springio/petclinic@sha256:...
      name: workload
      ports:
      - containerPort: 8080
        protocol: TCP
      resources: {}
```

Spring Boot Actuator Probes convention

The Spring Boot Actuator Probes convention is applied only if all of the following conditions are met:

- The `spring-boot-actuator` dependency exists and is **>= 2.6**
- The `JAVA_TOOL_OPTIONS` environment variable does not include the following properties or, if either of the properties is included, it is set to a value of `true`:
  - `-Dmanagement.health.probes.enabled`
  - `-Dmanagement.endpoint.health.probes.add-additional-paths`

The Spring Boot Actuator Probes convention does the following actions:

1. Uses the main server port, which is the `server.port` value on `JAVA_TOOL_OPTIONS`, to set the liveness and readiness probes. For more information see the Kubernetes documentation
2. Adds the following properties and values to the `JAVA_TOOL_OPTIONS` environment variable:
   - `-Dmanagement.health.probes.enabled="true"`
   - `-Dmanagement.endpoint.health.probes.add-additional-paths="true"`

   When this convention is applied, the probes are exposed as follows:
   - Liveness probe: `/livez`
   - Readiness probe: `/readyz`

Example of PodIntent after applying the convention:

```
apiVersion: conventions.carto.run/v1alpha1
kind: PodIntent
metadata:
  annotations:
    kubectl.kubernetes.io/last-applied-configuration: |
      {"apiVersion":"conventions.carto.run/v1alpha1","kind":"PodIntent","metadata":{"a
nnotations":{},"name":"spring-sample","namespace":"default"},"spec":{"template":{"spe
c":{"containers":[{"image":"springio/petclinic","name":"workload"}]}}}}

...

status:
  conditions:
  - lastTransitionTime: "..." # This status indicates that all worked as expected
    status: "True"
    type: ConventionsApplied
  - lastTransitionTime: "..."
    status: "True"
```

```
    type: Ready
  observedGeneration: 1
  template:
    metadata:

            port: 8080
            scheme: HTTP
        resources: {}
```

Service intent conventions

The Service intent conventions do not change the behavior of the final deployment, but you can use them as added information to process in the supply chain. For example, when an app requires to be bound to database service. This convention adds an annotation and a label to the `PodTemplateSpec` for each detected dependency. It also adds an annotation and a label to the `conventions.carto.run/applied-conventions`.

The list of the supported intents are:

MySQL

- **Name**: `service-intent-mysql`
- **Label**: `services.conventions.apps.tanzu.vmware.com/mysql`
- **Dependencies**: `mysql-connector-java`, `r2dbc-mysql`

PostgreSQL

- **Name**: `service-intent-postgres`
- **Label**: `services.conventions.apps.tanzu.vmware.com/postgres`
- **Dependencies**: `postgresql`, `r2dbc-postgresql`

MongoDB

- **Name**: `service-intent-mongodb`

- **Label**: `services.conventions.apps.tanzu.vmware.com/mongodb`
- **Dependencies**: `mongodb-driver-core`

RabbitMQ

- **Name**: `service-intent-rabbitmq`
- **Label**: `services.conventions.apps.tanzu.vmware.com/rabbitmq`
- **Dependencies**: `amqp-client`

Redis

- **Name**: `service-intent-redis`
- **Label**: `services.conventions.apps.tanzu.vmware.com/redis`
- **Dependencies**: `jedis`

Kafka

- **Name**: `service-intent-kafka`
- **Label**: `services.conventions.apps.tanzu.vmware.com/kafka`
- **Dependencies**: `kafka-clients`

Kafka-streams

- **Name**: `service-intent-kafka-streams`
- **Label**: `services.conventions.apps.tanzu.vmware.com/kafka-streams`
- **Dependencies**: `kafka-streams`

Example

When you apply the `Pod Intent` and the image contains a dependency, for example, of MySQL, then the output of the convention is:

```
  apiVersion: conventions.carto.run/v1alpha1
  kind: PodIntent
  metadata:
    annotations:
      kubectl.kubernetes.io/last-applied-configuration: |
        {"apiVersion":"conventions.carto.run/v1alpha1","kind":"PodIntent","metadata":
{"annotations":{},"name":"spring-sample","namespace":"default"},"spec":{"template":{"s
pec":{"containers":[{"image":"springio/petclinic","name":"workload"}]}}}}
    creationTimestamp: "..."
    generation: 1
    name: spring-sample
    namespace: default
    resourceVersion: "..."
    uid: ...
  spec:
    serviceAccountName: default
    template:
      metadata: {}
      spec:
        containers:
        - image: springio/petclinic
          name: workload
          resources: {}
  status:
    conditions:
    - lastTransitionTime: "..." # This status indicates that all worked as expected
      status: "True"
      type: ConventionsApplied
```

```
    - lastTransitionTime: "..."
      status: "True"
      type: Ready
    observedGeneration: 1
    template:
      metadata:
        annotations:
          boot.spring.io/actuator: http://:8080/actuator
          boot.spring.io/version: 2.3.3.RELEASE
          conventions.carto.run/applied-conventions: |-
            spring-boot-convention/spring-boot

            spring-boot-convention/service-intent-mysql
          services.conventions.apps.tanzu.vmware.com/mysql: mysql-connector-java/8.0.2
1
        labels:
          conventions.apps.tanzu.vmware.com/framework: spring-boot
          services.conventions.apps.tanzu.vmware.com/mysql: workload
      spec:
        containers:
        - env:
          - name: JAVA_TOOL_OPTIONS
            value: Dmanagement.endpoints.web.base-path="/actuator" -Dmanagement.serve
r.port="8081" -Dserver.port="8080"
          image: index.docker.io/springio/petclinic@sha256:...
          name: workload
          ports:
          - containerPort: 8080
            protocol: TCP
          resources: {}
```

Troubleshoot Spring Boot conventions

This topic tells you how to troubleshoot Spring Boot conventions.

Collect logs

If you have trouble, you can retrieve and examine logs from the Spring Boot convention server as follows:

1. The Spring Boot convention server creates a namespace to contain all of the associated resources. By default the namespace is `spring-boot-convention`. To inspect the logs, run:

   ```
   kubectl logs -l app=spring-boot-webhook -n spring-boot-convention
   ```

   For example:

   ```
   $ kubectl logs -l app=spring-boot-webhook -n spring-boot-convention

   {"level":"info","timestamp":"2021-11-11T16:00:26.597Z","caller":"spring-boot-co
   nventions/server.go:83","msg":"Successfully applied convention: spring-boot","c
   omponent":"spring-boot-conventions"}
   {"level":"info","timestamp":"2021-11-11T16:00:26.597Z","caller":"spring-boot-co
   nventions/server.go:83","msg":"Successfully applied convention: spring-boot-gra
   ceful-shutdown","component":"spring-boot-conventions"}
   {"level":"info","timestamp":"2021-11-11T16:00:26.597Z","caller":"spring-boot-co
   nventions/server.go:83","msg":"Successfully applied convention: spring-boot-we
   b","component":"spring-boot-conventions"}
   {"level":"info","timestamp":"2021-11-11T16:00:26.597Z","caller":"spring-boot-co
   nventions/server.go:83","msg":"Successfully applied convention: spring-boot-act
   uator","component":"spring-boot-conventions"}
   {"level":"info","timestamp":"2021-11-11T16:00:26.597Z","caller":"spring-boot-co
   ```

```
nventions/server.go:83","msg":"Successfully applied convention: service-intent-
mysql","component":"spring-boot-conventions"}
```

2. For all of the conventions that were applied successfully, a log entry is added. If an error occurs, a log entry is added with a description.

Overview of Spring Cloud Gateway for Kubernetes

Spring Cloud Gateway for Kubernetes is an API gateway solution based on the open-source Spring Cloud Gateway project. It provides a simple means to route internal or external API requests to application services that expose APIs.

Spring Cloud Gateway for Kubernetes handles cross-cutting concerns on behalf of API development teams, including single sign-on (SSO), access control, rate limiting, resiliency, security, and more.

It enables you to accelerate API delivery using modern cloud-native patterns with any programming language you choose for API development. It also integrates with your existing CI/CD pipeline strategy.

For more information about Spring Cloud Gateway for Kubernetes, see the Spring Cloud Gateway for Kubernetes documentation.

Spring Cloud Gateway for Kubernetes handles cross-cutting concerns on behalf of API development teams, including single sign-on (SSO), access control, rate limiting, resiliency, security, and more.

It enables you to accelerate API delivery using modern cloud-native patterns with any programming language you choose for API development. It also integrates with your existing CI/CD pipeline strategy.

For more information about Spring Cloud Gateway for Kubernetes, see the Spring Cloud Gateway for Kubernetes documentation.

Install Spring Cloud Gateway for Kubernetes

This topic describes how to install Spring Cloud Gateway for Kubernetes from the Tanzu Application Platform package repository.

Prerequisites

Before installing Spring Cloud Gateway, complete all prerequisites for installing Tanzu Application Platform. For more information, see Prerequisites.

Install

To install Spring Cloud Gateway:

1. See which versions of Spring Cloud Gateway are available to install from the Tanzu Application Platform repository by running:

```
tanzu package available list spring-cloud-gateway.tanzu.vmware.com --namespace
tap-install
```

For example:

```
$ tanzu package available list spring-cloud-gateway.tanzu.vmware.com --namespac
e tap-install

NAME                                    VERSION  RELEASED-AT
spring-cloud-gateway.tanzu.vmware.com  2.0.0    2022-02-01T00:00:00Z
```

2. (Optional) View the changes you can make to the default installation settings by running:

```
tanzu package available get spring-cloud-gateway.tanzu.vmware.com/VERSION-NUMBE
R \
  --namespace tap-install --values-schema
```

Where `VERSION-NUMBER` is the version of the package listed earlier.

For example:

```
tanzu package available get spring-cloud-gateway.tanzu.vmware.com/2.0.0 \
  --namespace tap-install --values-schema
```

You can use the information to generate a values override file for use in the following installation step.

For more information about values schema options, see the Spring Cloud Gateway for Kubernetes documentation.

Important

The value of `deployment.namespace` must always be set to the same value as the `--namespace` flag.

3. Install Spring Cloud Gateway by running:

Default values

Run this command to install Spring Cloud Gateway with the default values

```
tanzu package install spring-cloud-gateway \
  --package spring-cloud-gateway.tanzu.vmware.com \
  --version VERSION-NUMBER \
  --namespace tap-install
```

For example:

```
$ tanzu package install spring-cloud-gateway \
    --package spring-cloud-gateway.tanzu.vmware.com \
    --version 2.0.0 \
    --namespace tap-install

Installing package 'spring-cloud-gateway.tanzu.vmware.com'
Getting package metadata for 'spring-cloud-gateway.tanzu.vmware.com'
Creating service account 'spring-cloud-gateway-tap-install-sa'
Creating cluster admin role 'spring-cloud-gateway-tap-install-cluster-role'
Creating cluster role binding 'spring-cloud-gateway-tap-install-cluster-roleb
inding'
Creating package resource
Waiting for 'PackageInstall' reconciliation for 'spring-cloud-gateway'
```

```
'PackageInstall' resource install status: Reconciling
'PackageInstall' resource install status: ReconcileSucceeded

Added installed package 'spring-cloud-gateway'
```

Overriding values

Run this command to install Spring Cloud Gateway while overriding the default values

```
tanzu package install spring-cloud-gateway \
  --package spring-cloud-gateway.tanzu.vmware.com \
  --version VERSION-NUMBER \
  --namespace tap-install \
  --values-file values.yml
```

Overview of Supply Chain Choreographer for Tanzu

This topic introduces you to Supply Chain Choreographer.

Overview

Supply Chain Choreographer is based on open source Cartographer. It allows App Operators to create pre-approved paths to production by integrating Kubernetes resources with the elements of their existing toolchains, for example, Jenkins.

Each pre-approved supply chain creates a path to production. Orchestrating supply chain resources including, test, build, scan, and deploy allows developers to focus on delivering value to their users and provides App Operators the assurance that all code in production has passed through all the steps of an approved workflow.

Out of the Box Supply Chains

Out of the box supply chains are provided with Tanzu Application Platform.

The following three supply chains are included:

- Out of the Box Supply Chain Basic
- Out of the Box Supply Chain with Testing
- Out of the Box Supply Chain with Testing and Scanning

As auxiliary components, Tanzu Application Platform also includes:

- Out of the Box Templates, for providing templates used by the supply chains to perform common tasks such as fetching source code, running tests, and building container images.
- Out of the Box Delivery Basic, for delivering to a Kubernetes cluster the configuration built throughout a supply chain

Both Templates and Delivery Basic are requirements for the Supply Chains.

Supply Chain Choreographer supports the following pipeline types:

- Tekton pipelines
- Jenkins pipelines

Overview of Supply Chain Choreographer for Tanzu

This topic introduces you to Supply Chain Choreographer.

Overview

Supply Chain Choreographer is based on open source Cartographer. It allows App Operators to create pre-approved paths to production by integrating Kubernetes resources with the elements of their existing toolchains, for example, Jenkins.

Each pre-approved supply chain creates a path to production. Orchestrating supply chain resources including, test, build, scan, and deploy allows developers to focus on delivering value to their users and provides App Operators the assurance that all code in production has passed through all the steps of an approved workflow.

Out of the Box Supply Chains

Out of the box supply chains are provided with Tanzu Application Platform.

The following three supply chains are included:

- Out of the Box Supply Chain Basic
- Out of the Box Supply Chain with Testing
- Out of the Box Supply Chain with Testing and Scanning

As auxiliary components, Tanzu Application Platform also includes:

- Out of the Box Templates, for providing templates used by the supply chains to perform common tasks such as fetching source code, running tests, and building container images.
- Out of the Box Delivery Basic, for delivering to a Kubernetes cluster the configuration built throughout a supply chain

Both Templates and Delivery Basic are requirements for the Supply Chains.

Supply Chain Choreographer supports the following pipeline types:

- Tekton pipelines
- Jenkins pipelines

Install Supply Chain Choreographer

This topic describes how you can install Supply Chain Choreographer from the Tanzu Application Platform package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install Supply Chain Choreographer. For more information about profiles, see Components and installation profiles..

Supply Chain Choreographer provides the custom resource definitions the supply chain uses. Each pre-approved supply chain creates a clear road to production and orchestrates supply chain resources. You can test, build, scan, and deploy. Developers can focus on delivering value to users. Application operators can rest assured that all code in production has passed through an approved workflow.

For example, Supply Chain Choreographer passes the results of fetching source code to the component that builds a container image of it, and then passes the container image to a component that deploys the image.

Prerequisites

Before installing Supply Chain Choreographer:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.

Install

To install Supply Chain Choreographer:

1. Get the values schema to see what properties can be configured during installation. Run:

```
tanzu package available get cartographer.tanzu.vmware.com/0.7.1+tap.1 --values-
schema --namespace tap-install

KEY                                     DEFAULT  TYPE     DESCRIPTION
ca_cert_data                            ""       string   Optional: PEM Encode
d certificate data for image registries with private CA.
cartographer.concurrency.max_deliveries  2        integer  Optional: maximum nu
mber of Deliverables to process concurrently.
cartographer.concurrency.max_runnables   2        integer  Optional: maximum nu
mber of Runnables to process concurrently.
cartographer.concurrency.max_workloads   2        integer  Optional: maximum nu
mber of Workloads to process concurrently.
cartographer.resources.limits.cpu        1000m            Optional: maximum am
ount of cpu resources to allow the controller to use
cartographer.resources.limits.memory     128Mi            Optional: maximum am
ount of memory to allow the controller to use
cartographer.resources.requests.cpu      250m             Optional: minimum am
ount of cpu to reserve
cartographer.resources.requests.memory   128Mi            Optional: minimum am
ount of memory to reserve
```

2. Install v0.4.0 of the `cartographer.tanzu.vmware.com` package, naming the installation `cartographer`. Run:

```
tanzu package install cartographer \
  --namespace tap-install \
  --package cartographer.tanzu.vmware.com \
  --version 0.7.1+tap.1
```

Example output:

```
| Installing package 'cartographer.tanzu.vmware.com'
| Getting namespace 'tap-install'
| Getting package metadata for 'cartographer.tanzu.vmware.com'
| Creating service account 'cartographer-tap-install-sa'
| Creating cluster admin role 'cartographer-tap-install-cluster-role'
| Creating cluster role binding 'cartographer-tap-install-cluster-rolebinding'
- Creating package resource
\ Package install status: Reconciling

Added installed package 'cartographer' in namespace 'tap-install'
```

Out of the Box Supply Chain Basic for Supply Chain Choreographer

This topic provides an overview of Out of the Box Supply Chain Basic for Supply Chain Choreographer.

This package contains Cartographer supply chains that tie together a series of Kubernetes resources that drive a developer-provided workload from source code to a Kubernetes configuration ready to be deployed to a cluster. It contains the most basic supply chains that focus on providing a quick path to deployment making no use of testing or scanning resources.

The supply chains in this package perform the following:

- Building from source code:
    1. Watching a Git repository, Maven repository, or local directory for changes
    2. Building a container image out of the source code with Buildpacks
    3. Applying operator-defined conventions to the container definition
    4. Creating a deliverable object for deploying the application to a cluster
    5. (Beta) Alternatively, outputting a Carvel package containing the application to a Git repository. See Carvel Package Supply Chains.
- Using a prebuilt application image:
    1. Applying operator-defined conventions to the container definition
    2. Creating a deliverable object for deploying the application to a cluster
    3. (Beta) Alternatively, outputting a Carvel package containing the application to a Git repository. See Carvel Package Supply Chains.

Prerequisites

To use this package, you must:

- Install Out of the Box Templates.
- Configure the Developer namespace with auxiliary objects that are used by the supply chain as described in the following section.
- (Optionally) install Out of the Box Delivery Basic, if you are willing to deploy the application to the same cluster as the workload and supply chains.

Developer Namespace

The supply chains provide definitions of many of the objects that they create to transform the source code to a container image and make it available as an application in a cluster.

The developer must provide or configure particular objects in the developer namespace so that the supply chain can provide credentials and use permissions granted to a specific development team.

The objects that the developer must provide or configure include:

- **registries secrets**: Kubernetes secrets of type `kubernetes.io/dockerconfigjson` that contain credentials for pushing and pulling the container images built by the supply chain and the installation of Tanzu Application Platform.
- **service account**: The identity to be used for any interaction with the Kubernetes API made by the supply chain.
- **rolebinding**: Grant to the identity the necessary roles for creating the resources prescribed by the supply chain.

Registries Secrets

Regardless of the supply chain that a workload goes through, there must be Kubernetes secrets in the developer namespace containing credentials for both pushing and pulling the container image

that the supply chain builds when source code is provided. The developer namespace must also contain registry credentials for Kubernetes to run pods using images from the installation of Tanzu Application Platform.

1. Add read/write registry credentials for pushing and pulling application images:

   ```
   tanzu secret registry add registry-credentials \
     --server REGISTRY-SERVER \
     --username REGISTRY-USERNAME \
     --password REGISTRY-PASSWORD \
     --namespace YOUR-NAMESPACE
   ```

   Where:

   - `YOUR-NAMESPACE` is the name you want to use for the developer namespace. For example, use `default` for the default namespace.
   - `REGISTRY-SERVER` is the URL of the registry. For Docker Hub, this must be `https://index.docker.io/v1/`. Specifically, it must have the leading `https://`, the `v1` path, and the trailing `/`. For Google Container Registry (GCR), this is `gcr.io`. Based on the information used in Installing the Tanzu Application Platform package and profiles, you can use the same registry server as in `ootb_supply_chain_basic` - `registry` - `server`.

2. Add a placeholder secret for gathering the credentials used for pulling container images from the installation of Tanzu Application Platform:

   ```
   cat <<EOF | kubectl -n YOUR-NAMESPACE apply -f -
   apiVersion: v1
   kind: Secret
   metadata:
     name: tap-registry
     annotations:
       secretgen.carvel.dev/image-pull-secret: ""
   type: kubernetes.io/dockerconfigjson
   data:
     .dockerconfigjson: e30K
   EOF
   ```

With the two secrets created:

- `tap-registry` is a placeholder secret filled indirectly by `secretgen-controller` Tanzu Application Platform credentials set up during the installation of Tanzu Application Platform.
- `registry-credentials` is a secret providing credentials for the registry where application container images are pushed to.

The following section discusses setting up the identity required for the workload.

ServiceAccount

In a Kubernetes cluster, a ServiceAccount provides a way of representing an actor within the Kubernetes role-based access control (RBAC) system. In the case of a developer namespace, this represents a developer or development team.

You can directly attach secrets to the ServiceAccount through both the `secrets` and `imagePullSecets` fields. This allows you to provide indirect ways for resources to find credentials without knowing the exact name of the secrets.

```
apiVersion: v1
kind: ServiceAccount
metadata:
```

```
  name: default
secrets:
  - name: registry-credentials
  - name: tap-registry
imagePullSecrets:
  - name: registry-credentials
  - name: tap-registry
```

Important

The ServiceAccount must have the secrets created earlier linked to it. If it does not, services like Tanzu Build Service (used in the supply chain) lack the necessary credentials for pushing the images it builds for that workload.

RoleBinding

As the supply chain takes action in the cluster on behalf of the users who created the workload, it needs permissions within Kubernetes' RBAC system to do so.

Tanzu Application Platform v1.2 includes two ClusterRoles that describe all of the necessary permissions to grant to the service account:

- `workload` clusterrole, providing the necessary roles for the supply chains to manage the resources prescribed by them.
- `deliverable` clusterrole, providing the roles for deliveries to deploy to the cluster the application Kubernetes objects produced by the supply chain.

To provide those permissions to the identity you created for this workload, bind the `workload` ClusterRole to the ServiceAccount you created above:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: default-permit-workload
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: workload
subjects:
  - kind: ServiceAccount
    name: default
```

If this is a Build cluster, and you do not intend to run the application in it, this single RoleBinding is all that's necessary.

If you intend to also deploy the application that's been built, bind to the same ServiceAccount the `deliverable` ClusterRole too:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: default-permit-deliverable
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: deliverable
subjects:
  - kind: ServiceAccount
    name: default
```

For more information about authentication and authorization in Tanzu Application Platform, see Overview of Default roles for Tanzu Application Platform.

Developer workload

With the developer namespace set up with the preceding objects, such as secret, serviceaccount, and rolebinding, you can create the workload object.

To do so, use the `apps` plug-in from the Tanzu CLI:

```
tanzu apps workload create FLAGS WORKLOAD-NAME
```

Where:

- `FLAGS` are the one or more flags you want to include.
- `WORKLOAD-NAME` is the name of the workload you want to target.

Depending on what you are aiming to achieve, you can set different flags. To know more about those (including details about different features of the supply chains), see the following sections:

- Building from source, for more information about different ways of creating a workload where the application is built from source code.
- Using an existing image, for more information about how to use prebuilt images in the supply chains.
- GitOps vs RegistryOps, for a description of the different ways of propagating the deployment configuration through external systems (Git repositories and image registries).
- Carvel Package Workflow, for information about how to configure workloads to output Carvel Packages for delivery through Git repositories.

Out of the Box Supply Chain Basic for Supply Chain Choreographer

This topic provides an overview of Out of the Box Supply Chain Basic for Supply Chain Choreographer.

This package contains Cartographer supply chains that tie together a series of Kubernetes resources that drive a developer-provided workload from source code to a Kubernetes configuration ready to be deployed to a cluster. It contains the most basic supply chains that focus on providing a quick path to deployment making no use of testing or scanning resources.

The supply chains in this package perform the following:

- Building from source code:
    1. Watching a Git repository, Maven repository, or local directory for changes
    2. Building a container image out of the source code with Buildpacks
    3. Applying operator-defined conventions to the container definition
    4. Creating a deliverable object for deploying the application to a cluster
    5. (Beta) Alternatively, outputting a Carvel package containing the application to a Git repository. See Carvel Package Supply Chains.
- Using a prebuilt application image:
    1. Applying operator-defined conventions to the container definition
    2. Creating a deliverable object for deploying the application to a cluster

3. (Beta) Alternatively, outputting a Carvel package containing the application to a Git repository. See Carvel Package Supply Chains.

Prerequisites

To use this package, you must:

- Install Out of the Box Templates.
- Configure the Developer namespace with auxiliary objects that are used by the supply chain as described in the following section.
- (Optionally) install Out of the Box Delivery Basic, if you are willing to deploy the application to the same cluster as the workload and supply chains.

Developer Namespace

The supply chains provide definitions of many of the objects that they create to transform the source code to a container image and make it available as an application in a cluster.

The developer must provide or configure particular objects in the developer namespace so that the supply chain can provide credentials and use permissions granted to a specific development team.

The objects that the developer must provide or configure include:

- **registries secrets**: Kubernetes secrets of type `kubernetes.io/dockerconfigjson` that contain credentials for pushing and pulling the container images built by the supply chain and the installation of Tanzu Application Platform.
- **service account**: The identity to be used for any interaction with the Kubernetes API made by the supply chain.
- **rolebinding**: Grant to the identity the necessary roles for creating the resources prescribed by the supply chain.

Registries Secrets

Regardless of the supply chain that a workload goes through, there must be Kubernetes secrets in the developer namespace containing credentials for both pushing and pulling the container image that the supply chain builds when source code is provided. The developer namespace must also contain registry credentials for Kubernetes to run pods using images from the installation of Tanzu Application Platform.

1. Add read/write registry credentials for pushing and pulling application images:

   ```
   tanzu secret registry add registry-credentials \
     --server REGISTRY-SERVER \
     --username REGISTRY-USERNAME \
     --password REGISTRY-PASSWORD \
     --namespace YOUR-NAMESPACE
   ```

   Where:

   - `YOUR-NAMESPACE` is the name you want to use for the developer namespace. For example, use `default` for the default namespace.
   - `REGISTRY-SERVER` is the URL of the registry. For Docker Hub, this must be `https://index.docker.io/v1/`. Specifically, it must have the leading `https://`, the `v1` path, and the trailing `/`. For Google Container Registry (GCR), this is `gcr.io`. Based on the information used in Installing the Tanzu Application Platform package

and profiles, you can use the same registry server as in `ootb_supply_chain_basic` - `registry` - `server`.

2. Add a placeholder secret for gathering the credentials used for pulling container images from the installation of Tanzu Application Platform:

```
cat <<EOF | kubectl -n YOUR-NAMESPACE apply -f -
apiVersion: v1
kind: Secret
metadata:
  name: tap-registry
  annotations:
    secretgen.carvel.dev/image-pull-secret: ""
type: kubernetes.io/dockerconfigjson
data:
  .dockerconfigjson: e30K
EOF
```

With the two secrets created:

- `tap-registry` is a placeholder secret filled indirectly by `secretgen-controller` Tanzu Application Platform credentials set up during the installation of Tanzu Application Platform.
- `registry-credentials` is a secret providing credentials for the registry where application container images are pushed to.

The following section discusses setting up the identity required for the workload.

ServiceAccount

In a Kubernetes cluster, a ServiceAccount provides a way of representing an actor within the Kubernetes role-based access control (RBAC) system. In the case of a developer namespace, this represents a developer or development team.

You can directly attach secrets to the ServiceAccount through both the `secrets` and `imagePullSecets` fields. This allows you to provide indirect ways for resources to find credentials without knowing the exact name of the secrets.

```
apiVersion: v1
kind: ServiceAccount
metadata:
  name: default
secrets:
  - name: registry-credentials
  - name: tap-registry
imagePullSecrets:
  - name: registry-credentials
  - name: tap-registry
```

Important

The ServiceAccount must have the secrets created earlier linked to it. If it does not, services like Tanzu Build Service (used in the supply chain) lack the necessary credentials for pushing the images it builds for that workload.

RoleBinding

As the supply chain takes action in the cluster on behalf of the users who created the workload, it needs permissions within Kubernetes' RBAC system to do so.

Tanzu Application Platform v1.2 includes two ClusterRoles that describe all of the necessary permissions to grant to the service account:

- `workload` clusterrole, providing the necessary roles for the supply chains to manage the resources prescribed by them.
- `deliverable` clusterrole, providing the roles for deliveries to deploy to the cluster the application Kubernetes objects produced by the supply chain.

To provide those permissions to the identity you created for this workload, bind the `workload` ClusterRole to the ServiceAccount you created above:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: default-permit-workload
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: workload
subjects:
  - kind: ServiceAccount
    name: default
```

If this is a Build cluster, and you do not intend to run the application in it, this single RoleBinding is all that's necessary.

If you intend to also deploy the application that's been built, bind to the same ServiceAccount the `deliverable` ClusterRole too:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: default-permit-deliverable
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: deliverable
subjects:
  - kind: ServiceAccount
    name: default
```

For more information about authentication and authorization in Tanzu Application Platform, see Overview of Default roles for Tanzu Application Platform.

Developer workload

With the developer namespace set up with the preceding objects, such as secret, serviceaccount, and rolebinding, you can create the workload object.

To do so, use the `apps` plug-in from the Tanzu CLI:

```
tanzu apps workload create FLAGS WORKLOAD-NAME
```

Where:

- `FLAGS` are the one or more flags you want to include.
- `WORKLOAD-NAME` is the name of the workload you want to target.

Depending on what you are aiming to achieve, you can set different flags. To know more about those (including details about different features of the supply chains), see the following sections:

- Building from source, for more information about different ways of creating a workload where the application is built from source code.
- Using an existing image, for more information about how to use prebuilt images in the supply chains.
- GitOps vs RegistryOps, for a description of the different ways of propagating the deployment configuration through external systems (Git repositories and image registries).
- Carvel Package Workflow, for information about how to configure workloads to output Carvel Packages for delivery through Git repositories.

Install Out of the Box Supply Chain Basic for Supply Chain Choreographer

This topic shows you how to install the Out of the Box Supply Chain Basic package for Supply Chain Choreographer from the Tanzu Application Platform package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install Out of the Box Supply Chain Basic. For more information about profiles, see Components and installation profiles.

The Out of the Box Supply Chain Basic package provides the most basic ClusterSupplyChain that brings an application from source code to a deployed instance of it running in a Kubernetes environment.

Prerequisites

Fulfill the following prerequisites:

- Fulfill the prerequisites for installing Tanzu Application Platform.
- Install Supply Chain Choreographer.

Install

To install Out of the Box Supply Chain Basic:

1. Familiarize yourself with the set of values of the package that can be configured by running:

   ```
   tanzu package available get ootb-supply-chain-basic.tanzu.vmware.com/0.15.6 \
     --values-schema \
     -n tap-install
   ```

   For example:

   ```
   KEY                                  DESCRIPTION

   registry.repository                   Name of the repository in the image regi
   stry server where the application
                                         images from the workload should be pushe
   d (required).

   registry.server                       Name of the registry server where applic
   ation images should be pushed to
                                         (required).
   ```

```
source.credentials_secret              Name of a Secret in the developer namesp
ace which provides the credentials to the
                                       source code repository.

gitops.server_address                  Default server address to be used for fo
rming Git URLs for pushing
                                       Kubernetes configuration produced by the
supply chain. This must
                                       include the scheme/protocol (e.g. http
s:// or ssh://)

gitops.repository_owner                Default project or user of the repositor
y. Used to create URLs for pushing
                                       Kubernetes configuration produced by the
supply chain.

gitops.repository_name                 Default repository name used for forming
Git URLs for pushing Kubernetes
                                       configuration produced by the supply cha
in.

gitops.username                        Default user name to be used for the com
mits produced by the supply chain.

gitops.branch                          Default branch to use for pushing Kubern
etes configuration files produced
                                       by the supply chain.

gitops.commit_message                  Default git commit message to write when
publishing Kubernetes
                                       configuration files produces by the supp
ly chain to git.

gitops.email                           Default user email to be used for the co
mmits produced by the supply chain.

gitops.credentials_secret              Name of a Secret in the developer namesp
ace which provides the credentials to the
                                       GitOps repository.

gitops.ssh_secret                      DEPRECATED: Use gitops.credentials_secre
t and source.credentials_secret instead.
                                       Name of the default Secret containing SS
H credentials to lookup in the
                                       developer namespace for the supply chain
to fetch source code from and
                                       push configuration to.

gitops.commit_strategy                 Specification of how commits are made to
the branch; directly or through a
                                       pull request.

gitops.repository_prefix               DEPRECATED: Use server_address and repos
itory_owner instead.
                                       Default prefix to be used for forming Gi
t SSH URLs for pushing Kubernetes
                                       configuration produced by the supply cha
in.

gitops.pull_request.server_kind        The git source control platform used

gitops.pull_request.commit_branch      The branch to which commits will be mad
e, before opening a pull request
                                       to the branch specified in .gitops.branc
h If the string "" is specified,
                                       an essentially random string will be use
```

```
d for the branch name, in order
                                        to prevent collisions.

gitops.pull_request.pull_request_title The title for the pull request

gitops.pull_request.pull_request_body  Any further information to add to the pu
ll request

cluster_builder                        Name of the Tanzu Build Service ClusterB
uilder to
                                        use by default on image objects managed
by the supply chain.

service_account                        Name of the service account in the names
pace where the Workload
                                        is submitted to utilize for providing re
gistry credentials to
                                        Tanzu Build Service Image objects as wel
l as deploying the
                                        application.

maven.repository.url                   The URL of the Maven repository to be us
ed when pulling Maven
                                        artifacts.  HTTP is not supported.  e.
g.: "https://repo.maven.apache.org/maven"

maven.repository.secret_name           The name of the Secret resource that con
tains the credentials used
                                        to access the Maven repository.
```

2. Create a file named `ootb-supply-chain-basic-values.yaml` that specifies the corresponding values to the properties you want to change. For example:

```
registry:
  server: REGISTRY-SERVER
  repository: REGISTRY-REPOSITORY

source:
  credentials_secret: source-creds

gitops:
  server_address: https://github.com/
  repository_owner: vmware-tanzu
  branch: main
  username: supplychain
  email: supplychain
  commit_message: supplychain@cluster.local
  credentials_secret: gitops-creds
  commit_strategy: direct

maven:
  repository:
    url: https://my-maven-repository/releases
    secret_name: my-maven-repository-credentials

cluster_builder: default
service_account: default
```

3. With the configuration ready, install the package by running:

```
tanzu package install ootb-supply-chain-basic \
  --package ootb-supply-chain-basic.tanzu.vmware.com \
  --version 0.15.6 \
```

```
  --namespace tap-install \
  --values-file ootb-supply-chain-basic-values.yaml
```

Example output:

```
\ Installing package 'ootb-supply-chain-basic.tanzu.vmware.com'
| Getting package metadata for 'ootb-supply-chain-basic.tanzu.vmware.com'
| Creating service account 'ootb-supply-chain-basic-tap-install-sa'
| Creating cluster admin role 'ootb-supply-chain-basic-tap-install-cluster-rol
e'
| Creating cluster role binding 'ootb-supply-chain-basic-tap-install-cluster-ro
lebinding'
| Creating secret 'ootb-supply-chain-basic-tap-install-values'
| Creating package resource
- Waiting for 'PackageInstall' reconciliation for 'ootb-supply-chain-basic'
/ 'PackageInstall' resource install status: Reconciling

 Added installed package 'ootb-supply-chain-basic' in namespace 'tap-install'
```

Out of the Box Supply Chain with Testing for Supply Chain Choreographer

This topic provides an overview of Out of the Box Supply Chain with Testing for Supply Chain Choreographer.

This package contains Cartographer Supply Chains that tie together a series of Kubernetes resources that drive a developer-provided workload from source code to a Kubernetes configuration ready to be deployed to a cluster. It passes the source code forward to image building only if the testing pipeline supplied by the developers runs successfully.

This package includes all the capabilities of the Out of the Box Supply Chain Basic, but adds testing with Tekton.

For workloads that use either source code or prebuilt images, it performs the following:

- Building from source code:
    1. Watching a Git Repository or local directory for changes
    2. Running tests from a developer-provided Tekton pipeline
    3. Building a container image out of the source code with Buildpacks
    4. Applying operator-defined conventions to the container definition
    5. Deploying the application to the same cluster
    6. (Beta) Alternatively, outputting a Carvel Package containing the application to a Git Repository. See Carvel Package Supply Chains.
- Using a prebuilt application image:
    1. Applying operator-defined conventions to the container definition
    2. Creating a deliverable object for deploying the application to a cluster
    3. (Beta) Alternatively, outputting a Carvel Package containing the application to a Git Repository. See Carvel Package Supply Chains.

Prerequisites

To use this supply chain, ensure:

- Out of the Box Templates is installed.
- Out of the Box Supply Chain With Testing **is installed**.
- Out of the Box Supply Chain With Testing and Scanning **is NOT installed**.
- Developer namespace is configured with the objects per Out of the Box Supply Chain Basic guidance. This supply chain is in addition to the basic one.
- (optionally) Install Out of the Box Delivery Basic, if you are willing to deploy the application to the same cluster as the workload and supply chains.

To verify that you have the right set of supply chains installed (that is, the one with Scanning and *not* the one with testing), run:

```
tanzu apps cluster-supply-chain list
```

```
NAME                        LABEL SELECTOR
source-test-to-url          apps.tanzu.vmware.com/has-tests=true,apps.tanzu.vmware.com/w
orkload-type=web
source-to-url               apps.tanzu.vmware.com/workload-type=web
```

If you see `source-test-scan-to-url` in the list, the setup is wrong: you **must not have the *source-test-scan-to-url* installed** at the same time as *source-test-to-url*.

Developer namespace

As mentioned in the prerequisites section, this supply chain builds on the previous Out of the Box Supply Chain, so only additions are included here.

To ensure that you have configured the namespace correctly, the namespace must have the following objects in it (including the ones marked with '*new*' whose explanation and details are provided below):

- **registries secrets**: Kubernetes secrets of type `kubernetes.io/dockerconfigjson` that contain credentials for pushing and pulling the container images built by the supply chain and the installation of Tanzu Application Platform.

  For more information, see Out of the Box Supply Chain Basic.
- **service account**: The identity to be used for any interaction with the Kubernetes API made by the supply chain

  For more information, see Out of the Box Supply Chain Basic.
- **rolebinding**: Grant to the identity the necessary roles for creating the resources prescribed by the supply chain.

  For more information, see Out of the Box Supply Chain Basic.
- **Tekton pipeline** (*new*): A pipeline runs whenever the supply chain hits the stage of testing the source code.

The following sections provide details about the new objects compared to Out of the Box Supply Chain Basic.

Updates to the developer Namespace

For source code testing to be present in the supply chain, a Tekton Pipeline must exist in the same namespace as the Workload so that, at the right moment, the Tekton PipelineRun object that gets created to run the tests can reference such developer-provided Pipeline.

Aside from the objects previously defined in the Out of the Box Supply Chain Basic section, you must include one more:

- `tekton/Pipeline`: the definition of a series of tasks to run against the source code that was found by earlier resources in the Supply Chain.

Tekton/Pipeline

By default, the workload is matched to the corresponding pipeline to run using labels. Pipelines must have the label `apps.tanzu.vmware.com/pipeline: test` at a minimum, but you can add additional labels for granularity. This provides a default match if no other labels are provided. The pipeline expects two parameters:

- `source-url`, an HTTP address where a `.tar.gz` file containing all the source code to be tested is found
- `source-revision`, the revision of the commit or image reference (in case of `workload.spec.source.image` being set instead of `workload.spec.source.git`)

For example:

```
apiVersion: tekton.dev/v1beta1
kind: Pipeline
metadata:
  name: developer-defined-tekton-pipeline
  labels:
    apps.tanzu.vmware.com/pipeline: test      # (!) required
spec:
  params:
    - name: source-url                        # (!) required
    - name: source-revision                   # (!) required
  tasks:
    - name: test
      params:
        - name: source-url
          value: $(params.source-url)
        - name: source-revision
          value: $(params.source-revision)
      taskSpec:
        params:
          - name: source-url
          - name: source-revision
        # Remove this step template for Tanzu Application Platform v1.9.1 when running
on OpenShift.
        stepTemplate:
          securityContext:
            allowPrivilegeEscalation: false
            runAsUser: 1000
            capabilities:
              drop:
                - ALL
            seccompProfile:
              type: "RuntimeDefault"
            runAsNonRoot: true
        steps:
          - name: test
            image: gradle
            script: |-
              cd `mktemp -d`
              wget -qO- $(params.source-url) | tar xvz -m
              ./mvnw test
```

Currently, changes to the developer-provided Tekton Pipeline do not automatically trigger a re-run of the pipeline. That is, a new Tekton PipelineRun is not automatically created if a field in the

Pipeline object is changed. As a workaround, delete the latest PipelineRun to trigger a re-run.

Note

If your cluster has Pod Security Admission enabled, you must update all pipeline tasks to adhere to the admission policy. For more information, see Tekton Tasks on a cluster with Pod Security Admission.

Allow multiple Tekton pipelines in a namespace

You can configure your developer namespace to include more than one pipeline using either of the following methods:

- Use a single pipeline running on a container image that includes testing tools and runs a common script to execute tests. This allows you to accommodate multiple workloads based in different languages in the same namespace that use a common make test script, as shown in the following example:

```
apiVersion: tekton.dev/v1beta1
kind: Pipeline
metadata:
  name: developer-defined-tekton-pipeline
  labels:
    apps.tanzu.vmware.com/pipeline: test
spec:
  #...
        steps:
          - name: test
            image: <image_that_has_JDK_and_Go>
            script: |-
              cd `mktemp -d`
              wget -qO- $(params.source-url) | tar xvz -m
              make test
```

- Update the pipeline resources to include labels that differentiate between the pipelines. For example, differentiate between Java and Go pipelines by adding labels for Java and Go:

```
apiVersion: tekton.dev/v1beta1
kind: Pipeline
metadata:
  name: java-tests
  labels:
    apps.tanzu.vmware.com/pipeline: test
    apps.tanzu.vmware.com/language: java
spec:
  #...
        steps:
          - name: test
            image: gradle
            script: |-
              # ...
              ./mvnw test
---
apiVersion: tekton.dev/v1beta1
kind: Pipeline
metadata:
  name: go-tests
  labels:
    apps.tanzu.vmware.com/pipeline: test
    apps.tanzu.vmware.com/language: go
spec:
```

```
  #...
        steps:
          - name: test
            image: golang
            script: |-
              # ...
              go test -v ./...
```

To match the correct pipeline, you add a `testing_pipeline_matching_labels` parameter to the workload. For example, if you want to match to the Java pipeline, you have the following `workload.yaml`:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: sample-java-app
  labels:
    apps.tanzu.vmware.com/has-tests: true
    apps.tanzu.vmware.com/workload-type: web
    app.kubernetes.io/part-of: sample-java-app
spec:
  params:
    - name: testing_pipeline_matching_labels
      value:
        apps.tanzu.vmware.com/pipeline: test
        apps.tanzu.vmware.com/language: java
  ...
```

This matches the workload to the pipeline with the `apps.tanzu.vmware.com/language: java` label.

Developer Workload

With the Tekton Pipeline object submitted to the same namespace as the one where the Workload will be submitted to, you can submit your Workload.

Regardless of the workflow being targeted (local development or gitops), the Workload configuration details are the same as in Out of the Box Supply Chain Basic, except that you mark the workload with tests enabled using the `has-tests` label.

For example:

```
tanzu apps workload create tanzu-java-web-app \
  --git-branch main \
  --git-repo https://github.com/vmware-tanzu/application-accelerator-samples \
  --sub-path tanzu-java-web-app \
  --label apps.tanzu.vmware.com/has-tests=true \
  --label app.kubernetes.io/part-of=tanzu-java-web-app \
  --type web
```

```
Create workload:
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1
      3 + |kind: Workload
      4 + |metadata:
      5 + |  labels:
      6 + |    apps.tanzu.vmware.com/workload-type: web
      7 + |    apps.tanzu.vmware.com/has-tests: "true"
      8 + |    app.kubernetes.io/part-of: tanzu-java-web-app
      9 + |  name: tanzu-java-web-app
     10 + |  namespace: default
     11 + |spec:
     12 + |  source:
     13 + |    git:
```

```
14 + |      ref:
15 + |        branch: main
16 + |      url: https://github.com/vmware-tanzu/application-accelerator-samples
17 + |    subPath: tanzu-java-web-app
```

Out of the Box Supply Chain with Testing for Supply Chain Choreographer

This topic provides an overview of Out of the Box Supply Chain with Testing for Supply Chain Choreographer.

This package contains Cartographer Supply Chains that tie together a series of Kubernetes resources that drive a developer-provided workload from source code to a Kubernetes configuration ready to be deployed to a cluster. It passes the source code forward to image building only if the testing pipeline supplied by the developers runs successfully.

This package includes all the capabilities of the Out of the Box Supply Chain Basic, but adds testing with Tekton.

For workloads that use either source code or prebuilt images, it performs the following:

- Building from source code:
    1. Watching a Git Repository or local directory for changes
    2. Running tests from a developer-provided Tekton pipeline
    3. Building a container image out of the source code with Buildpacks
    4. Applying operator-defined conventions to the container definition
    5. Deploying the application to the same cluster
    6. (Beta) Alternatively, outputting a Carvel Package containing the application to a Git Repository. See Carvel Package Supply Chains.
- Using a prebuilt application image:
    1. Applying operator-defined conventions to the container definition
    2. Creating a deliverable object for deploying the application to a cluster
    3. (Beta) Alternatively, outputting a Carvel Package containing the application to a Git Repository. See Carvel Package Supply Chains.

Prerequisites

To use this supply chain, ensure:

- Out of the Box Templates is installed.
- Out of the Box Supply Chain With Testing **is installed**.
- Out of the Box Supply Chain With Testing and Scanning **is NOT installed**.
- Developer namespace is configured with the objects per Out of the Box Supply Chain Basic guidance. This supply chain is in addition to the basic one.
- (optionally) Install Out of the Box Delivery Basic, if you are willing to deploy the application to the same cluster as the workload and supply chains.

To verify that you have the right set of supply chains installed (that is, the one with Scanning and *not* the one with testing), run:

```
tanzu apps cluster-supply-chain list
```

```
NAME                        LABEL SELECTOR
source-test-to-url          apps.tanzu.vmware.com/has-tests=true,apps.tanzu.vmware.com/w
orkload-type=web
source-to-url               apps.tanzu.vmware.com/workload-type=web
```

If you see `source-test-scan-to-url` in the list, the setup is wrong: you **must not have the *source-test-scan-to-url* installed** at the same time as *source-test-to-url*.

Developer namespace

As mentioned in the prerequisites section, this supply chain builds on the previous Out of the Box Supply Chain, so only additions are included here.

To ensure that you have configured the namespace correctly, the namespace must have the following objects in it (including the ones marked with '*new*' whose explanation and details are provided below):

- **registries secrets**: Kubernetes secrets of type `kubernetes.io/dockerconfigjson` that contain credentials for pushing and pulling the container images built by the supply chain and the installation of Tanzu Application Platform.

  For more information, see Out of the Box Supply Chain Basic.

- **service account**: The identity to be used for any interaction with the Kubernetes API made by the supply chain

  For more information, see Out of the Box Supply Chain Basic.

- **rolebinding**: Grant to the identity the necessary roles for creating the resources prescribed by the supply chain.

  For more information, see Out of the Box Supply Chain Basic.

- **Tekton pipeline** (*new*): A pipeline runs whenever the supply chain hits the stage of testing the source code.

The following sections provide details about the new objects compared to Out of the Box Supply Chain Basic.

Updates to the developer Namespace

For source code testing to be present in the supply chain, a Tekton Pipeline must exist in the same namespace as the Workload so that, at the right moment, the Tekton PipelineRun object that gets created to run the tests can reference such developer-provided Pipeline.

Aside from the objects previously defined in the Out of the Box Supply Chain Basic section, you must include one more:

- `tekton/Pipeline`: the definition of a series of tasks to run against the source code that was found by earlier resources in the Supply Chain.

Tekton/Pipeline

By default, the workload is matched to the corresponding pipeline to run using labels. Pipelines must have the label `apps.tanzu.vmware.com/pipeline: test` at a minimum, but you can add additional labels for granularity. This provides a default match if no other labels are provided. The pipeline expects two parameters:

- `source-url`, an HTTP address where a `.tar.gz` file containing all the source code to be tested is found

- `source-revision`, the revision of the commit or image reference (in case of `workload.spec.source.image` being set instead of `workload.spec.source.git`)

For example:

```
apiVersion: tekton.dev/v1beta1
kind: Pipeline
metadata:
  name: developer-defined-tekton-pipeline
  labels:
    apps.tanzu.vmware.com/pipeline: test      # (!) required
spec:
  params:
    - name: source-url                        # (!) required
    - name: source-revision                   # (!) required
  tasks:
    - name: test
      params:
        - name: source-url
          value: $(params.source-url)
        - name: source-revision
          value: $(params.source-revision)
      taskSpec:
        params:
          - name: source-url
          - name: source-revision
        # Remove this step template for Tanzu Application Platform v1.9.1 when running
on OpenShift.
        stepTemplate:
          securityContext:
            allowPrivilegeEscalation: false
            runAsUser: 1000
            capabilities:
              drop:
                - ALL
            seccompProfile:
              type: "RuntimeDefault"
            runAsNonRoot: true
        steps:
          - name: test
            image: gradle
            script: |-
              cd `mktemp -d`
              wget -qO- $(params.source-url) | tar xvz -m
              ./mvnw test
```

Currently, changes to the developer-provided Tekton Pipeline do not automatically trigger a re-run of the pipeline. That is, a new Tekton PipelineRun is not automatically created if a field in the Pipeline object is changed. As a workaround, delete the latest PipelineRun to trigger a re-run.

Note

If your cluster has Pod Security Admission enabled, you must update all pipeline tasks to adhere to the admission policy. For more information, see Tekton Tasks on a cluster with Pod Security Admission.

Allow multiple Tekton pipelines in a namespace

You can configure your developer namespace to include more than one pipeline using either of the following methods:

- Use a single pipeline running on a container image that includes testing tools and runs a common script to execute tests. This allows you to accommodate multiple workloads based in different languages in the same namespace that use a common make test script, as shown in the following example:

```
apiVersion: tekton.dev/v1beta1
kind: Pipeline
metadata:
  name: developer-defined-tekton-pipeline
  labels:
    apps.tanzu.vmware.com/pipeline: test
spec:
  #...
        steps:
          - name: test
            image: <image_that_has_JDK_and_Go>
            script: |-
              cd `mktemp -d`
              wget -qO- $(params.source-url) | tar xvz -m
              make test
```

- Update the pipeline resources to include labels that differentiate between the pipelines. For example, differentiate between Java and Go pipelines by adding labels for Java and Go:

```
apiVersion: tekton.dev/v1beta1
kind: Pipeline
metadata:
  name: java-tests
  labels:
    apps.tanzu.vmware.com/pipeline: test
    apps.tanzu.vmware.com/language: java
spec:
  #...
        steps:
          - name: test
            image: gradle
            script: |-
              # ...
              ./mvnw test
---
apiVersion: tekton.dev/v1beta1
kind: Pipeline
metadata:
  name: go-tests
  labels:
    apps.tanzu.vmware.com/pipeline: test
    apps.tanzu.vmware.com/language: go
spec:
  #...
        steps:
          - name: test
            image: golang
            script: |-
              # ...
              go test -v ./...
```

To match the correct pipeline, you add a `testing_pipeline_matching_labels` parameter to the workload. For example, if you want to match to the Java pipeline, you have the following `workload.yaml`:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
```

```
  name: sample-java-app
  labels:
    apps.tanzu.vmware.com/has-tests: true
    apps.tanzu.vmware.com/workload-type: web
    app.kubernetes.io/part-of: sample-java-app
spec:
  params:
    - name: testing_pipeline_matching_labels
      value:
        apps.tanzu.vmware.com/pipeline: test
        apps.tanzu.vmware.com/language: java
  ...
```

This matches the workload to the pipeline with the `apps.tanzu.vmware.com/language: java` label.

Developer Workload

With the Tekton Pipeline object submitted to the same namespace as the one where the Workload will be submitted to, you can submit your Workload.

Regardless of the workflow being targeted (local development or gitops), the Workload configuration details are the same as in Out of the Box Supply Chain Basic, except that you mark the workload with tests enabled using the `has-tests` label.

For example:

```
tanzu apps workload create tanzu-java-web-app \
  --git-branch main \
  --git-repo https://github.com/vmware-tanzu/application-accelerator-samples \
  --sub-path tanzu-java-web-app \
  --label apps.tanzu.vmware.com/has-tests=true \
  --label app.kubernetes.io/part-of=tanzu-java-web-app \
  --type web
```

```
Create workload:
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1
      3 + |kind: Workload
      4 + |metadata:
      5 + |  labels:
      6 + |    apps.tanzu.vmware.com/workload-type: web
      7 + |    apps.tanzu.vmware.com/has-tests: "true"
      8 + |    app.kubernetes.io/part-of: tanzu-java-web-app
      9 + |  name: tanzu-java-web-app
     10 + |  namespace: default
     11 + |spec:
     12 + |  source:
     13 + |    git:
     14 + |      ref:
     15 + |        branch: main
     16 + |      url: https://github.com/vmware-tanzu/application-accelerator-samples
     17 + |    subPath: tanzu-java-web-app
```

Install Out of the Box Supply Chain with Testing for Supply Chain Choreographer

This topic describes how you can install Out of the Box Supply Chain with Testing for Supply Chain Choreographer from the Tanzu Application Platform package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install Out of the Box Supply Chain with Testing. For more information about profiles, see Components and installation profiles.

The Out of the Box Supply Chain with Testing package provides a ClusterSupplyChain that brings an application from source code to a deployed instance that:

- Runs in a Kubernetes environment.
- Runs developer-provided tests in the form of Tekton/Pipeline objects to validate the source code before building container images.

Prerequisites

Before installing Out of the Box Supply Chain with Testing:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- Install cartographer. For more information, see Install Supply Chain Choreographer.
- Install Out of the Box Delivery Basic
- Install Out of the Box Templates

Install

Install by following these steps:

1. Ensure you do not have Out of the Box Supply Chain With Testing and Scanning (`ootb-supply-chain-testing-scanning.tanzu.vmware.com`) installed:
    1. Run the following command:

        ```
        tanzu package installed list --namespace tap-install
        ```

    2. Verify `ootb-supply-chain-testing-scanning` is in the output:

        ```
        NAME                                PACKAGE-NAME
        ootb-delivery-basic                 ootb-delivery-basic.tanzu.vmware.com
        ootb-supply-chain-basic             ootb-supply-chain-basic.tanzu.vmware.
        com
        ootb-templates                      ootb-templates.tanzu.vmware.com
        ```

    3. If you see `ootb-supply-chain-testing-scanning` in the list, uninstall it by running:

        ```
        tanzu package installed delete ootb-supply-chain-testing-scanning --names
        pace tap-install
        ```

        Example output:

        ```
        Deleting installed package 'ootb-supply-chain-testing-scanning' in namesp
        ace 'tap-install'.
        Are you sure? [y/N]: y

        | Uninstalling package 'ootb-supply-chain-testing-scanning' from namespac
        e 'tap-install'
        \ Getting package install for 'ootb-supply-chain-testing-scanning'
        - Deleting package install 'ootb-supply-chain-testing-scanning' from name
        space 'tap-install'
        | Deleting admin role 'ootb-supply-chain-testing-scanning-tap-install-clu
        ```

```
ster-role'
| Deleting role binding 'ootb-supply-chain-testing-scanning-tap-install-c
luster-rolebinding'
| Deleting secret 'ootb-supply-chain-testing-scanning-tap-install-values'
| Deleting service account 'ootb-supply-chain-testing-scanning-tap-instal
l-sa'

 Uninstalled package 'ootb-supply-chain-testing-scanning' from namespace
'tap-install'
```

2. Verify that the values of the package can be configured by referencing the values below:

```
KEY                                DESCRIPTION

registry.repository                 Name of the repository in the image regi
stry server where the application
                                    images from the workload should be pushe
d (required).

registry.server                     Name of the registry server where applic
ation images should be pushed to
                                    (required).

source.credentials_secret           Name of a Secret in the developer namesp
ace which provides the credentials to the
                                    source code repository.

gitops.server_address               Default server address to be used for fo
rming Git URLs for pushing
                                    Kubernetes configuration produced by the
supply chain. This must
                                    include the scheme/protocol (e.g. http
s:// or ssh://)

gitops.repository_owner             Default project or user of the repositor
y. Used to create URLs for pushing
                                    Kubernetes configuration produced by the
supply chain.

gitops.repository_name              Default repository name used for forming
Git URLs for pushing Kubernetes
                                    configuration produced by the supply cha
in.

gitops.username                     Default user name to be used for the com
mits produced by the supply chain.

gitops.branch                       Default branch to use for pushing Kubern
etes configuration files produced
                                    by the supply chain.

gitops.commit_message               Default git commit message to write when
publishing Kubernetes
                                    configuration files produces by the supp
ly chain to git.

gitops.email                        Default user email to be used for the co
mmits produced by the supply chain.

gitops.credentials_secret           Name of a Secret in the developer namesp
ace which provides the credentials to the
                                    GitOps repository.

gitops.ssh_secret                   DEPRECATED: Use gitops.credentials_secre
t and source.credentials_secret instead.
                                    Name of the default Secret containing SS
```

```
H credentials to lookup in the
                                        developer namespace for the supply chain
to fetch source code from and
                                        push configuration to.

gitops.commit_strategy                  Specification of how commits are made to
the branch; directly or through a
                                        pull request.

gitops.repository_prefix                DEPRECATED: Use server_address and repos
itory_owner instead.
                                        Default prefix to be used for forming Gi
t SSH URLs for pushing Kubernetes
                                        configuration produced by the supply cha
in.

gitops.pull_request.server_kind          The git source control platform used

gitops.pull_request.commit_branch        The branch to which commits will be mad
e, before opening a pull request
                                        to the branch specified in .gitops.branc
h If the string "" is specified,
                                        an essentially random string will be use
d for the branch name, in order
                                        to prevent collisions.

gitops.pull_request.pull_request_title  The title for the pull request

gitops.pull_request.pull_request_body   Any further information to add to the p
ull request

cluster_builder           Name of the Tanzu Build Service ClusterBuilder to
                          use by default on image objects managed by the supply
chain.

service_account           Name of the service account in the namespace where th
e Workload
                          is submitted to utilize for providing registry creden
tials to
                          Tanzu Build Service Image objects as well as deployin
g the
                          application.
```

3. Create a file named `ootb-supply-chain-testing-values.yaml` that specifies the corresponding values to the properties you want to change. For example:

```
registry:
  server: REGISTRY-SERVER
  repository: REGISTRY-REPOSITORY

source:
  credentials_secret: source-creds

gitops:
  server_address: https://github.com/
  repository_owner: vmware-tanzu
  branch: main
  username: supplychain
  email: supplychain
  commit_message: supplychain@cluster.local
  credentials_secret: gitops-creds
  commit_strategy: direct

cluster_builder: default
service_account: default
```

4. With the configuration ready, install the package by running:

```
tanzu package install ootb-supply-chain-testing \
  --package ootb-supply-chain-testing.tanzu.vmware.com \
  --version 0.15.6 \
  --namespace tap-install \
  --values-file ootb-supply-chain-testing-values.yaml
```

Example output:

```
\ Installing package 'ootb-supply-chain-testing.tanzu.vmware.com'
| Getting package metadata for 'ootb-supply-chain-testing.tanzu.vmware.com'
| Creating service account 'ootb-supply-chain-testing-tap-install-sa'
| Creating cluster admin role 'ootb-supply-chain-testing-tap-install-cluster-ro
le'
| Creating cluster role binding 'ootb-supply-chain-testing-tap-install-cluster-
rolebinding'
| Creating secret 'ootb-supply-chain-testing-tap-install-values'
| Creating package resource
- Waiting for 'PackageInstall' reconciliation for 'ootb-supply-chain-testing'
\ 'PackageInstall' resource install status: Reconciling

Added installed package 'ootb-supply-chain-testing' in namespace 'tap-install'
```

Out of the Box Supply Chain with Testing and Scanning for Supply Chain Choreographer

This topic provides an overview of Out of the Box Supply Chain with Testing and Scanning for Supply Chain Choreographer.

This package contains Cartographer Supply Chains that tie together a series of Kubernetes resources that drive a developer-provided workload from source code to a Kubernetes configuration ready to be deployed to a cluster. It contains supply chains that pass the source code through testing and vulnerability scanning, and also the container image.

This package includes all the capabilities of the Out of the Box Supply Chain With Testing, but adds source and image scanning using Grype.

Workloads that use source code or prebuilt images perform the following:

- Building from source code:
    1. Watching a Git Repository or local directory for changes
    2. Running tests from a developer-provided Tekton pipeline
    3. Scanning the source code for known vulnerabilities using Grype
    4. Building a container image out of the source code with Buildpacks
    5. Scanning the image for known vulnerabilities
    6. Applying operator-defined conventions to the container definition
    7. Deploying the application to the same cluster
    8. (Beta) Alternatively, outputting a Carvel Package containing the application to a Git repository. See Carvel Package Supply Chains.
- Using a prebuilt application image:
    1. Scanning the image for known vulnerabilities
    2. Applying operator-defined conventions to the container definition

3. Creating a deliverable object for deploying the application to a cluster
4. (Beta) Alternatively, outputting a Carvel package containing the application to a Git repository. See Carvel Package Supply Chains.

Prerequisites

To use this supply chain, verify that:

- Out of the Box Templates is installed.
- Out of the Box Supply Chain With Testing **is NOT installed**.
- Out of the Box Supply Chain With Testing and Scanning **is installed**.
- The developer namespace is configured with the objects according to Out of the Box Supply Chain With Testing guidance. This supply chain exists in addition to the Supply Chain with testing.
- (Optional) Out of the Box Delivery Basic is installed if you want to deploy the application to the same cluster as the workload and supply chains.

Verify that you have the supply chains with scanning, not with testing, installed. Run:

```
tanzu apps cluster-supply-chain list
```

```
NAME                       LABEL SELECTOR
source-test-scan-to-url    apps.tanzu.vmware.com/has-tests=true,apps.tanzu.vmware.com/w
orkload-type=web
source-to-url              apps.tanzu.vmware.com/workload-type=web
```

If you see `source-test-to-url` in the list, the setup is wrong. You **must not have the *source-test-to-url* installed** at the same time as *source-test-scan-to-url*.

Developer namespace

This example builds on the previous Out of the Box Supply Chain examples, so only additions are included here.

To ensure that you configured the namespace correctly, it is important that the namespace has the objects that you configured in the other supply chain setups:

- **registries secrets**: Kubernetes secrets of type `kubernetes.io/dockerconfigjson` that contain credentials for pushing and pulling the container images built by the supply chain and the installation of Tanzu Application Platform.
- **service account**: The identity to be used for any interaction with the Kubernetes API made by the supply chain.
- **rolebinding**: Grant to the identity the necessary roles for creating the resources prescribed by the supply chain.

  For more information about the preceding objects, see Out of the Box Supply Chain Basic.
- **Tekton pipeline**: A pipeline runs whenever the supply chain hits the stage of testing the source code.

  For more information, see Out of the Box Supply Chain Testing.

And the new objects, that you create here:

- **scan policy**: Defines what to do with the results taken from scanning the source code and image produced. For more information, see ScanPolicy section.

- **source scan template**: A template of how TaskRuns are created for scanning the source code. See ScanTemplate section.
- **image scan template**: A template of how TaskRuns are created for scanning the image produced by the supply chain. See ScanTemplate section.

The following section includes details about the new objects, compared to Out of the Box Supply Chain With Testing.

Updates to the developer namespace

For source and image scans, scan templates and scan policies must exist in the same namespace as the workload. These define:

- `ScanTemplate`: how to run a scan, allowing one to change details about the execution of the scan (either for images or source code)
- `ScanPolicy`: how to evaluate whether the artifacts scanned are compliant. For example, allowing one to be either very strict, or restrictive about particular vulnerabilities found.

The names of the objects **must** match the names in the example with default installation configurations. This is overridden either by using the `ootb_supply_chain_testing_scanning` package configuration in the `tap-values.yaml` file or by using workload parameters:

- To override by using the `ootb_supply_chain_testing_scanning` package configuration, make the following modification to your `tap-values.yaml` file and perform a Tanzu Application Platform update.

  ```
  ootb_supply_chain_testing_scanning:
    scanning:
      source:
        policy: SCAN-POLICY
        template: SCAN-TEMPLATE
      image:
        policy: SCAN-POLICY
        template: SCAN-TEMPLATE
  ```

  Where `SCAN-POLICY` and `SCAN-TEMPLATE` are the names of the `ScanPolicy` and `ScanTemplate`.

- To override through workload parameters, use the these commands.

  ```
  tanzu apps workload apply WORKLOAD --param "scanning_source_policy=SCAN-POLICY"
  -n DEV-NAMESPACE
  tanzu apps workload apply WORKLOAD --param "scanning_source_template=SCAN-TEMPL
  ATE" -n DEV-NAMESPACE
  ```

  Where:

  - `WORKLOAD` is the name of the workload.
  - `SCAN-POLICY` and `SCAN-TEMPLATE` are the names of the `ScanPolicy` and `ScanTemplate`.
  - `DEV-NAMESPACE` is the developer namespace.

  For more information, see Create or update a workload.

ScanPolicy

The ScanPolicy defines a set of rules to evaluate for a particular scan to consider the artifacts (image or source code) either compliant or not.

When a ImageScan or SourceScan is created to run a scan, those reference a policy whose name **must** match the following sample `scan-policy`:

```
---
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ScanPolicy
metadata:
  name: scan-policy
  labels:
    'app.kubernetes.io/part-of': 'enable-in-gui'
spec:
  regoFile: |
    package main

    # Accepted Values: "Critical", "High", "Medium", "Low", "Negligible", "UnknownSeve
rity"
    notAllowedSeverities := ["Critical", "High", "UnknownSeverity"]
    ignoreCves := []

    contains(array, elem) = true {
      array[_] = elem
    } else = false { true }

    isSafe(match) {
      severities := { e | e := match.ratings.rating.severity } | { e | e := match.rati
ngs.rating[_].severity }
      some i
      fails := contains(notAllowedSeverities, severities[i])
      not fails
    }

    isSafe(match) {
      ignore := contains(ignoreCves, match.id)
      ignore
    }

    deny[msg] {
      comps := { e | e := input.bom.components.component } | { e | e := input.bom.comp
onents.component[_] }
      some i
      comp := comps[i]
      vulns := { e | e := comp.vulnerabilities.vulnerability } | { e | e := comp.vulne
rabilities.vulnerability[_] }
      some j
      vuln := vulns[j]
      ratings := { e | e := vuln.ratings.rating.severity } | { e | e := vuln.ratings.r
ating[_].severity }
      not isSafe(vuln)
      msg = sprintf("CVE %s %s %s", [comp.name, vuln.id, ratings])
    }
```

See Writing Policy Templates.

ScanTemplate

A ScanTemplate defines the PodTemplateSpec used by a TaskRun to run a particular scan (image or source). When the supply chain initiates an ImageScan or SourceScan, they reference these templates which must live in the same namespace as the workload with the names matching the following:

- source scanning (`blob-source-scan-template`)
- image scanning (`private-image-scan-template`)

You can install the Grype ScanTemplates in the namespace that you are writing the workload to with Namespace Provisioner. See Provision developer namespaces in Namespace Provisioner.

1. Label the namespace that you are writing the workload to with the default *namespace_selector* `apps.tanzu.vmware.com/tap-ns=""`.

```
kubectl label namespaces YOUR-DEV-NAMESPACE apps.tanzu.vmware.com/tap-ns=""
```

Note

Although you can customize the templates, if you are following the Getting Started guide, VMware recommends that you follow what is provided in the installation of `grype.scanning.apps.tanzu.vmware.com`. For more information, see About Source and Image Scans.

Enable storing scan results

To enable SCST - Scan to store scan results by using SCST - Store, see Developer namespace setup for exporting the SCST - Store CA certificate and authentication token to the developer namespace.

Allow multiple Tekton pipelines in a namespace

You can configure your developer namespace to include more than one pipeline using either of the following methods:

- Use a single pipeline running on a container image that includes testing tools and runs a common script to execute tests. This allows you to accommodate multiple workloads based in different languages in the same namespace that use a common make test script, as shown in the following example:

```
apiVersion: tekton.dev/v1beta1
kind: Pipeline
metadata:
  name: developer-defined-tekton-pipeline
  labels:
    apps.tanzu.vmware.com/pipeline: test
spec:
  #...
        steps:
          - name: test
            image: <image_that_has_JDK_and_Go>
            script: |-
              cd `mktemp -d`
              wget -qO- $(params.source-url) | tar xvz -m
              make test
```

- Update the pipeline resources to include labels that differentiate between the pipelines. For example, differentiate between Java and Go pipelines by adding labels for Java and Go:

```
apiVersion: tekton.dev/v1beta1
kind: Pipeline
metadata:
  name: java-tests
  labels:
    apps.tanzu.vmware.com/pipeline: test
    apps.tanzu.vmware.com/language: java
spec:
  #...
        steps:
          - name: test
```

```
            image: gradle
            script: |-
              # ...
              ./mvnw test
---
apiVersion: tekton.dev/v1beta1
kind: Pipeline
metadata:
  name: go-tests
  labels:
    apps.tanzu.vmware.com/pipeline: test
    apps.tanzu.vmware.com/language: go
spec:
  #...
        steps:
          - name: test
            image: golang
            script: |-
              # ...
              go test -v ./...
```

To match the correct pipeline, you add a `testing_pipeline_matching_labels` parameter to the workload. For example, if you want to match to the Java pipeline, you have the following `workload.yaml`:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: sample-java-app
  labels:
    apps.tanzu.vmware.com/has-tests: true
    apps.tanzu.vmware.com/workload-type: web
    app.kubernetes.io/part-of: sample-java-app
spec:
  params:
    - name: testing_pipeline_matching_labels
      value:
        apps.tanzu.vmware.com/pipeline: test
        apps.tanzu.vmware.com/language: java
  ...
```

This matches the workload to the pipeline with the `apps.tanzu.vmware.com/language: java` label.

Developer workload

With the ScanPolicy and ScanTemplate objects, with the required names set, submitted to the same namespace where the workload is submitted, you are ready to submit your workload.

Regardless of the workflow being targeted, such as local development or GitOps, the workload configuration details are the same as in Out of the Box Supply Chain Basic, except that you mark the workload as having tests enabled.

For example:

```
tanzu apps workload create tanzu-java-web-app \
  --git-branch main \
  --git-repo https://github.com/vmware-tanzu/application-accelerator-samples \
  --sub-path tanzu-java-web-app \
  --label apps.tanzu.vmware.com/has-tests=true \
  --label app.kubernetes.io/part-of=tanzu-java-web-app \
  --type web
```

```
Create workload:
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1
      3 + |kind: Workload
      4 + |metadata:
      5 + |  labels:
      6 + |    apps.tanzu.vmware.com/workload-type: web
      7 + |    apps.tanzu.vmware.com/has-tests: "true"
      8 + |    app.kubernetes.io/part-of: tanzu-java-web-app
      9 + |  name: tanzu-java-web-app
     10 + |  namespace: default
     11 + |spec:
     12 + |  source:
     13 + |    git:
     14 + |      ref:
     15 + |        branch: main
     16 + |      url: https://github.com/vmware-tanzu/application-accelerator-samples
     17 + |    subPath: tanzu-java-web-app
```

CVE triage workflow

The Supply Chain halts progression if either a SourceScan (`sourcescans.scanning.apps.tanzu.vmware.com`) or an ImageScan (`imagescans.scanning.apps.tanzu.vmware.com`) fails policy enforcement through the ScanPolicy (`scanpolicies.scanning.apps.tanzu.vmware.com`). This can prevent source code from building or images deploying that contain vulnerabilities that are in violation of the user-defined scan policy. For information about learning how to handle these vulnerabilities and unblock your Supply Chain, see Triaging and Remediating CVEs.

Scan Images using a different scanner

Supply Chain Security Tools - Scan includes additional integrations for running an image scan using Snyk and VMware Carbon Black.

Out of the Box Supply Chain with Testing and Scanning for Supply Chain Choreographer

This topic provides an overview of Out of the Box Supply Chain with Testing and Scanning for Supply Chain Choreographer.

This package contains Cartographer Supply Chains that tie together a series of Kubernetes resources that drive a developer-provided workload from source code to a Kubernetes configuration ready to be deployed to a cluster. It contains supply chains that pass the source code through testing and vulnerability scanning, and also the container image.

This package includes all the capabilities of the Out of the Box Supply Chain With Testing, but adds source and image scanning using Grype.

Workloads that use source code or prebuilt images perform the following:

- Building from source code:
    1. Watching a Git Repository or local directory for changes
    2. Running tests from a developer-provided Tekton pipeline
    3. Scanning the source code for known vulnerabilities using Grype
    4. Building a container image out of the source code with Buildpacks
    5. Scanning the image for known vulnerabilities

6. Applying operator-defined conventions to the container definition
7. Deploying the application to the same cluster
8. (Beta) Alternatively, outputting a Carvel Package containing the application to a Git repository. See Carvel Package Supply Chains.

- Using a prebuilt application image:
    1. Scanning the image for known vulnerabilities
    2. Applying operator-defined conventions to the container definition
    3. Creating a deliverable object for deploying the application to a cluster
    4. (Beta) Alternatively, outputting a Carvel package containing the application to a Git repository. See Carvel Package Supply Chains.

Prerequisites

To use this supply chain, verify that:

- Out of the Box Templates is installed.
- Out of the Box Supply Chain With Testing **is NOT installed**.
- Out of the Box Supply Chain With Testing and Scanning **is installed**.
- The developer namespace is configured with the objects according to Out of the Box Supply Chain With Testing guidance. This supply chain exists in addition to the Supply Chain with testing.
- (Optional) Out of the Box Delivery Basic is installed if you want to deploy the application to the same cluster as the workload and supply chains.

Verify that you have the supply chains with scanning, not with testing, installed. Run:

```
tanzu apps cluster-supply-chain list
```

```
NAME                       LABEL SELECTOR
source-test-scan-to-url    apps.tanzu.vmware.com/has-tests=true,apps.tanzu.vmware.com/w
orkload-type=web
source-to-url              apps.tanzu.vmware.com/workload-type=web
```

If you see `source-test-to-url` in the list, the setup is wrong. You **must not have the *source-test-to-url* installed** at the same time as *source-test-scan-to-url*.

Developer namespace

This example builds on the previous Out of the Box Supply Chain examples, so only additions are included here.

To ensure that you configured the namespace correctly, it is important that the namespace has the objects that you configured in the other supply chain setups:

- **registries secrets**: Kubernetes secrets of type `kubernetes.io/dockerconfigjson` that contain credentials for pushing and pulling the container images built by the supply chain and the installation of Tanzu Application Platform.
- **service account**: The identity to be used for any interaction with the Kubernetes API made by the supply chain.
- **rolebinding**: Grant to the identity the necessary roles for creating the resources prescribed by the supply chain.

For more information about the preceding objects, see Out of the Box Supply Chain Basic.

- **Tekton pipeline**: A pipeline runs whenever the supply chain hits the stage of testing the source code.

  For more information, see Out of the Box Supply Chain Testing.

And the new objects, that you create here:

- **scan policy**: Defines what to do with the results taken from scanning the source code and image produced. For more information, see ScanPolicy section.
- **source scan template**: A template of how TaskRuns are created for scanning the source code. See ScanTemplate section.
- **image scan template**: A template of how TaskRuns are created for scanning the image produced by the supply chain. See ScanTemplate section.

The following section includes details about the new objects, compared to Out of the Box Supply Chain With Testing.

Updates to the developer namespace

For source and image scans, scan templates and scan policies must exist in the same namespace as the workload. These define:

- `ScanTemplate`: how to run a scan, allowing one to change details about the execution of the scan (either for images or source code)
- `ScanPolicy`: how to evaluate whether the artifacts scanned are compliant. For example, allowing one to be either very strict, or restrictive about particular vulnerabilities found.

The names of the objects **must** match the names in the example with default installation configurations. This is overridden either by using the `ootb_supply_chain_testing_scanning` package configuration in the `tap-values.yaml` file or by using workload parameters:

- To override by using the `ootb_supply_chain_testing_scanning` package configuration, make the following modification to your `tap-values.yaml` file and perform a Tanzu Application Platform update.

  ```
  ootb_supply_chain_testing_scanning:
    scanning:
      source:
        policy: SCAN-POLICY
        template: SCAN-TEMPLATE
      image:
        policy: SCAN-POLICY
        template: SCAN-TEMPLATE
  ```

  Where `SCAN-POLICY` and `SCAN-TEMPLATE` are the names of the `ScanPolicy` and `ScanTemplate`.

- To override through workload parameters, use the these commands.

  ```
  tanzu apps workload apply WORKLOAD --param "scanning_source_policy=SCAN-POLICY"
  -n DEV-NAMESPACE
  tanzu apps workload apply WORKLOAD --param "scanning_source_template=SCAN-TEMPL
  ATE" -n DEV-NAMESPACE
  ```

  Where:

  - `WORKLOAD` is the name of the workload.
  - `SCAN-POLICY` and `SCAN-TEMPLATE` are the names of the `ScanPolicy` and `ScanTemplate`.
  - `DEV-NAMESPACE` is the developer namespace.

For more information, see Create or update a workload.

ScanPolicy

The ScanPolicy defines a set of rules to evaluate for a particular scan to consider the artifacts (image or source code) either compliant or not.

When a ImageScan or SourceScan is created to run a scan, those reference a policy whose name **must** match the following sample `scan-policy`:

```
---
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ScanPolicy
metadata:
  name: scan-policy
  labels:
    'app.kubernetes.io/part-of': 'enable-in-gui'
spec:
  regoFile: |
    package main

    # Accepted Values: "Critical", "High", "Medium", "Low", "Negligible", "UnknownSeve
rity"
    notAllowedSeverities := ["Critical", "High", "UnknownSeverity"]
    ignoreCves := []

    contains(array, elem) = true {
      array[_] = elem
    } else = false { true }

    isSafe(match) {
      severities := { e | e := match.ratings.rating.severity } | { e | e := match.rati
ngs.rating[_].severity }
      some i
      fails := contains(notAllowedSeverities, severities[i])
      not fails
    }

    isSafe(match) {
      ignore := contains(ignoreCves, match.id)
      ignore
    }

    deny[msg] {
      comps := { e | e := input.bom.components.component } | { e | e := input.bom.comp
onents.component[_] }
      some i
      comp := comps[i]
      vulns := { e | e := comp.vulnerabilities.vulnerability } | { e | e := comp.vulne
rabilities.vulnerability[_] }
      some j
      vuln := vulns[j]
      ratings := { e | e := vuln.ratings.rating.severity } | { e | e := vuln.ratings.r
ating[_].severity }
      not isSafe(vuln)
      msg = sprintf("CVE %s %s %s", [comp.name, vuln.id, ratings])
    }
```

See Writing Policy Templates.

ScanTemplate

A ScanTemplate defines the PodTemplateSpec used by a TaskRun to run a particular scan (image or source). When the supply chain initiates an ImageScan or SourceScan, they reference these templates which must live in the same namespace as the workload with the names matching the following:

- source scanning (`blob-source-scan-template`)
- image scanning (`private-image-scan-template`)

You can install the Grype ScanTemplates in the namespace that you are writing the workload to with Namespace Provisioner. See Provision developer namespaces in Namespace Provisioner.

1. Label the namespace that you are writing the workload to with the default *namespace_selector* `apps.tanzu.vmware.com/tap-ns=""`.

   ```
   kubectl label namespaces YOUR-DEV-NAMESPACE apps.tanzu.vmware.com/tap-ns=""
   ```

Note

Although you can customize the templates, if you are following the Getting Started guide, VMware recommends that you follow what is provided in the installation of `grype.scanning.apps.tanzu.vmware.com`. For more information, see About Source and Image Scans.

Enable storing scan results

To enable SCST - Scan to store scan results by using SCST - Store, see Developer namespace setup for exporting the SCST - Store CA certificate and authentication token to the developer namespace.

Allow multiple Tekton pipelines in a namespace

You can configure your developer namespace to include more than one pipeline using either of the following methods:

- Use a single pipeline running on a container image that includes testing tools and runs a common script to execute tests. This allows you to accommodate multiple workloads based in different languages in the same namespace that use a common make test script, as shown in the following example:

  ```
  apiVersion: tekton.dev/v1beta1
  kind: Pipeline
  metadata:
    name: developer-defined-tekton-pipeline
    labels:
      apps.tanzu.vmware.com/pipeline: test
  spec:
    #...
          steps:
            - name: test
              image: <image_that_has_JDK_and_Go>
              script: |-
                cd `mktemp -d`
                wget -qO- $(params.source-url) | tar xvz -m
                make test
  ```

- Update the pipeline resources to include labels that differentiate between the pipelines. For example, differentiate between Java and Go pipelines by adding labels for Java and Go:

```
apiVersion: tekton.dev/v1beta1
kind: Pipeline
metadata:
  name: java-tests
  labels:
    apps.tanzu.vmware.com/pipeline: test
    apps.tanzu.vmware.com/language: java
spec:
  #...
        steps:
          - name: test
            image: gradle
            script: |-
              # ...
              ./mvnw test
---
apiVersion: tekton.dev/v1beta1
kind: Pipeline
metadata:
  name: go-tests
  labels:
    apps.tanzu.vmware.com/pipeline: test
    apps.tanzu.vmware.com/language: go
spec:
  #...
        steps:
          - name: test
            image: golang
            script: |-
              # ...
              go test -v ./...
```

To match the correct pipeline, you add a `testing_pipeline_matching_labels` parameter to the workload. For example, if you want to match to the Java pipeline, you have the following `workload.yaml`:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: sample-java-app
  labels:
    apps.tanzu.vmware.com/has-tests: true
    apps.tanzu.vmware.com/workload-type: web
    app.kubernetes.io/part-of: sample-java-app
spec:
  params:
    - name: testing_pipeline_matching_labels
      value:
        apps.tanzu.vmware.com/pipeline: test
        apps.tanzu.vmware.com/language: java
  ...
```

This matches the workload to the pipeline with the `apps.tanzu.vmware.com/language: java` label.

Developer workload

With the ScanPolicy and ScanTemplate objects, with the required names set, submitted to the same namespace where the workload is submitted, you are ready to submit your workload.

Regardless of the workflow being targeted, such as local development or GitOps, the workload configuration details are the same as in Out of the Box Supply Chain Basic, except that you mark the workload as having tests enabled.

For example:

```
tanzu apps workload create tanzu-java-web-app \
  --git-branch main \
  --git-repo https://github.com/vmware-tanzu/application-accelerator-samples \
  --sub-path tanzu-java-web-app \
  --label apps.tanzu.vmware.com/has-tests=true \
  --label app.kubernetes.io/part-of=tanzu-java-web-app \
  --type web
```

```
Create workload:
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1
      3 + |kind: Workload
      4 + |metadata:
      5 + |  labels:
      6 + |    apps.tanzu.vmware.com/workload-type: web
      7 + |    apps.tanzu.vmware.com/has-tests: "true"
      8 + |    app.kubernetes.io/part-of: tanzu-java-web-app
      9 + |  name: tanzu-java-web-app
     10 + |  namespace: default
     11 + |spec:
     12 + |  source:
     13 + |    git:
     14 + |      ref:
     15 + |        branch: main
     16 + |      url: https://github.com/vmware-tanzu/application-accelerator-samples
     17 + |    subPath: tanzu-java-web-app
```

CVE triage workflow

The Supply Chain halts progression if either a SourceScan (`sourcescans.scanning.apps.tanzu.vmware.com`) or an ImageScan (`imagescans.scanning.apps.tanzu.vmware.com`) fails policy enforcement through the ScanPolicy (`scanpolicies.scanning.apps.tanzu.vmware.com`). This can prevent source code from building or images deploying that contain vulnerabilities that are in violation of the user-defined scan policy. For information about learning how to handle these vulnerabilities and unblock your Supply Chain, see Triaging and Remediating CVEs.

Scan Images using a different scanner

Supply Chain Security Tools - Scan includes additional integrations for running an image scan using Snyk and VMware Carbon Black.

Install Out of the Box Supply Chain with Testing and Scanning for Supply Chain Choreographer

This topic describes how you can install Out of the Box Supply Chain with Testing and Scanning for Supply Chain Choreographer from the Tanzu Application Platform package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install Out of the Box Supply Chain with Testing and Scanning. For more information about profiles, see Components and installation profiles.

The Out of the Box Supply Chain with Testing and Scanning package provides a ClusterSupplyChain that brings an application from source code to a deployed instance that:

- Runs in a Kubernetes environment.
- Performs validations in terms of running application tests.
- Scans the source code and image for vulnerabilities.

Install

To install Out of the Box Supply Chain with Testing and Scanning:

1. Complete all prerequisites to install Tanzu Application Platform.
2. Install Supply Chain Choreographer.
3. Install Out of the Box Delivery Basic.
4. Install Tekton Pipelines.
5. Install Out of the Box Templates.
6. Ensure you do not have Out of The Box Supply Chain With Testing (`ootb-supply-chain-testing.tanzu.vmware.com`) installed:
    1. Run the following command:

        ```
        tanzu package installed list --namespace tap-install
        ```

    2. Inspect to determine if `ootb-supply-chain-testing` is in the output:

        ```
        NAME                                PACKAGE-NAME
        ootb-delivery-basic                 ootb-delivery-basic.tanzu.vmware.com
        ootb-supply-chain-testing           ootb-supply-chain-testing.tanzu.vmwar
        e.com
        ootb-templates                      ootb-templates.tanzu.vmware.com
        ```

    3. If you see `ootb-supply-chain-testing` in the list, uninstall it by running:

        ```
        tanzu package installed delete ootb-supply-chain-testing --namespace tap-
        install
        ```

        Example output:

        ```
        Deleting installed package 'ootb-supply-chain-testing' in namespace 'tap-
        install'.
        Are you sure? [y/N]: y

        | Uninstalling package 'ootb-supply-chain-testing' from namespace 'tap-in
        stall'
        \ Getting package install for 'ootb-supply-chain-testing'
        - Deleting package install 'ootb-supply-chain-testing' from namespace 'ta
        p-install'
        | Deleting admin role 'ootb-supply-chain-testing-tap-install-cluster-rol
        e'
        | Deleting role binding 'ootb-supply-chain-testing-tap-install-cluster-ro
        lebinding'
        | Deleting secret 'ootb-supply-chain-testing-tap-install-values'
        | Deleting service account 'ootb-supply-chain-testing-tap-install-sa'

         Uninstalled package 'ootb-supply-chain-testing' from namespace 'tap-inst
        all'
        ```

7. Check the values of the package that can be configured by running:

```
tanzu package available get ootb-supply-chain-testing-scanning.tanzu.vmware.co
m/0.15.6 \
  --values-schema \
  -n tap-install
```

For example:

```
KEY                                  DESCRIPTION

registry.repository                   Name of the repository in the image regi
stry server where the application
                                      images from the workload should be pushe
d (required).

registry.server                       Name of the registry server where applic
ation images should be pushed to
                                      (required).

source.credentials_secret             Name of a Secret in the developer namesp
ace which provides the credentials to the
                                      source code repository.

gitops.server_address                 Default server address to be used for fo
rming Git URLs for pushing
                                      Kubernetes configuration produced by the
supply chain. This must
                                      include the scheme/protocol (e.g. http
s:// or ssh://)

gitops.repository_owner               Default project or user of the repositor
y. Used to create URLs for pushing
                                      Kubernetes configuration produced by the
supply chain.

gitops.repository_name                Default repository name used for forming
Git URLs for pushing Kubernetes
                                      configuration produced by the supply cha
in.

gitops.username                       Default user name to be used for the com
mits produced by the supply chain.

gitops.branch                         Default branch to use for pushing Kubern
etes configuration files produced
                                      by the supply chain.

gitops.commit_message                 Default git commit message to write when
publishing Kubernetes
                                      configuration files produces by the supp
ly chain to git.

gitops.email                          Default user email to be used for the co
mmits produced by the supply chain.

gitops.credentials_secret             Name of a Secret in the developer namesp
ace which provides the credentials to the
                                      GitOps repository.

gitops.ssh_secret                     DEPRECATED: Use gitops.credentials_secre
t and source.credentials_secret instead.
                                      Name of the default Secret containing SS
H credentials to lookup in the
                                      developer namespace for the supply chain
to fetch source code from and
                                      push configuration to.
```

```
gitops.commit_strategy                 Specification of how commits are made to
the branch; directly or through a
                                       pull request.

gitops.repository_prefix               DEPRECATED: Use server_address and repos
itory_owner instead.
                                       Default prefix to be used for forming Gi
t SSH URLs for pushing Kubernetes
                                       configuration produced by the supply cha
in.

gitops.pull_request.server_kind         The git source control platform used

gitops.pull_request.commit_branch       The branch to which commits will be mad
e, before opening a pull request
                                       to the branch specified in .gitops.branc
h If the string "" is specified,
                                       an essentially random string will be use
d for the branch name, in order
                                       to prevent collisions.

gitops.pull_request.pull_request_title  The title for the pull request

gitops.pull_request.pull_request_body   Any further information to add to the p
ull request

cluster_builder           Name of the Tanzu Build Service ClusterBuilder to
                          use by default on image objects managed by the supply
chain.

service_account           Name of the service account in the namespace where th
e Workload
                          is submitted to utilize for providing registry creden
tials to
                          Tanzu Build Service Image objects as well as deployin
g the
                          application.
```

8. Create a file named `ootb-supply-chain-testing-scanning-values.yaml` that specifies the corresponding values to the properties you want to change. For example:

```
registry:
  server: REGISTRY-SERVER
  repository: REGISTRY-REPOSITORY

source:
  credentials_secret: source-creds

gitops:
  server_address: https://github.com/
  repository_owner: vmware-tanzu
  branch: main
  username: supplychain
  email: supplychain
  commit_message: supplychain@cluster.local
  credentials_secret: gitops-creds
  commit_strategy: direct

cluster_builder: default
service_account: default
```

Important

The `gitops.repository_prefix` field must end with `/`.

9. With the configuration ready, install the package by running:

```
tanzu package install ootb-supply-chain-testing-scanning \
  --package ootb-supply-chain-testing-scanning.tanzu.vmware.com \
  --version 0.15.6 \
  --namespace tap-install \
  --values-file ootb-supply-chain-testing-scanning-values.yaml
```

Example output:

```
\ Installing package 'ootb-supply-chain-testing-scanning.tanzu.vmware.com'

```

Out of the Box Templates for Supply Chain Choreographer

This topic describes the templates you can use with Supply Chain Choreographer.

Templates define Kubernetes objects based on configuration in the workload, supply chain Tanzu Application Platform values, and results output from other templated objects. A supply chain organizes a set of templates into a directed acyclic graph. This package contains templates that are used by the Out of the Box Supply Chains and the Out of the Box Delivery. You must install this package to have Workloads delivered properly.

The OOTB Template package includes:

- Cartographer Templates: See reference
- Cartographer ClusterRunTemplates: See reference
- Tekton Tasks
- ClusterRoles
- openshift SecurityContextConstraints

For information about OOTB Supply Chains and Delivery, see:

- Out of the Box Supply Chain Basic
- Out of the Box Supply Chain with Testing
- Out of the Box Supply Chain with Testing and Scanning
- Out of the Box Delivery Basic

Out of the Box Templates for Supply Chain Choreographer

This topic describes the templates you can use with Supply Chain Choreographer.

Templates define Kubernetes objects based on configuration in the workload, supply chain Tanzu Application Platform values, and results output from other templated objects. A supply chain organizes a set of templates into a directed acyclic graph. This package contains templates that are used by the Out of the Box Supply Chains and the Out of the Box Delivery. You must install this package to have Workloads delivered properly.

The OOTB Template package includes:

- Cartographer Templates: See reference
- Cartographer ClusterRunTemplates: See reference

Install Out of the Box Templates for Supply Chain Choreographer

This topic describes how you can install Out of the Box Templates for Supply Chain Choreographer from the Tanzu Application Platform package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install Out of the Box Templates. For more information about profiles, see Components and installation profiles.

The Out of the Box Templates package is used by all the Out of the Box Supply Chains to provide the templates that are used by the Supply Chains to create the objects that drive source code all the way to a deployed application in a cluster.

Prerequisites

Before installing Out of the Box Templates:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- Install cartographer. For more information, see Install Supply Chain Choreographer.
- Install Tekton Pipelines.

Install

To install Out of the Box Templates:

1. View the configurable values of the package by running:

```
tanzu package available get ootb-templates.tanzu.vmware.com/0.7.0 \
  --values-schema \
  -n tap-install
```

For example:

```
KEY                  DEFAULT  TYPE    DESCRIPTION
excluded_templates   []       array   List of templates to exclude from the
                                       installation (e.g. ['git-writer'])
```

2. Create a file named `ootb-templates.yaml` that specifies the corresponding values to the properties you want to change.

   For example, the contents of the file might look like this:

   ```
   excluded_templates: []
   ```

3. After the configuration is ready, install the package by running:

   ```
   tanzu package install ootb-templates \
     --package ootb-templates.tanzu.vmware.com \
     --version 0.7.0 \
     --namespace tap-install \
     --values-file ootb-templates-values.yaml
   ```

   Example output:

   ```
   \ Installing package 'ootb-templates.tanzu.vmware.com'
   | Getting package metadata for 'ootb-templates.tanzu.vmware.com'
   | Creating service account 'ootb-templates-tap-install-sa'
   | Creating cluster admin role 'ootb-templates-tap-install-cluster-role'
   | Creating cluster role binding 'ootb-templates-tap-install-cluster-rolebindin
   g'
   | Creating secret 'ootb-templates-tap-install-values'
   | Creating package resource
   - Waiting for 'PackageInstall' reconciliation for 'ootb-templates'
   / 'PackageInstall' resource install status: Reconciling

    Added installed package 'ootb-templates' in namespace 'tap-install'
   ```

Out of the Box Delivery Basic for Supply Chain Choreographer

This topic is an overview of the Out of the Box Delivery Basic package for Supply Chain Choreographer.

This package provides a reusable ClusterDelivery object that delivers the Kubernetes configuration that the Out of the Box Supply Chain produces to an environment, including Basic, Testing, and Testing With Scanning supply chains.

Prerequisites

To make use of this package you must have installed:

- Supply Chain Cartographer
- Out of the Box Templates

Using Out of the Box Delivery Basic

Out of the Box Delivery Basic support both GitOps and local development workflows:

```
GITOPS

    Deliverable:
      points at a git repository where source code is found and
      kubernetes configuration is pushed to

LOCAL DEVELOPMENT

    Deliverable:

      points at a container image registry where the supplychain
      pushes source code and configuration to

---

DELIVERY

    takes a Deliverable (local or gitops) and passes is through
    a series of resources:

           config-provider  <---[config]--- deployer
                 .                             .
                 .                             .
    GitRepository/ImageRepository         kapp-ctrl/App
                                                - knative/Service
                                                - ResourceClaim
                                                - ServiceBinding
                                                ...
```

You must install this package to have Workloads delivered properly with the Basic, Testing, and Testing With Scanning Out of the Box Supply Chains.

Consumers do not interact directly with this package. Instead, this package is used after the supply chains create a carto.run/Deliverable object to express the intention of having the Workloads that go through them delivered to an environment. The environment is the same Kubernetes cluster as the Supply Chains.

Out of the Box Delivery Basic for Supply Chain Choreographer

This topic is an overview of the Out of the Box Delivery Basic package for Supply Chain Choreographer.

This package provides a reusable ClusterDelivery object that delivers the Kubernetes configuration that the Out of the Box Supply Chain produces to an environment, including Basic, Testing, and Testing With Scanning supply chains.

Prerequisites

To make use of this package you must have installed:

- Supply Chain Cartographer
- Out of the Box Templates

Using Out of the Box Delivery Basic

Out of the Box Delivery Basic support both GitOps and local development workflows:

```
GITOPS

    Deliverable:
      points at a git repository where source code is found and
      kubernetes configuration is pushed to

LOCAL DEVELOPMENT

    Deliverable:

      points at a container image registry where the supplychain
      pushes source code and configuration to

---

DELIVERY

    takes a Deliverable (local or gitops) and passes is through
    a series of resources:

           config-provider  <---[config]--- deployer
                 .                             .
                 .                             .
    GitRepository/ImageRepository         kapp-ctrl/App
                                                - knative/Service
                                                - ResourceClaim
                                                - ServiceBinding
                                                ...
```

You must install this package to have Workloads delivered properly with the Basic, Testing, and Testing With Scanning Out of the Box Supply Chains.

Consumers do not interact directly with this package. Instead, this package is used after the supply chains create a carto.run/Deliverable object to express the intention of having the Workloads that go through them delivered to an environment. The environment is the same Kubernetes cluster as the Supply Chains.

More information

Install Out of the Box Delivery Basic for Supply Chain Choreographer

This topic shows you how to install the Out of the Box Delivery Basic package for Supply Chain Choreographer from the Tanzu Application Platform package repository.

Note

> Follow the steps in this topic if you do not want to use a profile to install Out of the Box Delivery Basic. For more information about profiles, see Components and installation profiles.

The Out of the Box Delivery Basic package is used by all the Out of the Box Supply Chains to deliver the objects that have been produced by them to a Kubernetes environment.

Prerequisites

Before installing Out of the Box Delivery Basic:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- Install cartographer. For more information, see Install Supply Chain Choreographer.

Install

To install Out of the Box Delivery Basic:

1. Familiarize yourself with the set of values of the package that can be configured by running:

   ```
   tanzu package available get ootb-delivery-basic.tanzu.vmware.com/0.7.0 \
     --values-schema \
     -n tap-install
   ```

   For example:

   ```
   KEY                  DEFAULT  TYPE    DESCRIPTION
   service_account      default  string  Name of the service account in the
                                         namespace where the Deliverable is
                                         submitted to.
   ```

2. Create a file named `ootb-delivery-basic-values.yaml` that specifies the corresponding values to the properties you want to change.

   For example, the contents of the file might look like this:

   ```
   service_account: default
   ```

3. With the configuration ready, install the package by running:

   ```
   tanzu package install ootb-delivery-basic \
     --package ootb-delivery-basic.tanzu.vmware.com \
     --version 0.7.0 \
     --namespace tap-install \
     --values-file ootb-delivery-basic-values.yaml
   ```

   Example output:

   ```
   \ Installing package 'ootb-delivery-basic.tanzu.vmware.com'
   | Getting package metadata for 'ootb-delivery-basic.tanzu.vmware.com'
   | Creating service account 'ootb-delivery-basic-tap-install-sa'
   | Creating cluster admin role 'ootb-delivery-basic-tap-install-cluster-role'
   | Creating cluster role binding 'ootb-delivery-basic-tap-install-cluster-rolebi
   nding'
   | Creating secret 'ootb-delivery-basic-tap-install-values'
   | Creating package resource
   - Waiting for 'PackageInstall' reconciliation for 'ootb-delivery-basic'
   / 'PackageInstall' resource install status: Reconciling
   ```

```
Added installed package 'ootb-delivery-basic' in namespace 'tap-install'
```

How-to guides for Supply Chain Choreographer for Tanzu

This topic describes the how-to guides you can use for Supply Chain Choreographer for Tanzu.

How-to guides

The following how-to guides apply to Supply Chain Choreographer for Tanzu:

- Install Supply Chain Choreographer
- Install Out of the Box Delivery Basic
- Install Out of the Box Supply Chain Basic
- Install Out of the Box Supply Chain with Testing
- Install Out of the Box Supply Chain with Testing and Scanning
- Install Out of the Box Templates
- Tanzu Build Service Integration
- Building from source
- Git authentication
- Output Carvel Packages from your Supply Chain
- Deploy Carvel Packages using Carvel App CR
- Deploy Carvel Packages using Flux CD Kustomization
- Deploy Carvel Packages using Argo CD
- Use Blue-green deployments with Contour and Carvel Packages
- Use Canary deployments with Contour and Carvel Packages
- Use Blue-green deployments with Flagger

Out of the Box Supply Chain with testing on Jenkins for Supply Chain Choreographer

This topic provides an overview of Out of the Box Supply Chain with testing on Jenkins for Supply Chain Choreographer.

The Out of the Box templates package includes a Tekton `Task` resource, which triggers a build for a specified Jenkins job.

You can configure the Jenkins task in both the Out of the Box Supply Chain with Testing and Out of the Box Supply Chain With Testing and Scanning to trigger a Jenkins job. The task is implemented as a Tekton `Task` and can now run from a Tekton `Pipeline`.

Prerequisites

Follow the instructions from either Out of the Box Supply Chain With Testing or Out of the Box Supply Chain With Testing and Scanning to install the required packages. You need to set up only one of these packages.

Either of these Supply Chains can use the Jenkins service during the `source-tester` phase of the pipeline.

Using the Out of the Box Jenkins Task

The intent of the Jenkins task provided using Out of the Box templates is to help Tanzu Application Platform users to integrate with and make use of the modern application deployment pipeline provided by our platform while maintaining their existing test suites on their Jenkins services.

The Out of the Box Jenkins task makes use of an existing Jenkins Job to run test suites on source code.

Configuring a Jenkins job in an existing Jenkins Pipeline

This section of the guide shows how to configure a Jenkins job that you can kick off by the Tanzu Application Platform Jenkins task.

Example Jenkins Job

Here is an example of a script that you can add to your pipeline that specifies source URL and source revision information for your source code target. This example uses a Jenkins instance that is deployed on a Kubernetes cluster although this is not the only possible configuration for a Jenkins instance.

```
#!/bin/env groovy

pipeline {
  agent {
    // Use an agent that is appropriate
    // for your Jenkins installation.
    // This is only an example
    kubernetes {
      label 'maven'
    }
  }

  stages {
    stage('Checkout code') {
      steps {
        script {
          sourceUrl = params.SOURCE_REVISION
          indexSlash = sourceUrl.indexOf("/")
          if (indexSlash == -1) {
            // TAP 1.6+
            revision = sourceUrl.substring(sourceUrl.indexOf(":") + 1)
          } else {
            // pre TAP 1.6
            revision = sourceUrl.substring(indexSlash + 1)
          }
        }
        sh "git clone ${params.GIT_URL} target"
        dir("target") {
          sh "git checkout ${revision}"
        }
      }
    }

    stage('Maven test') {
      steps {
        container('maven') {
          dir("target") {
            // Example tests with maven
            sh "mvn clean test --no-transfer-progress"
          }
        }
      }
```

```
    }
  }
}
```

Where:

- `SOURCE_URL` **string** The URL of the source code being tested. The `source-provider` resource in the supply chain provides this code and is only resolvable inside the Kubernetes cluster. This URL is only useful if your Jenkins service is running inside the cluster or if there is ingress set up and the Jenkins service can make requests to services inside the cluster.
- `SOURCE_REVISION` **string** The revision of the source code being tested. The format of this value can vary depending on the implementation of the `source_provider` resource. If the `source-provider` is the Flux CD `GitRepository` resource, then the value of the `SOURCE_REVISION` is the Git branch name followed by the commit SHA, both separated by a (`/`) slash character. For example, `main/2b1ed6c3c4f74f15b0e4de2732234eafd050eb1ca`. Your Jenkins pipeline script must extract the commit SHA from the `SOURCE_REVISION` to be useful.

Note

If you can't use the `SOURCE_URL` because your Jenkins service cannot make requests into the Kubernetes cluster, you can supply the source code URL to the Jenkins job with other parameters instead.

The following fields are also required in the Jenkins Job definition

- `SOURCE_REVISION` **string**
- `GIT_URL` **string**

To configure your `Workload` to pass the `GIT_URL` parameter into the Jenkins task:

```
tanzu apps workload create workload \
  --namespace your-test-namespace \
  --git-branch main \
  --git-repo https://your.git/repository.git \
  --label apps.tanzu.vmware.com/has-tests=true \
  --label app.kubernetes.io/part-of=test-workload \
  --param-yaml testing_pipeline_matching_labels='{"apps.tanzu.vmware.com/pipeline":"je
nkins-pipeline"}' \
  --param-yaml testing_pipeline_params='{"secret-name":"my-secret","job-name":"jenkins
-job-name","job-params":"[{\"name\":\"GIT_URL\",\"value\":\"https://your.git/repositor
y.git\"}]"}' \
  --type web \
  --yes
```

The `Workload` is described in the later Developer Workload section.

Create a secret with authentication credentials

A secret must be created in the developer namespace to contain the credentials required to authenticate and interact with your Jenkins instance's builds. The following properties are required:

- `url` **required**: URL of the Jenkins instance that hosts the job, including the scheme. For example: `https://my-jenkins.com`.
- `username` **required**: User name of the user that has access to trigger a build on Jenkins.
- `password` **required**: Password of the user that has access to trigger a build on Jenkins.

- `ca-cert` **optional**: The PEM-encoded CA certificate to verify the Jenkins instance identity.

Use the Kubernetes CLI tool (kubectl) to create the secret. You can provide the optional PEM-encoded CA certificate as a file using the `--from-file` flag:

```
kubectl create secret generic my-secret \
  --from-literal=url=https://jenkins.instance \
  --from-literal=username=literal-username \
  --from-file=password=/path/to/file/with/password.txt \
  --from-file=ca-cert=/path/to/ca-certificate.pem \
```

The expected format of the secret is as follows:

```
apiVersion: v1
kind: Secret
metadata:
  name: MY-SECRET # secret name that will be referenced by the workload
type: Opaque
stringData:
  url: JENKINS-URL # target jenkins instance url
  username: USERNAME # jenkins username
  password: PASSWORD # jenkins password or token
  ca-cert: PEM-CA-CERT # PEM encoded certificate
```

Where:

- `MY-SECRET` is the secret name that is referenced by the workload.
- `JENKINS-URL` is the target Jenkins instance URL.
- `USERNAME` is the Jenkins username.
- `PASSWORD` is the Jenkins password or token.
- `PEM-CA-CERT` is the PEM encoded certificate.

Create a Tekton pipeline

The developer must create a Tekton `Pipeline` object with the following parameters:

- `source-url`, **required**: An HTTP address where a `.tar.gz` file containing all the source code being tested is supplied.
- `source-revision`, **required**: The revision of the commit or image reference found by the `source-provider`.
- `secret-name`, **required**: The secret that contains the URL, user name, password, and certificate (optional) to the Jenkins instance that houses the job that is required to run.
- `job-name`, **required**: The name of the Jenkins job that is required to run.
- `job-params`, **required**: A list of key-value pairs, encoded as a JSON string, that passes in parameters needed for the Jenkins job.

Tasks:

- `jenkins-task`, **required**: This `Task` is one of the tasks that the pipeline runs to trigger the Jenkins job. The Out of the Box Templates package installs the `tap-tasks` namespace on the cluster.

Results:

- `jenkins-job-url`: A string result that outputs the URL of the Jenkins build that the Tekton task triggered. The `jenkins-task` `Task` populates the output.

Here is an example of how to create a tekton pipeline with the required parameters

```
cat <<EOF | kubectl apply -f -
---
apiVersion: tekton.dev/v1beta1
kind: Pipeline
metadata:
  name: developer-defined-jenkins-tekton-pipeline
  namespace: developer-namespace
  labels:
    #! This label should be provided to the Workload so that
    #! the supply chain can find this pipeline
    apps.tanzu.vmware.com/pipeline: jenkins-pipeline
spec:
  results:
  - name: jenkins-job-url   #! To show the job URL on the
    #! Tanzu Developer Portal
    value: $(tasks.jenkins-task.results.jenkins-job-url)
  params:
  - name: source-url        #! Required
  - name: source-revision   #! Required
  - name: secret-name       #! Required
  - name: job-name          #! Required
  - name: job-params        #! Required
  tasks:
  #! Required: Include the built-in task that triggers the
  #! given job in Jenkins
  - name: jenkins-task
    taskRef:
      resolver: cluster
      params:
        - name: kind
          value: task
        - name: namespace
          value: tap-tasks
        - name: name
          value: jenkins-task
    params:
      - name: source-url
        value: $(params.source-url)
      - name: source-revision
        value: $(params.source-revision)
      - name: secret-name
        value: $(params.secret-name)
      - name: job-name
        value: $(params.job-name)
      - name: job-params
        value: $(params.job-params)
EOF
```

Patching the default Service Account

Tanzu Application Platform includes a Namespace Provisioner which is not enabled by default. This section requires that you do not use the Namespace Provisioner.

The `jenkins-task` `Task` resource uses a container image with the Jenkins Adapter application to trigger the Jenkins job and wait for it to complete. This container image is distributed with Tanzu Application Platform on VMware Tanzu Network, but it is not installed at the same time as the other packages. It is pulled at the time that the supply chain executes the job. As a result, it does not implicitly have access to the `imagePullSecrets` with the required credentials.

Important

The `ServiceAccount` that a developer can configure with their `Workload` is *not* passed to the task and is not used to pull the Jenkins Adapter container image. If you followed the Tanzu Application Platform Install Guide, then you have a `Secret` named `tap-registry` in each of your cluster's namespaces. You can patch the default Service Account in your workload's namespace so that your supply chain can pull the Jenkins Adapter image. For example:

```
kubectl patch serviceaccount default \
  --patch '{"imagePullSecrets": [{"name": "tap-registry"}]}' \
  --namespace developer-namespace
```

Create a Developer Workload

Submit your `Workload` to the same namespace as the Tekton `Pipeline` defined earlier.

To enable the supply chain to run Jenkins tasks, the `Workload` must include the following parameters:

```
parameters:

  #! Required: selects the pipeline
  - name: testing_pipeline_matching_labels
    value:
      #! This label must match the label on the pipeline created earlier
      apps.tanzu.vmware.com/pipeline: jenkins-pipeline

  #! Required: Passes parameters to pipeline
  - name: testing_pipeline_params
    value:

      #! Required: Name of the Jenkins job
      job-name: my-jenkins-job

      #! Required: The secret created earlier to access Jenkins
      secret-name: my-secret

      #! Required: The `job-params` element is required, but the parameter string
      #! might be empty. If empty, then set this value to `[]`.  If non-empty then the
      #! value contains a JSON-encoded list of parameters to pass to the Jenkins job.
      #! Ensure that the quotation marks inside the JSON-encoded string are escaped.
      job-params: "[{\"name\":\"A\",\"value\":\"x\"},{\"name\":\"B\",\"value\":\"y
\"},...]"
```

You can create the workload by using the `apps` CLI plug-in. For example:

```
readonly GIT_BRANCH="my-git-branch"
readonly WORKLOAD_NAME="my-workload-name"
readonly GITHUB_REPO="github-repository-url"
readonly DEVELOPER_WORKSPACE_NAME="my-developer-namespace"

tanzu apps workload create "${WORKLOAD_NAME}" \
  --namespace "${DEVELOPER_WORKSPACE_NAME}" \
  --git-branch "${GIT_BRANCH}" \
  --git-repo "${GITHUB_REPO}" \
  --label apps.tanzu.vmware.com/has-tests=true \
  --label app.kubernetes.io/part-of="${WORKLOAD_NAME}" \
  --param-yaml testing_pipeline_matching_labels='{"apps.tanzu.vmware.com/pipeline":"je
nkins-pipeline"}' \
  --param-yaml testing_pipeline_params='{"secret-name":"jenkins-secret", "job-name":
"jenkins-job", "job-params":"[{"name":"GIT_URL", "value":"https://github.com/spring-pr
```

```
ojects/spring-petclinic"}, {"name":"GIT_BRANCH", "value":"main"}]"}'\
  --type web
```

Where:

- `GIT_URL` is the URL of your GitHub repository.
- `GIT_BRANCH` is the branch you want to target.

The value of the `job-params` parameter is a list of zero-or-more parameters that are sent to the Jenkins job. The parameter is entered into the `Workload` as a list of name-value pairs as shown in the example above.

Important

None of the fields in the `Workload` resource are implicitly passed to the Jenkins job. You have to set them in the `job-params` explicitly. An exception to this is the `SOURCE_URL` and `SOURCE_REVISION` parameters are sent to the Jenkins job implicitly by the Jenkins Adapter trigger application. For example, you can use the `SOURCE_REVISION` to verify which commit SHA to test. See Making a Jenkins Test Job earlier for details about how to use the Git URL and source revision in a Jenkins test job.

Watch the quoting of the `job-params` value closely. In the earlier `tanzu apps workload create` example, the `job-params` value is a string with a JSON structure in it. The value of the `--param-yaml testing_pipeline_params` parameter is a JSON string. Add backslash (`\`) escape characters before the double quote characters (`"`) in the `job-params` value.

Example output from the `tanzu apps workload create` command:

```
Create workload:
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1
      3 + |kind: Workload
      4 + |metadata:
      5 + |  labels:

```

Building container images with Supply Chain Choreographer

This topic describes the methods you can use to build container images for Supply Chain Choreographer for Tanzu.

Methods for building container images

You can build a container image by using:

- A Maven artifact. See Building from source
- A Dockerfile based build. See Dockerfile-based builds
- Tanzu Build Service with buildpacks. See Tanzu Build Service Integration

Building from source with Supply Chain Choreographer

You can build from source by providing source code for the workload with any Supply Chain package.

You can provide source code for the workload from one of three places:

1. A Git repository.
2. A directory in your local computer's file system.
3. A Maven repository.

```
Supply Chain

-- fetch source                 * either from Git or local directory
  -- test
    -- build
      -- scan
        -- apply-conventions
          -- push config
```

This document provides details about each approach.

Note

To provide a prebuilt container image instead of building the application from the beginning by using the supply chain, see Using an existing image.

Git source

To provide source code from a Git repository to the supply chains, you must fill `workload.spec.source.git`. With the Tanzu CLI, you can do so by using the following flags:

- `--git-branch`: branch within the Git repository to checkout
- `--git-commit`: commit SHA within the Git repository to checkout
- `--git-repo`: Git URL to remote source code
- `--git-tag`: tag within the Git repository to checkout

For example, after installing `ootb-supply-chain-basic`, to create a `Workload` the source code for which comes from the `main` branch of the `github.com/vmware-tanzu/application-accelerator-samples` Git repository, and the subdirectory `tanzu-java-web-app` run:

```
tanzu apps workload create tanzu-java-web-app \
  --app tanzu-java-web-app \
  --type web \
```

```
  --git-repo https://github.com/vmware-tanzu/application-accelerator-samples \
  --sub-path tanzu-java-web-app \
  --git-branch main
```

Expect to see the following output:

```
Create workload:
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1
      3 + |kind: Workload
      4 + |metadata:
      5 + |  labels:
      6 + |    app.kubernetes.io/part-of: tanzu-java-web-app
      7 + |    apps.tanzu.vmware.com/workload-type: web
      8 + |  name: tanzu-java-web-app
      9 + |  namespace: default
     10 + |spec:
     11 + |  source:
     12 + |    git:
     13 + |      ref:
     14 + |        branch: main
     15 + |      url: https://github.com/vmware-tanzu/application-accelerator-samples
     16 + |    subPath: tanzu-java-web-app
```

Important

The Git repository URL must include the scheme: `http://`, `https://`, or `ssh://`.

Private `GitRepository`

To fetch source code from a repository that requires credentials, you must provide those by using a Kubernetes secret object that the `GitRepository` object created for that workload references. See How It Works to learn more about detecting changes to the repository.

```
Workload/tanzu-java-web-app
└─GitRepository/tanzu-java-web-app
                  └────────> secretRef: {name: GIT-SECRET-NAME}
                                                  |
                                        either a default from TAP installation or
                                             source_credentials_secret Workload paramete
r
```

Platform operators who install the Out of the Box Supply Chain packages by using Tanzu Application Platform profiles can customize the default name of the secret (`git-ssh`) by editing the corresponding `ootb_supply_chain*` property in the `tap-values.yaml` file:

```
ootb_supply_chain_basic:
  source:
    credentials_secret: GIT-SECRET-NAME
```

For platform operators who install the `ootb-supply-chain-*` package individually by using `tanzu package install`, they can edit the `ootb-supply-chain-*-values.yml` as follows:

```
source:
  credentials_secret: GIT-SECRET-NAME
```

You can also override the default secret name directly in the workload by using the `source_credentials_secret` parameter, regardless of how Tanzu Application Platform is installed. You can use the `--param` flag in Tanzu CLI. For example:

```
tanzu apps workload create tanzu-java-web-app \
  --app tanzu-java-web-app \
  --type web \
  --git-repo https://github.com/vmware-tanzu/application-accelerator-samples \
  --sub-path tanzu-java-web-app \
  --git-branch main \
  --param source_credentials_secret=SECRET-NAME
```

Expect to see the following output:

```
Create workload:
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1
      3 + |kind: Workload
      4 + |metadata:
      5 + |  labels:
      6 + |    app.kubernetes.io/part-of: tanzu-java-web-app
      7 + |    apps.tanzu.vmware.com/workload-type: web
      8 + |  name: tanzu-java-web-app
      9 + |  namespace: default
     10 + |spec:
     11 + |  params:
     12 + |  - name: source_credentials_secret  #! parameter that overrides the default
     13 + |    value: GIT-SECRET-NAME     #! secret name
     14 + |  source:
     15 + |    git:
     16 + |      ref:
     17 + |        branch: main
     18 + |      url: https://github.com/vmware-tanzu/application-accelerator-samples
     19 + |    subPath: tanzu-java-web-app
```

Note

A secret reference is only provided to `GitRepository` if `source_credentials_secret` is set to a non-empty string in some fashion, either by a package property or a workload parameter. To force a `GitRepository` to not reference a secret, set the value to an empty string (`""`).

After defining the name of the Kubernetes secret, you can define the secret.

HTTP(S) Basic-authentication and Token-based authentication

Use HTTP(S) transport:

1. Ensure that the repository in the `Workload` specification uses `http://` or `https://` schemes in any URLs that relate to the repositories. For example, `https://github.com/my-org/my-repo` instead of `github.com/my-org/my-repo` or `ssh://github.com:my-org/my-repo`.
2. In the same namespace as the workload, create a Kubernetes secret object of type `kubernetes.io/basic-auth` with the name matching the one expected by the supply chain. For example:

   ```
   apiVersion: v1
   kind: Secret
   metadata:
     name: GIT-SECRET-NAME
     annotations:
       tekton.dev/git-0: GIT-SERVER        # ! required
   type: kubernetes.io/basic-auth
   stringData:
   ```

```
  username: GIT-USERNAME
  password: GIT-PASSWORD
```

HTTPS with a Custom CA Certificate

For Git repositories hosted with a custom CA, setup a Kubernetes secret with a custom CA. For more information, see HTTPS with a Custom CA Certificate.

SSH authentication

Aside from using HTTP(S) as a transport, you can also use SSH:

1. Ensure that the repository URL in the workload specification uses `ssh://` as the scheme in the URL, for example, `ssh://git@github.com:my-org/my-repo.git`
2. Create a Kubernetes secret object of type `kubernetes.io/ssh-auth`:

```
apiVersion: v1
kind: Secret
metadata:
  name: GIT-SECRET-NAME
  annotations:
    tekton.dev/git-0: GIT-SERVER
type: kubernetes.io/ssh-auth
stringData:
  ssh-privatekey: SSH-PRIVATE-KEY     # private key with push-permissions
  identity: SSH-PRIVATE-KEY           # private key with pull permissions
  identity.pub: SSH-PUBLIC-KEY        # public of the `identity` private key
  known_hosts: GIT-SERVER-PUBLIC-KEYS # git server public keys
```

How it works

With the `workload.spec.source.git` filled, the supply chain takes care of managing a child `GitRepository` object that keeps track of commits made to the Git repository stated in `workload.spec.source.git`.

For each revision found, `gitrepository.status.artifact` gets updated providing information about an HTTP endpoint that the controller makes available for other components to fetch the source code from within the cluster.

The digest of the latest commit:

```
apiVersion: source.toolkit.fluxcd.io/v1
kind: GitRepository
metadata:
  name: tanzu-java-web-app
spec:
  gitImplementation: go-git
  ignore: '!.git'
  interval: 1m0s
  ref: {branch: main}
  timeout: 20s
  url: https://github.com/vmware-tanzu/application-accelerator-samples
status:
  artifact:
    checksum: 375c2daee5fc8657c5c5b49711a8e94d400994d7
    lastUpdateTime: "2022-04-07T15:02:30Z"
    path: gitrepository/default/tanzu-java-web-app/d85df1fc.tar.gz
    revision: main/d85df1fc28c6b86ca54bd613f55991645d3b257c
    url: http://source-controller.flux-system.svc.cluster.local./gitrepository/defaul
t/tanzu-java-web-app/d85df1fc.tar.gz
  conditions:
```

```
  - lastTransitionTime: "2022-04-07T15:02:30Z"
    message: 'Fetched revision: main/d85df1fc28c6b86ca54bd613f55991645d3b257c'
    reason: GitOperationSucceed
    status: "True"
    type: Ready
  observedGeneration: 1
```

Cartographer passes the artifact URL and revision to further components in the supply chain. Those components must consume the source code from an internal URL where a tarball with the source code is fetched, without having to process any Git-specific details in multiple places.

Workload parameters

You can pass the following parameters by using the workload object's `workload.spec.params` field to override the default behavior of the `GitRepository` object created for keeping track of the changes to a repository:

- `gitImplementation`: name of the Git implementation (`go-git`) to fetch the source code.
- `source_credentials_secret`: name of the secret in the same namespace as the workload where credentials to fetch the repository are found.

You can also customize the following parameters with defaults for the whole cluster. Do this by using properties for either `tap-values.yaml` when installing supply chains by using Tanzu Application Platform profiles, or `ootb-supply-chain-*-values.yml` when installing the OOTB packages individually):

- `source.credentials_secret`: the same as `source_credentials_secret` workload parameter

Local source

You can provide source code from a local directory such as, from a directory in the developer's file system. The Tanzu CLI provides two flags to specify the source code location in the file system and where the source code is pushed to as a container image:

- `--local-path`: path on the local file system to a directory of source code to build for the workload
- `--source-image`: destination image repository where source code is staged before being built

This way, whether the cluster the developer targets is local (a cluster in the developer's machine) or not, the source code is made available by using a container image registry.

For example, if a developer has source code under the current directory (`.`) and access to a repository in a container image registry, you can create a workload as follows:

```
tanzu apps workload create tanzu-java-web-app \
  --app tanzu-java-web-app \
  --type web \
  --local-path . \
  --source-image $REGISTRY/test
```

```
Publish source in "." to "REGISTRY-SERVER/REGISTRY-REPOSITORY"?
It may be visible to others who can pull images from that repository

  Yes

Publishing source in "." to "REGISTRY-SERVER/REGISTRY-REPOSITORY"...
Published source

Create workload:
```

```
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1
      3 + |kind: Workload
      4 + |metadata:
      5 + |  labels:
      6 + |    app.kubernetes.io/part-of: tanzu-java-web-app
      7 + |    apps.tanzu.vmware.com/workload-type: web
      8 + |  name: tanzu-java-web-app
      9 + |  namespace: default
     10 + |spec:
     11 + |  source:
     12 + |    image: REGISTRY-SERVER/REGISTRY-REPOSITORY:latest@<digest>
```

Where:

- `REGISTRY-SERVER` is the container image registry.
- `REGISTRY-REPOSITORY` is the repository in the container image registry.

Authentication

Both the cluster and the developer's machine must be configured to properly provide credentials for accessing the container image registry where the local source code is published to.

Developer

The Tanzu CLI must push the source code to the container image registry indicated by `--source-image`. To do so, the CLI must find the credentials, so the developer must configure their machine accordingly.

To ensure credentials are available, use `docker` to make the necessary credentials available for the Tanzu CLI to perform the image push. Run:

```
docker login REGISTRY-SERVER -u REGISTRY-USERNAME -p REGISTRY-PASSWORD
```

Supply chain components

Aside from the developer's ability to push source code to the container image registry, the cluster must also have the proper credentials, so it can pull that container image, unpack it, run tests, and build the application.

To provide the cluster with the credentials, point the ServiceAccount used by the workload at the Kubernetes secret that contains the credentials.

If the registry that the developer targets is the same one for which credentials were provided while setting up the workload namespace, no further action is required. Otherwise, follow the same steps as recommended for the application image.

How it works

A workload specifies that source code must come from an image by setting `workload.spec.source.image` to point at the registry provided by using `--source-image`. Instead of having a GitRepository object created, an ImageRepository object is instantiated, with its specification filled in such a way to keep track of images pushed to the registry provided by the user.

Take the following workload as an example:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
```

```
  name: app
  labels:
    app.kubernetes.io/part-of: app
    apps.tanzu.vmware.com/workload-type: web
spec:
  source:
    image: 10.188.0.3:5000/test:latest
```

Instead of a `GitRepository` object, an `ImageRepository` is created:

```
  Workload/app
  │
- ├─GitRepository/app
+ ├─ImageRepository/app
  │
  ├─Image/app
  │ ├─Build/app-build-1
  │ │ └─Pod/app-build-1-build-pod
  │ ├─PersistentVolumeClaim/app-cache
  │ └─SourceResolver/app-source
  │
  ├─PodIntent/app
  │
  ├─ConfigMap/app
  │
  └─Runnable/app-config-writer
    └─TaskRun/app-config-writer-2zj7w
      └─Pod/app-config-writer-2zj7w-pod
```

`ImageRepository` provides the same semantics as `GitRepository`, except that it looks for source code in container image registries rather than Git repositories.

Maven Artifact

This approach aids integration with existing CI systems, such as Jenkins, and can pull artifacts from existing Maven repositories, including Jfrog Artifactory.

There are no dedicated fields in the `Workload` resource for specifying the Maven artifact configuration. You must fill in the `name`/`value` pairs in the `params` structure.

For example:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: my-workload
  labels:
    apps.tanzu.vmware.com/workload-type: web
spec:
  params:
  - name: maven
    value:
      groupId: com.example
      artifactId: springboot-initial
      version: RELEASE      # latest 'RELEASE' or a specific version (e.g.: '1.2.2')
      type: jar             # optional (defaults to 'jar')
      classifier: sources   # optional
```

There are two ways to create a workload that defines a specific version of a Maven artifact as source in the Tanzu CLI.

The first way is to define the source through CLI flags. For example:

```
tanzu apps workload apply my-workload \
      --maven-artifact springboot-initial \
      --maven-version 2.6.0 \
      --maven-group com.example \
      --type web --app spring-boot-initial -y
```

Another flag that can be used alongside the others in this type of command is `--maven-type`, which refers to the Maven packaging type and defaults to `jar` if not specified.

The second one is through complex params (in JSON or YAML format). To specify the Maven info with this method, run:

```
tanzu apps workload apply my-workload \
      --param-yaml maven='{"artifactId": "springboot-initial", "version": "2.6.0", "gr
oupId": "com.example"}'\
      --type web --app spring-boot-initial -y
```

To create a workload that defines the `RELEASE` version of a maven artifact as source, run:

```
tanzu apps workload apply my-workload \
      --param-yaml maven='{"artifactId": "springboot-initial", "version": "RELEASE",
"groupId": "com.example"}'\
      --type web --app spring-boot-initial -y
```

The Maven repository URL and required credentials are defined in the supply chain, not the workload. For more information, see Installing OOTB Basic.

Maven Repository Secret

The MavenArtifact only supports authentication using basic authentication.

Additionally, MavenArtifact supports security using the TLS protocol. The Application Operator can configure the MavenArtifact to use a custom, or self-signed certificate authority (CA).

The MavenArtifact expects that all of the earlier credentials are provided in one secret, formatted as shown later:

```
---
apiVersion: v1
kind: Secret
metadata:
  name: maven-credentials
type: Opaque
data:
  username: <BASE64>  # basic auth user name
  password: <BASE64>  # basic auth password
  caFile: <BASE64>    # PEM Encoded certificate data for custom CA
```

You cannot use the Tanzu CLI to create secrets such as this, but you can use the kubectl CLI instead.

For example:

```
kubectl create secret generic maven-credentials \
  --from-literal=username=literal-username \
  --from-file=password=/path/to/file/with/password.txt \
  --from-file=caFile=/path/to/ca-certificate.pem
```

Use Dockerfile-based builds with Supply Chain Choreographer

This topic explains how you can use Dockerfile-based builds with Supply Chain Choreographer.

For source-based supply chains, when you specify the `dockerfile` parameter in a workload, the builds switch from using Kpack to using kaniko. Source-based supply chains are supply chains that don't take a pre-built image. kaniko is an open-source tool for building container images from a Dockerfile without running Docker inside a container.

Use Dockerfile-based builds with Supply Chain Choreographer

Parameter name	Description	Example
`dockerfile`	The relative path to the Dockerfile file in the build context.	`./Dockerfile`
`docker_build_context`	The relative path to the directory where the build context is.	`.`
`docker_build_extra_args`	The list of flags to pass directly to kaniko, such as providing arguments to a build.	`- --build-arg=MY_KEY=MY_VALUE`

Example 1

To build a container image from the `github.com/my-foo/bar` repository where the Dockerfile resides in the root of that repository, you can switch from using Kpack to building from that Dockerfile by passing the `dockerfile` parameter:

```
$ tanzu apps workload create my-foo \
  --git-repo https://github.com/my-foo/bar \
  --git-branch dev \
  --label app.kubernetes.io/part-of=foo \
  --param dockerfile=./Dockerfile \
  --type web

  Create workload:
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1
      3 + |kind: Workload
      4 + |metadata:
      5 + |  labels:
      6 + |    apps.tanzu.vmware.com/workload-type: web
      7 + |  name: my-foo
      8 + |  namespace: dev
      9 + |spec:
     10 + |  params:
     11 + |  - name: dockerfile
     12 + |    value: ./Dockerfile
     13 + |  source:
     14 + |    git:
     15 + |      ref:
     16 + |        branch: dev
     17 + |      url: https://github.com/my-foo/bar
```

Example 2

If the context to be used for the build must be set to a different directory within the repository, use the `docker_build_context` parameter to change that:

```
$ tanzu apps workload create my-foo \
  --git-repo https://github.com/my-foo/bar \
  --git-branch dev \
  --param dockerfile=MyDockerfile \
  --param docker_build_context=./src
```

Important

This feature has no platform operator configurations to be passed through the `tap-values.yaml` file, but if `ootb-supply-chain-*.registry.ca_cert_data` or `shared.ca_cert_data` is configured in `tap-values`, the certificates are considered when pushing the container image.

OpenShift

kaniko can perform container image builds without a Docker daemon or privileged containers. It does require the use of:

- Capabilities usually dropped from the more restrictive SecurityContextConstraints (SCC) enabled by default in OpenShift.
- The root user.

To overcome the limitations imposed by the default unprivileged SCC, Tanzu Application Platform installs:

- `SecurityContextConstraints/ootb-templates-kaniko-restricted-v2-with-anyuid` with enough extra privileges for kaniko to operate.
- `ClusterRole/ootb-templates-kaniko-restricted-v2-with-anyuid` to permit the use of SCC to any actor binding to that cluster role.

Each developer namespace needs a role binding that binds the role to an actor: `ServiceAccount`. For example:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: workload-kaniko-scc
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: ootb-templates-kaniko-restricted-v2-with-anyuid
subjects:
  - kind: ServiceAccount
    name: default
```

With the SCC created and the ServiceAccount bound to the role that permits the use of the SCC, OpenShift accepts the pods created to run kaniko to build the container images.

For more information, see Set up developer namespaces to use your installed packages.

For more information about SCC, see the Openshift documentation.

Tanzu Kubernetes Grid and clusters with PSA enabled

Tanzu Kubernetes Grid v1.26 and later clusters with the Pod Security admission feature enabled and set to `enforce` cannot run kaniko without configuration changes. This is because the webhook

requires containers to run as a non-root user and kaniko needs to run as a root user. This kaniko limitation relates to how image builds are run.

To workaround this limitation, label the namespace that kaniko runs as `privileged`. For example:

```
pod-security.kubernetes.io/enforce: privileged
```

For more information about this kaniko limitation, see the kaniko documentation.

For more information about the Pod Security admission feature, see the Kubernetes documentation.

Tanzu Build Service integration for Supply Chain Choreographer

This topic describes how you can configure and use the Tanzu Build Service integration for Supply Chain Choreographer.

By default, the Out of the Box supply chains (`ootb-supply-chain-*`) in Tanzu Application Platform make use of Tanzu Build Service for building container images out of source code.

You can configure a **platform operator** by using `tap-values.yaml`:

1. The default container image registry where application images must be pushed:

   ```
   ootb_supply_chain_basic:
     registry:
       server: <>
       repository: <>
   ```

2. The name of the Kpack `ClusterBuilder` used by default:

   ```
   ootb_supply_chain_basic:
     cluster_builder: my-custom-cluster-builder
   ```

You can configure an **application operator** by using `Workload`:

- `spec.build.env` are the environment variables used during the build:

  ```
  kind: Workload
  apiVersion: carto.run/v1alpha1
  metadata:
  name: tanzu-java-web-app
  spec:
  # ...
  build:
    env:
      - name: PORT
        value: "8080"
      - name: CA_CERTIFICATE
        valueFrom:
          secretKeyRef:
            name: secret-in-the-same-namespace-as-workload
            key: crt.pem
  ```

- `spec.params.clusterBuilder` is the name of the ClusterBuilder to use for builds of that Workload:

  ```
  kind: Workload
  apiVersion: carto.run/v1alpha1
  metadata:
  name: tanzu-java-web-app
  ```

```
spec:
# ...
params:
  - name: clusterBuilder
    value: nodejs-cluster-builder
```

- `spec.params.buildServiceBindings` is the object carrying the definition of a list of service bindings to use at build time:

```
---
kind: Workload
apiVersion: carto.run/v1alpha1
metadata:
name: tanzu-java-web-app
spec:

```

Note

See the Kpack ServiceBinding documentation in GitHub for more details about build-time service bindings.

these configuration only take effect when Kpack is used for building a container image. If you use Dockerfile-based builds by leveraging the `dockerfile` parameter, see dockerfile-based builds for more information.

Configure and deploy to multiple environments with custom parameters

This topic describes how to use carvel packages, Git repositories, and Flux CD to deploy workloads to multiple environments with Supply Chain Choreographer. By using a continuous delivery (CD) tool, you can apply Carvel packages to a runtime.

Overview

Flux CD is the VMware recommended CD tool. You can configure different parameters for each environment, such as replicas or host names. When you edit package parameters and commit them to a Git repository, Flux CD watches the Git repository and applies the package to your runtime environments.

Feature limits

To configure and deploy to multiple environments with custom parameters, ensure that your supply chains are compatible with the feature limits.

This feature is in beta and has the following limitation:

- Innerloop development is not supported.

Using Carvel packages

You can configure your supply chain to outputs Carvel packages and deliver configuration for each environment. For information about using Carvel, see Carvel Package Supply Chains (beta).

Using GitOps delivery with Flux CD

You can deliver packages created by the Carvel package supply chain, and add them to clusters, by using a GitOps repository. For information about this delivery method, see Use Gitops Delivery with Flux CD (beta).

Using GitOps delivery with Carvel App

Alternatively, you can deliver packages created by the Carvel package supply chain, and add them to clusters by using a GitOps repository. For information about this delivery method, see Use Gitops Delivery with Carvel App

Using GitOps delivery with Argo CD

You can deliver packages created by the Carvel package supply chain, and add them to clusters by using a GitOps repository. For information about this delivery method, see Use Gitops Delivery with Argo CD.

Configuring blue-green deployment

You can use blue-green deployment to transfer user traffic from one version of an app to a later version while both are running. For information about setting up blue-green deployment, see Use blue-green deployment with Contour and PackageInstall (beta).

Configuring canary deployment

You can use canary deployment to gradually shift traffic from one version of an application to a later version, and at the same time, perform analysis to verify if the later version is either promoted or rolled back. For information about setting up canary deployments, see Use canary deployment with Contour and Carvel packages for Supply Chain Choreographer.

Carvel Package Supply Chains (beta)

This topic explains what Carvel Package Supply Chains do, how they work, how operators can enable them, and how to create a `Workload` that uses them. You can use the Carvel Package Supply Chains with Supply Chain Choreographer to deliver applications to multiple production environments with configuration for each environment.

The Out of the Box Basic Supply Chain, Out of the Box Supply Chain with Testing, and Out of the Box Supply Chain with Testing and Scanning packages provide variations of the OOTB supply chains that output Carvel Packages.

Overview of the Carvel Package Supply Chains

The out of the box Supply Chains output a `Deliverable` object. These `Deliverable`s are deployed to a cluster by the Out of the Box Delivery Supply Chain. The Carvel Package Supply Chains instead output a Carvel `Package` object to a GitOps repository. These `Packages` have configurable parameters such as `hostname` and `replicas` that are configured per environment. GitOps tools such as Flux CD and Argo CD can deploy the `Package`s onto multiple environments.

Note

The Kubernetes resources created for your `Workload` are the same for Carvel Package supply chains, but with additional, optional resources such as `networking.k8s.io/v1 Ingress`.

What do the Carvel Package Supply Chains do?

There are two Carvel Package Supply Chains per package: - Out of the Box Basic Supply Chain contains `source-to-url-package` and `basic-image-to-url-package`. - Out of the Box Supply Chain with Testing contains `source-test-to-url-package` and `testing-image-to-url-package`. - Out of the Box Supply Chain with Testing and Scanning contains `source-test-scan-to-url-package` and `scanning-image-scan-to-url-package`

These supply chains are identical to their non Carvel Package counterparts, except for three resources:

- A new `carvel-package` resource is added. The supply chain stamps out a Tekton Task that bundles all application Kubernetes resources into a Carvel `Package`.
- `config-writer` is modified to write the Carvel `Package` to a GitOps repository.
- `deliverable` resource is removed.

When a `Workload` is created and all Supply Chain resources are stamped out, a Carvel `Package` is written to the GitOps repository at the path `<package_name>/packages/<package_id>.yaml`. `<package_name>` by default to `<workload_name>.<workload_namespace>.tap`, and is customized with the `name_suffix` parameter. `<package_id>` is a SemVer compatible version generated by the Bash command `$(date "+%Y%m%d%H%M%S.0.0")`.

For example:

```
app.default.tap/
  packages/
    20230321004057.0.0.yaml
```

Note

By default, the `<package_name>` directory is created in the root directory of the GitOps repository. You can optionally create this directory at a subpath by configuring the `gitops_subpath` parameter.

For example, the following Carvel `Package` definition is stored in `<package_id>.yaml`:

```
apiVersion: data.packaging.carvel.dev/v1alpha1
kind: Package
metadata:
  name: app.default.tap.20230321004057.0.0
spec:
```

```
refName: app.default.tap
version: 20230321004057.0.0
releaseNotes: |
  Release v20230321004057.0.0 of package app.default.tap
template:
  spec:

      cluster_issuer:
        title: Cluster Issuer
        type: string
        default: tap-ingress-selfsigned
      http_route:
        type: object
        additionalProperties: false
        nullable: true
        properties:
          gateways:
            type: array
            items:
              type: object
              additionalProperties: false
              properties:
                protocol:
                  type: string
                  default: ""
                name:
                  type: string
                  default: ""
            default:
            - protocol: https
              name: default-gateway
```

By default, the Carvel `Package` generated by the Supply Chain has configurable parameters.

For the `server` workload type, the default parameters are:

- `workload_name`: Name of the workload. Required. Default is `""`.
- `replicas`: Number of pods that you want for the `apps/v1 Deployment`. Default is `1`.
- `hostname`: Host name for the `networking.k8s.io/v1 Ingress`. If you don't need ingress, leave host name as an empty string. If host name is not in the file, you see an error.
- `port`: Port for the `networking.k8s.io/v1 Ingress`. Default is `8080`.
- `cluster_issuer`: CertManager Issuer to use to generate certificate for Kubernetes `Ingress`. Default is `"tap-ingress-selfsigned"`.
- `http_route`: Configuration of `gateway.networking.k8s.io/v1beta1 HttpRoute`. This is intended for use with Tanzu Application Engine. VMware does not recommend this setting when running on Tanzu Application Platform.

For the `web` workload type, the default parameters are:

- `workload_name`: Name of the workload. Required. Default is `""`.

For the `worker` workload type, the default parameters are:

- `workload_name`: Name of the workload. Required. Default is `""`.
- `replicas`: Number of pods that you want for the `apps/v1 Deployment`. Default is `1`.

You can configure the Supply Chain to produce Carvel `Packages` with custom parameters. See the installation section.

When a new commit is pushed to the source code Git Repository, such as `source-to-url-package`, or a new pre-built image is created, like `basic-image-to-url-package`, the Supply Chain stamps out a new version of the Carvel `Package`. This definition is written to `<package_name>/packages/<package_id>.yaml` with a new `<package_id>`.

The Carvel `Package` stored in GitOps repositories are deployed to multiple run clusters using GitOps tools, such as Flux CD or Argo CD. See Deploy Carvel Packages using Flux CD Kustomization.

Installing the Carvel Package Supply Chains as an Operator

This section describes operator tasks for enabling and configuring the Carvel Package Supply Chains.

Prerequisites

The Carvel Package Supply Chains require access to a GitOps repository and credentials. See GitOps versus RegistryOps.

Installation

In `tap-values`, configure any Out of the Box Supply Chain and the Out of the Box Templates package with the following parameters:

Note

If you are installing Out of the Box Supply Chain with Testing, replace `ootb_supply_chain_basic` with `ootb_supply_chain_testing` in all of the following steps. If you are installing Out of the Box Supply Chain with Testing and Scanning, replace `ootb_supply_chain_basic` with `ootb_supply_chain_testing_scanning` in all of the following steps.

1. (Required) Enable the Carvel Package workflow.

```
ootb_supply_chain_basic:
  carvel_package:
    workflow_enabled: true
```

2. (Optional) Set a GitOps subpath. This verifies the path in your GitOps repository where Carvel Packages are written. Defaults to `""`. See Template reference.

```
ootb_supply_chain_basic:
  carvel_package:
    workflow_enabled: true
    gitops_subpath: path/to/my/dir
```

3. (Optional) Set a name suffix. Carvel Package names are chosen using the `<workload_name>.<workload_namespace>.<name_suffix>` template. Defaults to `tap`. See Template reference.

```
ootb_supply_chain_basic:
  carvel_package:
    workflow_enabled: true
    name_suffix: vmware.com
```

4. (Optional) Enable OpenAPIv3 Schema Definition Generation. Defaults to `true`. See Template reference.

```
ootb_supply_chain_basic:
  carvel_package:
    workflow_enabled: true
    openapiv3_enabled: true
```

   If the size of the resulting OpenAPIv3 specification exceeds roughly 3 KB, the Supply Chain does not function. See the known issue.

5. (Optional) Configure the Out of the Box Templates with custom Carvel Package parameters. See Template reference.

   - Packages created by the Carvel Package Supply Chains contain the YTT Schema and YTT Overlays.
   - Supply Chain decides which YTT Schema and YTT Overlays to use based on the `selector` field. Operators can specify as many labels as they want under `selector.matchLabels`. The `selector` with the highest amount of matching labels is used.
     - A `selector` is only considered a match if all labels under `selector.matchLabels` match. If there is more than one matching `selector`, the `selector` with more labels is used. If there is more than one matching `selector`, and they have the same amount of labels, the Supply Chain fails. If there is no matching `selector`, the Supply Chain fails.
   - The `ootb_templates.carvel_package.openapiv3_enabled = true` package has a generated OpenAPIv3 API specification.
   - Setting `ootb_templates.carvel_package.parameters` overrides the default Carvel Package parameters. If an operator wants to leave the parameters the same for `web` and `worker` types, but add a parameter for `server`, they must copy the default `ootb_templates.carvel_package.parameters` from the template reference, and then make the modification.

```
ootb_templates:
  carvel_package:
```

```
    parameters:
    - selector:
        matchLabels:
          apps.tanzu.vmware.com/workload-type: server
      schema: |
        #@data/values-schema
        ---
        #@schema/title "Replicas"
        #@schema/desc "Number of replicas."
        replicas: 1
      overlays: |
        #@ load("@ytt:overlay", "overlay")
        #@ load("@ytt:data", "data")
        #@overlay/match by=overlay.subset({"apiVersion":"apps/v1", "kind": "Dep
loyment"})
        ---
        spec:
          #@overlay/match missing_ok=True
          replicas: #@ data.values.replicas
    # copy the existing parameters for worker + web here
```

6. Configure your Out of the Box Supply Chain package with your GitOps parameters. See GitOps versus RegistryOps.
7. Install the Out of the Box Supply Chain package.

Verifying the Carvel Package Supply Chains are Installed

1. Run `kubectl get ClusterSupplyChains`.
2. Confirm you see both Carvel Package supply chains with status `Ready: True`:
    - Out of the Box Basic Supply Chain contains `source-to-url-package` and `basic-image-to-url-package`.
    - Out of the Box Supply Chain with Testing contains `source-test-to-url-package` and `testing-image-to-url-package`.
    - Out of the Box Supply Chain with Testing and Scanning contains `source-test-scan-to-url-package` and `scanning-image-scan-to-url-package`

Using the Carvel Package Supply Chains as a Developer

This section describes developer tasks for using the Carvel Package Supply Chains.

Prerequisites

Your operator must install the Carvel Package Supply Chains.

You must create your workload in a developer namespace. See Developer namespace.

Create a Workload

To use the Carvel Package Supply Chains, you must add the label `apps.tanzu.vmware.com/carvel-package-workflow=true` to your workload.

1. Use the `--label apps.tanzu.vmware.com/carvel-package-workflow=true` Tanzu CLI flag.

   For example:

```
tanzu apps workload create tanzu-java-web-app \
--namespace DEVELOPER_NAMESPACE \
--app tanzu-java-web-app \
--type server \
```

```
--label apps.tanzu.vmware.com/carvel-package-workflow=true \
--image springcommunity/spring-framework-petclinic
```

Expect to see the following output:

```
Create workload:
    1 + |---
    2 + |apiVersion: carto.run/v1alpha1
    3 + |kind: Workload
    4 + |metadata:
    5 + |  labels:
    6 + |    app.kubernetes.io/part-of: tanzu-java-web-app
    7 + |    apps.tanzu.vmware.com/carvel-package-workflow: "true"
    8 + |    apps.tanzu.vmware.com/workload-type: server
    9 + |  name: tanzu-java-web-app
   10 + |  namespace: DEVELOPER_NAMESPACE
   11 + |spec:
   12 + |  image: springcommunity/spring-framework-petclinic
```

You can override most parameters set by the operator.

Note

Developers cannot override `carvel_package_parameters` as it presents a security risk.

1. (Optional) Set a GitOps subpath. This verifies the path in your GitOps repository where Carvel Packages are written. Defaults to `""`. See Template reference.

   Set this parameter by modifying `workload.spec.params.carvel_package_gitops_subpath`, using the `--param carvel_package_gitops_subpath=path/to/my/dir` Tanzu CLI flag.

2. (Optional) Set a name suffix. Carvel Package names are chosen using the template `<workload_name>.<workload_namespace>.<name_suffix>`. Defaults to `tap`. See Template reference.

   Set this parameter by modifying `workload.spec.params.carvel_package_name_suffix`, using the `--param carvel_package_name_suffix=vmware.com` Tanzu CLI flag.

3. (Optional) Enable OpenAPIv3 specification generation. Defaults to `true`. See Template reference.

   Set this parameter by modifying `workload.spec.params.carvel_package_openapiv3_enabled`, using the `--param carvel_package_openapiv3_enabled=false` Tanzu CLI flag.

4. (Optional) You can override GitOps parameters. See GitOps versus RegistryOps.

Verify the Carvel Package was Created

Verify that you see a Carvel `Package` stored in your GitOps repository. For example, at the path `tanzu-java-web-app.default.tap/packages/20230321004057.0.0.yaml` you see a valid Carvel `Package` definition.

Git commit SHA in Package version

By default, the Git revision identifier for the software in the Carvel Package is added to the package version, in the format `+build.${git_commit}`, in the following cases:

1. The `source-to-url-package` builds the package and the image building resource is either `kpack-template` or the `kaniko-template`. These templates add the label Git commit SHA of

the source code used to the label `org.opencontainers.image.revision` on the OCI image container.

2. An OCI image container is used with the label `org.opencontainers.image.revision`. The package version might look similar to `20230518150903.0.0+build.6db88c7` where `6db88c7` is the Git commit SHA.

Next Steps

You can deploy the Carvel `Package` using tools such as Flux CD or Argo CD. See Deploy Carvel Packages using Flux CD Kustomization.`

Use Gitops delivery with a Carvel app (beta)

This topic explains how you can deliver Carvel `Packages`, created by the Carvel Package Supply Chains, from a GitOps repository to one or more run clusters using Carvel App. You can use Carvel Package Supply Chains with Supply Chain Choreographer.

Prerequisites

To use GitOps Delivery with Carvel App, you must complete the following prerequisites:

- You must create a `Workload` that uses the Carvel Package supply chains. For information about Carvel Packages, see Carvel Package Supply Chains. You must have at least one Carvel `Package` generated by this `Workload` stored in your GitOps repository.
- You must have at least one run cluster. run clusters serve as your deployment environments. They can either be Tanzu Application Platform clusters, or Kubernetes clusters, but they must have kapp-controller and Contour installed. See the Carvel documentation and the Contour documentation.
- If you plan to use a build cluster to control the deployment on all of the run clusters, you must create a Build cluster that has network access to your run clusters. If you intend to deploy directly on the run cluster without using a build cluster, a build cluster is only necessary for building the package.

Set up run cluster namespaces

Each run cluster must have a namespace and `ServiceAccount` with the correct permissions to deploy the Carvel `Packages`, `PackageInstalls` and Kubernetes `Secrets`. Create a namespace and `ServiceAccount` with the following permissions:

```
---
apiVersion: rbac.authorization.k8s.io/v1
kind: Role
metadata:
  namespace: RUN-CLUSTER-NS
  name: app-package-and-pkgi-install-role
rules:
  - apiGroups: ["data.packaging.carvel.dev"]
    resources: ["packages"]
    verbs: ["get", "list", "create", "update", "delete", "patch"]
  - apiGroups: ["packaging.carvel.dev"]
    resources: ["packageinstalls"]
    verbs: ["get", "list", "create", "update", "delete", "patch"]
  - apiGroups: [""]
    resources: ["secrets"]
    verbs: ["get", "list", "create", "update", "delete", "patch"]
```

Where `RUN-CLUSTER-NS` is the run cluster namespace you want to use.

If your run cluster is a Tanzu Application Platform cluster, see Set up developer namespaces to use your installed packages.

If your run cluster is not a Tanzu Application Platform cluster, the `ServiceAccount` must also have the following permissions:

```
---
apiVersion: rbac.authorization.k8s.io/v1
kind: Role
metadata:
  namespace: RUN-CLUSTER-NS
  name: app-cr-role
rules:
- apiGroups: ["apps"]
  resources: ["deployments"]
  verbs: ["get", "list", "create", "update", "delete"]
- apiGroups: [""]
  resources: ["configmaps", "services"]
  verbs: ["get", "list", "create", "update", "delete"]
- apiGroups: ["networking.k8s.io"]
  resources: ["ingresses"]
  verbs: ["get", "list", "create", "update", "delete"]
```

Where `RUN-CLUSTER-NS` is the name of your run cluster you want to create a namespace with.

Create Carvel PackageInstalls and secrets

For each Carvel `Package` and each run cluster, you must create a Carvel `PackageInstall` and a `Secret`. The Carvel `PackageInstall` and the `Secret` is stored in your GitOps repository and deployed to run clusters by the Carvel `App`.

The following example shows GitOps repository structure after completing the procedures in this section:

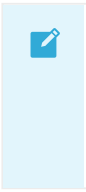
```
app.default.tap/
  packages/
    20230321004057.0.0.yaml  # Package
  staging/
    packageinstall.yaml      # PackageInstall
    params.yaml              # Secret
  prod/
    packageinstall.yaml      # PackageInstall
    params.yaml              # Secret
```

1. For each run cluster, create a `Secret` that has the values for each `Package` parameter. To see the configurable properties of the `Package`, inspect the `Package` CR's valuesSchema. See Carvel Package Supply Chains. Store the `Secret` in your GitOps repository at `PACKAGE-NAME/RUN-CLUSTER/params.yaml`.

   ```
   ---
   apiVersion: v1
   kind: Secret
   metadata:
    name: app-values
   stringData:
    values.yaml: |
      ---
      workload_name: app
      replicas: 2
      hostname: app.mycompany.com
   ```

Where:

- `PACKAGE-NAME` is the name of your Carvel package you want to use.
- `RUN-CLUSTER` is the name of the run cluster you want to use with the package.



Note

You must set a value for the `workload_name` parameter. You can skip setting other fields to use the default parameter values.

1. For each run cluster, create a `PackageInstall`. Reference the `Secret` you created earlier. Store the `PackageInstall` in your GitOps repository at `PACKAGE-NAME/RUN-CLUSTER/packageinstall.yaml`.

```
---
apiVersion: packaging.carvel.dev/v1alpha1
kind: PackageInstall
metadata:
 name: app
spec:
 serviceAccountName: RUN-CLUSTER-NS-SA # ServiceAccount on run cluster with per
missions to deploy Package, see "Set up run Cluster Namespaces"
 packageRef:
   refName: app.default.tap # name of the Package
   versionSelection:
     constraints: 20230321004057.0.0 # version of the Package
 values:
 - secretRef:
     name: app-values # Secret created in previous step
```

Where:

- `PACKAGE-NAME` is the name of your Carvel package you want to use.
- `RUN-CLUSTER` is the name of the run cluster you want to use with the package.
- `RUN-CLUSTER-NS-SA` is the ServiceAccount on your run cluster with permissions to deploy the package.

To continuously deploy the latest version of your `Package`, set `versionSelection.constraints: >=0.0.0`. To revert to a previous version, update the `versionSelection.constraints:` field and annotate the PackageInstall:

```
packaging.carvel.dev/downgradable: ""
```

See the Carvel documentation.

1. Push the `PackageInstalls` and `Secrets` to your GitOps repository.

Create an app

1. You must give the build cluster access to the run clusters. On the build cluster create a `Secret` containing the run cluster's kubeconfig for each run cluster:

```
kubectl create secret generic RUN-CLUSTER-kubeconfig \
   -n BUILD-CLUSTER-NS \
   --from-file=value.yaml=PATH-TO-RUN-CLUSTER-KUBECONFIG
```

Where:

- `RUN-CLUSTER` is the name of the run cluster you want to use with your app.
- `BUILD-CLUSTER-NS` is the namespace of the build cluster you want to use.
- `PATH-TO-RUN-CLUSTER-KUBECONFIG` is the location of your run cluster kubeconfig.
- Each Carvel `App` custom resource (CR) must specify either a service account, by using `spec.serviceAccountName`, in the same namespace where the App CR is located on the Build cluster. Or specify a `Secret` with kubeconfig contents for a target destination run cluster, by using `spec.cluster.kubeconfigSecretRef.name`, to explicitly provide the privileges required for managing app resources. The example in this section uses a target run cluster.
- The Carvel App custom resource represents a collection of Kubernetes resources that kapp-controller can fetch and deploy to a cluster. The `App` points at the Git repository branch where kapp-controller resources, such as `PackageRepository` and `Packages`, are defined. By default, an `App` custom resource syncs the cluster with its fetch source every 30 seconds to prevent the cluster state from drifting from its source of truth. Create the following `App` on your Build cluster:

```
---
apiVersion: kappctrl.k14s.io/v1alpha1
kind: App
metadata:
 name: hello-app-app
 namespace: BUILD-CLUSTER-NS
spec:
 # specifies that app should be deployed to destination cluster;
 # by default, cluster is same as where this resource resides
 cluster:
   # specifies namespace in destination cluster
   namespace: ns2
   # specifies secret containing kubeconfig
   kubeconfigSecretRef:
     # specifies secret name within app's namespace
     name: cluster1
     # specifies key that contains kubeconfig
     key: value
 fetch:
 - git:
     url: # GitOps repo URL ex: https://github.com/mycompany/my-gitops
     ref: # GitOps repo branchex: origin/main
     subPath: PATH-FOR-PACKAGES # ex: hello-app.dev.tap/packages/
 - git:
     url: # GitOps repo URL ex: https://github.com/mycompany/my-gitops
     ref: # GitOps repo branch ex: origin/main
     subPath: PATH-FOR-PACKAGE-INSTALLS # ex: hello-app.dev.tap/runcluster1
 template:
 - ytt: {}

  deploy:
 - kapp:
     intoNs: DESIRED-NAMESPACE
     rawOptions: ["--dangerous-allow-empty-list-of-resources=true"]
```

  Where:

  - `DESIRED-NAMESPACE` is the namespace you want to use with your app.
  - `PATH-FOR-PACKAGE-INSTALLS` is the package install path.
  - `PATH-FOR-PACKAGES` is the package path.
  - `BUILD-CLUSTER-NS` is the build cluster namespace.

> **Note**
>
> The fetch section includes entries for all the locations in the GitOps repository to deploy, and append with other run clusters if needed.

Verify applications

To verify your installation:

1. Target a run cluster. Confirm that all Packages from the GitOps repository are deployed:

   ```
   kubectl get packages -A
   ```

2. Target a run cluster. Confirm that all PackageInstalls are reconciled:

   ```
   kubectl get packageinstalls -A
   ```

You can access your application on each run cluster.

Use Gitops delivery with Flux CD (beta)

This topic explains how you can deliver Carvel `Packages`, created by the Carvel Package Supply Chains, from a GitOps repository to one or more run clusters using Flux CD and Supply Chain Choreographer.

Prerequisites

To use Gitops Delivery with Flux CD, you must complete the following prerequisites:

- You must create a `Workload` that uses a Carvel Package Supply Chain. You must have at least one Carvel `Package` generated by this `Workload` stored in your GitOps repository. See Carvel Package Supply Chains (beta).
- You must have at least one run cluster. Run clusters are your deployment environments. They can either be Tanzu Application Platform clusters, or regular Kubernetes clusters, but they must have kapp-controller and Contour installed. See the Carvel documentation and the Contour documentation.
- To use a build cluster to control the deployment on all the run clusters, you must create a build cluster that has network access to your run clusters. You must also install Flux CD Kustomize Controller. See Install Kustomize Controller Prerequisite. If you intend to deploy directly on the run cluster without a build cluster, a build cluster is only necessary for building the package.

Install Kustomize Controller Prerequisite

As mentioned earlier, to use a build cluster to control the deployment on run clusters, you must install Flux CD kustomize-controller. You can do the installation using the flux cli. Use release v2.1.2.

> **Caution**
>
> Newer releases of Kustomize Controller are not compatible with Tanzu Application Platform v1.7.x and later.

To install Flux CD:

```
# https://fluxcd.io/flux/get-started/
brew install fluxcd/tap/flux@0.41  (for example, when on macOS)
flux install -n flux-system --components kustomize-controller --version v2.1.2
```

Set up run cluster namespaces

Each run cluster must have a namespace and `ServiceAccount` with the correct permissions to deploy the Carvel `Packages`, `PackageInstalls` and Kubernetes `Secrets`. Create a namespace and `ServiceAccount` with the following permissions:

```
---
apiVersion: rbac.authorization.k8s.io/v1
kind: Role
metadata:
  namespace: <run-cluster-ns>
  name: app-package-and-pkgi-install-role
rules:
  - apiGroups: ["data.packaging.carvel.dev"]
    resources: ["packages"]
    verbs: ["get", "list", "create", "update", "delete", "patch"]
  - apiGroups: ["packaging.carvel.dev"]
    resources: ["packageinstalls"]
    verbs: ["get", "list", "create", "update", "delete", "patch"]
  - apiGroups: [""]
    resources: ["secrets"]
    verbs: ["get", "list", "create", "update", "delete", "patch"]
```

If your run cluster is a Tanzu Application Platform cluster, see Set up developer namespaces to use your installed packages.

If your run cluster is not a Tanzu Application Platform cluster, the `ServiceAccount` must also have the following permissions:

```
---
apiVersion: rbac.authorization.k8s.io/v1
kind: Role
metadata:
  namespace: <run-cluster-ns>
  name: app-cr-role
rules:
- apiGroups: ["apps"]
  resources: ["deployments"]
  verbs: ["get", "list", "create", "update", "delete"]
- apiGroups: [""]
  resources: ["configmaps", "services"]
  verbs: ["get", "list", "create", "update", "delete"]
- apiGroups: ["networking.k8s.io"]
  resources: ["ingresses"]
  verbs: ["get", "list", "create", "update", "delete"]
```

Create Carvel PackageInstalls and secrets

For each Carvel `Package` and each run cluster, you must create a Carvel `PackageInstall` and a `Secret`. The Carvel `PackageInstall` and the `Secret` are stored in your GitOps repository and deployed to run clusters by Flux CD.

The following example shows GitOps repository structure after completing this section:

```
app.default.tap/
  packages/
    20230321004057.0.0.yaml  # Package
  staging/
    packageinstall.yaml      # PackageInstall
    params.yaml              # Secret
  prod/
    packageinstall.yaml      # PackageInstall
    params.yaml              # Secret
```

1. For each run cluster, create a `Secret` that has the values for each `Package` parameter. You can see the configurable properties of the `Package` by inspecting the `Package` CR's valuesSchema, or in the Carvel Package Supply Chains documentation. Store the `Secret` in your GitOps repository at `<package_name>/<run_cluster>/params.yaml`.

   ```
   ---
   apiVersion: v1
   kind: Secret
   metadata:
    name: app-values
   stringData:
    values.yaml: |
      ---
      workload_name: app
      replicas: 2
      hostname: app.mycompany.com
   ```

   Note

   You must set a value for the `workload_name` parameter. You can skip setting other fields to use the default parameter values.

2. For each run cluster, create a `PackageInstall`. Reference the `Secret` you created earlier. Store the `PackageInstall` in your GitOps repository at `<package_name>/<run_cluster>/packageinstall.yaml`.

   ```
   ---
   apiVersion: packaging.carvel.dev/v1alpha1
   kind: PackageInstall
   metadata:
    name: app
   spec:
    serviceAccountName: <run-cluster-ns-sa> # ServiceAccount on run cluster with p
   ermissions to deploy Package, see "Set up run Cluster Namespaces"
    packageRef:
      refName: app.default.tap # name of the Package
      versionSelection:
        constraints: 20230321004057.0.0 # version of the Package
    values:
    - secretRef:
        name: app-values # Secret created in previous step
   ```

To continuously deploy the latest version of your `Package`, set `versionSelection.constraints: >=0.0.0`. To revert to a previous version, update the `versionSelection.constraints:` field and annotate the PackageInstall:

```
packaging.carvel.dev/downgradable: ""
```

See the Carvel documentation.

1. Push the newly created `PackageInstalls` and `Secrets` to your GitOps repository.

Create Flux CD GitRepository and Flux CD Kustomizations on the build cluster

Configure Flux CD on the Build cluster to deploy your `Packages`, `PackageInstalls`, and `Secrets` to each of your run clusters.

1. Give your Build cluster access to your run clusters. On the Build cluster, for each run cluster, create a `Secret` containing the run cluster's kubeconfig. Create the Kubernetes `Secret` in the same namespace as the Kustomization resource:

```
kubectl create secret generic <run-cluster>-kubeconfig \
   -n <build-cluster-ns> \
   --from-file=value.yaml=<path-to-run-cluster-kubeconfig>
```

Note

The kubeconfig must be self-contained and not rely on binaries, or environment and credential files from the kustomize-controller pod. Kubeconfigs that specify a command to provide client credentials such as `gke-gcloud-auth-plugin` won't work without a custom per-provider installation of kustomize-controller.

2. Configure your Build cluster to clone the GitOps repository. On the Build cluster, create the following Flux CD `GitRepository`:

```
---
apiVersion: source.toolkit.fluxcd.io/v1
kind: GitRepository
metadata:
 name: <package-name>-gitops-repo
 namespace: <build-cluster-ns>
spec:
 url: # GitOps repo URL
 ignore: |
   !.git
 interval: 30s
 ref:
   branch: # GitOps repo branch
 timeout: 60s

 # only required if GitOps repo is private (recommended). The secret below shou
ld be present in the same namespace as the GitRepository.
 secretRef:
   name: <package-name>-gitops-auth

# only required if GitOps repo is private (recommended)
---
apiVersion: v1
kind: Secret
metadata:
 name: <package-name>-gitops-auth
 namespace: <build-cluster-ns>
type: Opaque
data:
 username: # base64 encoded GitHub (or other git remote) username
 password: # base64 encoded GitHub (or other git remote) personal access token
```

3. Configure your Build cluster to deploy your `Package` to the run clusters. For each run cluster, on the Build cluster, create the following Flux CD `Kustomization`:

```
---
apiVersion: kustomize.toolkit.fluxcd.io/v1beta2
kind: Kustomization
metadata:
 name: <package-name>-<run-cluster>-packages
 namespace: <build-cluster-ns>
spec:
 sourceRef:
   kind: GitRepository
   name: <package-name>-gitops-repo
   namespace: <build-cluster-ns>
 path: "./<package-name>/packages"
 interval: 5m
 timeout: 5m
 prune: true
 wait: true

 # where to deploy
 kubeConfig:
   secretRef:
     name: <run-cluster>-kubeconfig
 targetNamespace: <run-cluster-ns>
 serviceAccountName: <run-cluster-ns-sa>
```

Note

The Kustomization resource does not accept a `metadata.name` field longer than 63 characters.

4. Configure your Build cluster to deploy your `PackageInstalls` and `Secrets` to the run clusters. For each run cluster, on the Build cluster, create the following Flux CD `Kustomization`:

```
---
apiVersion: kustomize.toolkit.fluxcd.io/v1beta2
kind: Kustomization
metadata:
 # for the second run cluster, for example hello-app-prod2-packages
 name: <package-name>-<run-cluster>-packageinstalls
 namespace: <build-cluster-ns>
spec:
 sourceRef:
   kind: GitRepository
   name: <package-name>-gitops-repo
   namespace: <build-cluster-ns>
 path: "./<package-name>/<run-cluster>"
 interval: 5m
 timeout: 5m
 prune: true
 wait: true

 # where to deploy
 kubeConfig:
   secretRef:
     name: <run-cluster>-kubeconfig
 targetNamespace: <run-cluster-ns>
 serviceAccountName: <run-cluster-ns-sa>
```

Note

The Kustomization resource does not accept a `metadata.name` field longer than 63 characters.

Verify installation

To verify your installation:

1. On your Build cluster, confirm that your Flux CD GitRepository and Kustomizations are reconciling:

   ```
   kubectl get gitrepositories,kustomizations -A
   ```

2. Target a run cluster. Confirm that all Packages from the GitOps repository are deployed:

   ```
   kubectl get packages -A
   ```

3. Target a run cluster. Confirm that all PackageInstalls are reconciled:

   ```
   kubectl get packageinstalls -A
   ```

Now you can access your application on each run cluster.

Use Gitops delivery with Argo CD (beta)

This topic explains how you can deliver Carvel `Packages`, created by the Carvel Package Supply Chains, from a GitOps repository to one or more run clusters using Argo CD for Supply Chain Choreographer.

Prerequisites

To use Gitops Delivery with Argo CD, you must complete the following prerequisites:

- Create a `Workload` that uses a Carvel Package Supply Chain. You must have at least one Carvel `Package` generated by this `Workload` stored in your GitOps repository. See Carvel Package Supply Chains (beta).
- Have at least one run cluster. Run clusters serve as your deployment environments. They can either be Tanzu Application Platform clusters, or Kubernetes clusters, but they must have kapp-controller and Contour installed. See the Carvel documentation and the Contour documentation.
- Create a build cluster that has network access to your run clusters to use a build cluster to control the deployment on all the run clusters. You must also install Argo CD. If you intend to deploy directly on the run cluster without a build cluster, a build cluster is only necessary for building the package.

Set up run cluster namespaces

Each run cluster must have a namespace and `ServiceAccount` with the correct permissions to deploy the Carvel `Packages`.

If your run cluster is a Tanzu Application Platform cluster, see Set up developer namespaces to use installed packages.

If your run cluster is not a Tanzu Application Platform cluster, create a namespace and `ServiceAccount` with the following permissions:

```
---
apiVersion: rbac.authorization.k8s.io/v1
kind: Role
metadata:
  namespace: <run-cluster-ns>
  name: app-cr-role
rules:
- apiGroups: ["apps"]
  resources: ["deployments"]
  verbs: ["get", "list", "create", "update", "delete"]
- apiGroups: [""]
  resources: ["configmaps", "services"]
  verbs: ["get", "list", "create", "update", "delete"]
- apiGroups: ["networking.k8s.io"]
  resources: ["ingresses"]
  verbs: ["get", "list", "create", "update", "delete"]
```

Create Carvel PackageInstalls and secrets

For each Carvel `Package` and run cluster, you must create a Carvel `PackageInstall` and a `Secret`. The Carvel `PackageInstall` and the `Secret` are stored in your GitOps repository and deployed to run clusters by Flux CD.

The following example shows a GitOps repository structure after completing this section:

```
app.default.tap/
  packages/
    20230321004057.0.0.yaml  # Package
  staging/
    packageinstall.yaml      # PackageInstall
    params.yaml              # Secret
  prod/
    packageinstall.yaml      # PackageInstall
    params.yaml              # Secret
```

For each run cluster:

1. Create a `Secret` that has the values for each `Package` parameter. You can view the configurable properties of the `Package` by inspecting the `Package` CR's valuesSchema, or in the Carvel Package Supply Chains documentation. Store the `Secret` in your GitOps repository at `<package_name>/<run_cluster>/params.yaml`.

   Note

   You can skip this step to use the default parameter values.

   ```
   ---
   apiVersion: v1
   kind: Secret
   metadata:
    name: app-values
   stringData:
    values.yaml: |
      ---
      workload_name: app
      replicas: 2
      hostname: app.mycompany.com
   ```

2. Create a `PackageInstall`. Reference the `Secret` you created earlier. Store the `PackageInstall` in your GitOps repository at `<package_name>/<run_cluster>/packageinstall.yaml`.

Note

If you skipped creation of the `Secret`, omit the `values` key.

```
---
apiVersion: packaging.carvel.dev/v1alpha1
kind: PackageInstall
metadata:
 name: app
spec:
 serviceAccountName: <run-cluster-ns-sa> # ServiceAccount on run cluster with p
ermissions to deploy Package, see "Set up run Cluster Namespaces"
 packageRef:
   refName: app.default.tap # name of the Package
   versionSelection:
     constraints: 20230321004057.0.0 # version of the Package
 values:
 - secretRef:
     name: app-values # Secret created in previous step
```

Note

To continuously deploy the latest version of your `Package`, you can set `versionSelection.constraints: >=0.0.0`

3. Push the `PackageInstalls` and `Secrets` to your GitOps repository.

Create an Argo CD application on the Build cluster

Configure Argo CD on the Build cluster to deploy your `Packages`, `PackageInstalls`, and `Secrets` to each run cluster:

1. Register a cluster's credentials to Argo CD. This is only necessary when deploying to an external cluster.
    - First list all clusters contexts in your current kubeconfig:

```
kubectl config get-contexts -o name
```

    - Choose a context name from the list and supply it to the argocd cluster. This command installs a ServiceAccount, argocd-manager, into the kube-system namespace of that kubectl context, binding the service account to an admin-level ClusterRole. Argo CD uses this service account token to perform its management tasks, such as deployment and monitoring.

    For example, for `run-cluster1` context, run:

```
argocd cluster add run-cluster-1
```

Note

> You can modify the rules of the argocd-manager-role role so that it only has create, update, patch, delete privileges to a limited set of namespaces, groups, kinds. However get, list, and watch privileges are required at the cluster-scope.

2. Create an application from a Git repository.
    - Set the current namespace to argocd:

```
kubectl config set-context --current --namespace=argocd
```

    - Create a hello-world-app:

```
argocd app create hello-world-app --repo https://github.com/mycompany/gitops-re
po
```

3. Deploy the application.
    - After you create the application, you can view its status:

```
argocd app get hello-world-app
```

    The output is similar to the following:

```
    Name:               hello-world-app
    Server:             https://kubernetes.default.svc
    Namespace:          default
    URL:                https://10.97.164.88/applications/hello-world-app
    Repo:               https://github.com/mycompany/gitops-repo.git
    Target:
    Path:               hello-world-app
    Sync Policy:        <none>
    Sync Status:        OutOfSync from  (1ff8a67)
    Health Status:      Missing

    GROUP  KIND        NAMESPACE  NAME                 STATUS     HEALTH
    apps   Deployment  default    hello-world-app-dep  OutOfSync  Missing
           Service     default    hello-world-app-svc  OutOfSync  Missing
    The application status is initially in OutOfSync state since the applicatio
n has yet to be deployed, and no Kubernetes resources have been created. To syn
c (deploy) the application, run:
```

    This command retrieves the manifests from the repository and performs a kubectl apply. The hello-world-app app is running and you can now view its resource components, logs, events, and health status.

```
argocd app sync hello-world-app
```

Verify installation

To verify your installation:

1. On your Build cluster, confirm that your Flux CD GitRepository and Kustomizations are reconciling:

```
kubectl get gitrepositories,kustomizations -A
```

2. Target a run cluster. Confirm that all Packages from the GitOps repository are deployed:

```
kubectl get packages -A
```

3. Target a run cluster. Confirm that all PackageInstalls are reconciled:

```
kubectl get packageinstalls -A
```

Now you can access your application on each run cluster.

Use blue-green deployment with Contour and PackageInstall for Supply Chain Choreographer (beta)

Blue-green deployment is an application delivery model that lets you gradually transfer user traffic from one version of your app to a later version while both are running in production. This topic outlines how to use blue-green deployment with Packages and PackageInstalls.

Prerequisites

To use blue-green deployment, you must complete the following prerequisites:

- Complete the prerequisites in Configure and deploy to multiple environments with custom parameters.
- Configure Carvel for your supply chain. See Carvel Package Supply Chains (beta).
- Configure Flux CD for your supply chain. See Deploy Package and PackageInstall using Flux CD Kustomization.

Add HTTPProxy to the blue deployment

The following example deploys a sample application, `hello-app`, to production using a Carvel Package and PackageInstall.

1. Create a Contour HTTPProxy resource to route traffic to the `hello-app` service from the URL `www.hello-app.mycompany.com`.

```
apiVersion: projectcontour.io/v1
kind: HTTPProxy
metadata:
  name: www
  namespace: prod
spec:
  virtualhost:
    fqdn: www.hello-app.mycompany.com
  routes:
    - conditions:
      - prefix: /
        services:
        - name: hello-app
          port: 8080
```

Note

The services names used in HTTPProxy has to match the names of existing services. In this case, the name `hello-app` matches the service installed by the PackageInstall.

2. Apply the HTTPProxy to your cluster:

```
kubectl apply -f httpproxy.yaml
```

3. Verify that the HTTPProxy is present and the route serves traffic to your app.

   ```
   kubectl get HTTPProxy --namespace=prod
   ```

   This displays a list of all the HTTPproxies in the current namespace with their current names.

   ```
   kubectl get HTTPProxy --namespace=prod
   NAMESPACE        NAME                      FQDN
   TLS SECRET            STATUS    STATUS DESCRIPTION
   prod             www                       www.hello-app.mycompany.com
   hello-app-cert        valid     Valid HTTPProxy
   ```

Create the green deployment

After a new version of the package is added to the GitOps repository, create a new PackageInstall for v1.0.1 to create the green deployment.

1. Create a `green-secret.yaml` file with a secret that contains the following ytt overlay.

   ```
   ---
   apiVersion: v1
   kind: Secret
   metadata:
     name: green-overlay-secret
     namespace: prod
   stringData:
     custom-package-overlay.yaml: |
       #@ load("@ytt:overlay", "overlay")
       #@ kd = overlay.subset({"apiVersion":"apps/v1", "kind": "Deployment"})
       #@ ks = overlay.subset({"apiVersion":"v1", "kind": "Service"})
       #@ ki = overlay.subset({"apiVersion":"networking.k8s.io/v1", "kind": "Ingre
   ss"})
       #@ na = overlay.subset({"metadata":{"name":"hello-app"}})

       #@overlay/match by=overlay.and_op(kd, na)
       ---
       metadata:
         #@overlay/replace
         name: hello-app-green

       #@overlay/match by=overlay.and_op(ks, na)
       ---
       metadata:
         #@overlay/replace
         name: hello-app-green

       #@overlay/match by=overlay.and_op(ki, na)
       ---
       metadata:
         #@overlay/replace
         name: hello-app-green
   ```

   This secret changes the names of the service and deployment in the Carvel Package to allow you to install another version of the app in the same namespace.

2. Apply the secret to your cluster by running:

   ```
   kubectl apply -f green-secret.yaml
   ```

3. Create a parameter secret for the new PackageInstall:

```
---
apiVersion: v1
kind: Secret
metadata:
  name: green-dev-values
  namespace: prod
stringData:
  values.yaml: |
    ---
    replicas: 2
    hostname: hello-app-green.mycompany.com
```

4. Apply the parameter secret to your cluster by running:

```
kubectl apply -f green-dev-values.yaml
```

5. Create a PackageInstall to include the `ext.packaging.carvel.dev/ytt-paths-from-secret-name.x` annotation to reference your new overlay secret.

```
---
apiVersion: packaging.carvel.dev/v1alpha1
kind: PackageInstall
metadata:
  name: green.hello-app.dev.tap
  namespace: prod
  annotations:
    ext.packaging.carvel.dev/ytt-paths-from-secret-name.0: green-overlay-secret
spec:
  serviceAccountName: default
  packageRef:
    refName: hello-app.dev.tap
    versionSelection:
      constraints: "1.0.1"
  values:
  - secretRef:
      name: green-dev-values
```

Divide traffic between the blue and green deployments

Use the following procedure to divide traffic between your blue and green deployments.

1. Update the HTTPproxy created with the blue deployment to route traffic to both the blue and green deployments. The names of the services must match the names of the already created services.

```
---
apiVersion: projectcontour.io/v1
kind: HTTPProxy
metadata:
  name: www
  namespace: prod
spec:
  virtualhost:
    fqdn: www.hello-app.mycompany.com
  routes:
  - conditions:
    - prefix: /
      services:
      - name: hello-app-green
        port: 8080
```

```
        weight: 20
      - name: hello-app
        port: 8080
        weight: 80
```

2. Update the weights of traffic for each service by editing the HTTPProxy.
3. Access the service several times and confirm both versions are serving traffic in the same percentage.

   ```
   curl -k https://www.hello-app.mycompany.com
   ```

After the new green app is ready to handle the complete load and the `-green` version is not required, use the following steps to remove the old version and rename the new version:

1. Ensure that all the traffic is using the correct version of the app. For example:

   ```
   apiVersion: projectcontour.io/v1
   kind: HTTPProxy
   metadata:
     name: www
     namespace: prod
   spec:
     virtualhost:
       fqdn: www.hello-app.mycompany.com
     routes:
       - conditions:
         - prefix: /
           services:
           - name: hello-app-green
             port: 8080
             weight: 100 # all traffic routed to the green app
   ```

2. Identify the name of the deployment and service that are part of the PackageInstall you no longer need:

   ```
   kubectl get PackageInstall --namespace=prod
   ```

   This displays a list of all the deployments and services in the current Kubernetes namespace, with their current names. For example:

   ```
   NAME                      PACKAGE NAME       PACKAGE VERSION      DESCRIPTION
   green.hello-app.dev.tap   hello-app.dev.tap   1.0.1            Reconcile succee
   ded
   hello-app.dev.tap         hello-app.dev.tap   1.0.0            Reconcile succee
   ded
   ```

3. Delete the PackageInstall:

   ```
   kubectl delete PackageInstall hello-app.dev.tap --namespace=prod
   ```

4. Rename the service and deployments without the green prefix. For example, update the overlay secret:

   ```
   ---
   apiVersion: v1
   kind: Secret
   metadata:
     name: overlay-secret
     namespace: prod
   stringData:
   ```

```
  custom-package-overlay.yaml: |
    #@ load("@ytt:overlay", "overlay")
    #@ load("@ytt:data", "data")

    #@ kd = overlay.subset({"apiVersion":"apps/v1", "kind": "Deployment"})
    #@ ks = overlay.subset({"apiVersion":"v1", "kind": "Service"})
    #@ ki = overlay.subset({"apiVersion":"networking.k8s.io/v1", "kind": "Ingre
ss"})
    #@ na = overlay.subset({"metadata":{"name":"hello-app-green"}})

    #@overlay/match by=overlay.and_op(kd, na)
    ---
    metadata:
      #@overlay/replace
      name: hello-app
    #@overlay/match by=overlay.and_op(ks, na)
    ---
    metadata:
      #@overlay/replace
      name: hello-app
    #@overlay/match by=overlay.and_op(ki, na)
    ---
    metadata:
      #@overlay/replace
      name: hello-app
    ---
    apiVersion: projectcontour.io/v1
    kind: HTTPProxy
    metadata:
      name: www
      namespace: prod
    spec:
      virtualhost:
        fqdn: www.hello-app.mycompany.com
      routes:
        - conditions:
          - prefix: /
            services:
            - name: hello-app # note the name is changed back
              port: 8080
              weight: 100
```

5. Update your PackageInstall to include the `ext.packaging.carvel.dev/ytt-paths-from-secret-name.x` annotation to reference your new overlay secret. For example:

```
---
apiVersion: packaging.carvel.dev/v1alpha1
kind: PackageInstall
metadata:
  name: green.hello-app.dev.tap
  namespace: prod
  annotations:
    ext.packaging.carvel.dev/ytt-paths-from-secret-name.0: overlay-secret
spec:
  serviceAccountName: default
  packageRef:
    refName: hello-app.dev.tap
    versionSelection:
      constraints: "1.0.1"
  values:
  - secretRef:
      name: hello-app-values
```

6. After the deployment is complete, you can delete the secrets with the overlays.

Verify application

To verify the name of the deployment and service that are part of the PackageInstall:

1. Verify your application by running:

   ```
   kubectl get PackageInstall --namespace=prod
   ```

   This displays a list of all the deployments and services in the current Kubernetes namespace with their current names. For example:

   ```
   NAME                     PACKAGE NAME       PACKAGE VERSION      DESCRIPTION
   hello-app.dev.tap       hello-app.dev.tap     1.0.1            Reconcile succee
   ded
   ```

   The name is back to the original name and the version is `1.0.1`.

Use canary deployment with Contour and Carvel packages for Supply Chain Choreographer (beta)

This topic tells you how to automate canary releases using Contour ingress controller and Flagger with Packages and PackageInstalls.

Canary deployment is an incremental approach to releasing an application where traffic is divided between the existing deployed version and a new version. It introduces the new version to a smaller group of users before extending it to the entire user base.

Prerequisites

To use canary deployment, you must complete the following prerequisites:

- Complete the prerequisites in Configure and deploy to multiple environments with custom parameters.
- Configure your Supply Chain to output Carvel Packages. See Output Carvel Packages from your Supply Chain.
- Deploy Carvel Packages using the tool of your choice:
  - Deploy Carvel Packages using Carvel App CR
  - Deploy Carvel Packages using Flux CD Kustomization
  - Deploy Carvel Packages using Argo CD
- Install Flagger on your Kubernetes cluster. See Flagger Install on Kubernetes.

How to use Contour ingress controller and Flagger to create a canary release

Flagger is a tool that facilitates a controlled process of shifting traffic to a canary deployment while monitoring essential performance metrics, such as the success rate of HTTP requests, average request duration, and the health of the application's pods. By analyzing these key indicators, Flagger decides whether to promote the canary deployment to a wider audience or abort it if any issues arise.

For information about creating canary releases, see Contour canary Deployments in the Flagger documentation.

Using Contour ingress controller and Flagger to create a canary release involves the following steps:

1. Install Flagger on your Kubernetes cluster.
2. Add the label `app.kubernetes.io/name` to your `Workload`.

   The target deployment must have a single label selector in the format `app: <DEPLOYMENT-NAME>`. In addition to `app`, Flagger supports `name` and `app.kubernetes.io/name` selectors.

   Note

   You can use `tanzu apps workload apply <WORKLOAD-NAME> --label "app.kubernetes.io/name=<WORKLOAD-NAME>"` to edit an existing workload and add the required label.

3. Create a canary resource that defines a canary release with progressive traffic shifting.
   - To configure the canary resource, you must specify the Kubernetes Deployment that corresponds to your Workload. Ensure that you set `spec.targetRef.name` to match the name of your Tanzu Application Platform Workload, which is the same as its Kubernetes Deployment name.
   - Flagger generates some Kubernetes objects. The primary deployment represents the stable release of your application. It receives all incoming traffic while the target deployment is scaled down to zero. Flagger monitors changes in the target deployment, including secrets and configmaps. Before promoting the new version as the primary release, Flagger conducts a thorough canary analysis to ensure that it is stabile.
   - In the canary resource, you can define the canary analysis. Flagger uses this analysis definition to verify the duration of the canary phase, which runs periodically until it reaches the maximum traffic weight or the specified number of iterations.
   - During each iteration, Flagger executes webhooks, evaluates metrics, and checks for any exceeded failed checks threshold. If the threshold is surpassed, indicating potential issues, Flagger takes immediate action to halt the analysis and roll back the canary. If no issues are found, Flagger rolls out the new version as the primary release.

   An example of a canary resource created for a workload, called `tanzu-java-web-app`, is deployed in the namespace `dev-namespace`. Replace `myapps.tanzu.biz` with your own domain:

```
apiVersion: flagger.app/v1beta1
kind: Canary
metadata:
  name: tanzu-java-web-app
  namespace: dev-namespace
spec:
  # deployment reference
  targetRef:
    apiVersion: apps/v1
    kind: Deployment
    name: tanzu-java-web-app
  service:
    # name of the Kubernetes service generated by Flagger. Defaults to spec.tar
getRef.name
    name: tanzu-java-web-app-flagger-service
    # service port
    port: 80
```

```
    # container port
    targetPort: 8080
    # Contour request timeout
    timeout: 15s
    # Contour retry policy
    retries:
      attempts: 3
      perTryTimeout: 5s
      # supported values for retryOn - https://projectcontour.io/docs/main/conf
ig/api/#projectcontour.io/v1.RetryOn
      retryOn: "5xx"
  # define the canary analysis timing and KPIs
  analysis:
    # schedule interval (default 60s)
    interval: 30s
    # max number of failed metric checks before rollback
    threshold: 5
    # max traffic percentage routed to canary
    # percentage (0-100)
    maxWeight: 50
    # canary increment step
    # percentage (0-100)
    stepWeight: 5
    # Contour Prometheus checks
    metrics:
      - name: request-success-rate
        # minimum req success rate (non 5xx responses)
        # percentage (0-100)
        thresholdRange:
          min: 99
        interval: 1m
      - name: request-duration
        # maximum req duration P99 in milliseconds
        thresholdRange:
          max: 500
        interval: 30s
    # testing
    webhooks:
      - name: acceptance-test
        type: pre-rollout
        url: http://flagger-loadtester.test/
        timeout: 30s
        metadata:
          type: bash
          cmd: "curl -s http://tanzu-java-web-app-flagger-service-canary.dev-na
mespace | grep Greetings"
      - name: load-test
        url: http://flagger-loadtester.test/
        type: rollout
        timeout: 5s
        metadata:
          cmd: "hey -z 1m -q 10 -c 2 -host tanzu-java-web-app.myapps.tanzu.biz
http://envoy.tanzu-system-ingress"
```

- Save the resource you created as `canary.yaml` and apply it to your cluster:

```
export WORKLOAD_NAMESPACE=dev-namespace
kubectl apply -n $WORKLOAD_NAMESPACE -f canary.yaml
```

- In the earlier example, you use the load testing service `flagger-loadtester` to generate traffic during the canary analysis.
- To install the load testing service:

```
kubectl create ns test
kubectl apply -k https://github.com/fluxcd/flagger//kustomize/tester?ref=main
```

4. Add an HTTPProxy to include the proxy generated by Flagger.

   The following example HTTPProxy resource references `tanzu-java-web-app-flagger-service` and is deployed in the namespace `dev-namespace`:

   ```
   apiVersion: projectcontour.io/v1
   kind: HTTPProxy
   metadata:
     name: tanzu-java-web-app-ingress
     namespace: dev-namespace
   spec:
     virtualhost:
       fqdn: tanzu-java-web-app.myapps.tanzu.biz
     includes:
     - name: tanzu-java-web-app-flagger-service
       namespace: dev-namespace
       conditions:
         - prefix: /
   ```

   Save the resource you created as `httpproxy.yaml` and then apply it to your cluster:

   ```
   export WORKLOAD_NAMESPACE=dev-namespace
   kubectl apply -n $WORKLOAD_NAMESPACE -f httpproxy.yaml
   ```

   Confirm the HTTPProxy created by Contour has `Valid` status:

   ```
   kubectl get httpproxies -n $WORKLOAD_NAMESPACE
   ```

5. Make changes to GitOps repository and observe the progressive delivery in action

   As changes are made to your GitOps repository, the GitOps tools in place in your environment, such as Flux CD and Argo CD, deploy the new `Package`s onto your clusters. Flagger detects any changes to the target deployment, including secrets and configmaps, and starts a new rollout. The new version is either promoted or rolled back.

   You can monitor the traffic shifting with:

   ```
   watch kubectl get canary -n $WORKLOAD_NAMESPACE
   kubectl describe canary
   CANARY-RESOURCE-NAME -n $WORKLOAD_NAMESPACE
   ```

   Where `CANARY-RESOURCE-NAME` is the name of the canary resource you want to use.

- Contour canary Deployments
- Flagger - How it works

Use blue-green deployment with Flagger for Supply Chain Choreographer (beta)

This topic tells you how to use blue-green deployment with Packages and PackageInstalls using Flagger for Supply Chain Choreographer (beta).

Overview

Blue-green deployment is an application delivery model that lets you gradually transfer user traffic from one version of your app to a later version while both are running in production.

Prerequisites

To use blue-green deployment, you must complete the following prerequisites:

- Complete the prerequisites in Configure and deploy to multiple environments with custom parameters.
- Configure Carvel for your supply chain. See Carvel Package Supply Chains (beta).
- Configure a GitOps tool to deploy the package. See Deploy Package and PackageInstall using Flux CD Kustomization or ArgoCD.

Deployment name

To get the name of the deployment you want to use:

1. Identify the name of the deployment and service that are part of the PackageInstall:

   ```
   kubectl get deployment --namespace=prod
   ```

   This displays a list of all the deployments and services in the current Kubernetes namespace, with their current names. For example:

   ```
   NAME                          READY   UP-TO-DATE   AVAILABLE   AGE
   hello-app-00001-deployment    1/1     1            1           103
   ```

Flagger Canary resource

Create a canary custom resource using the Flagger instructions using the deployment name from the earlier step.

Flagger creates three ClusterIP services: `hello-app.dev.tap-primary`, `hello-app.dev.tap-canary`, `hello-app.dev.tap`. It also creates a shadow deployment named `app-primary` that represents the blue version. When a new version is detected, Flagger scales up the green version and runs the conformance tests, the tests target the `hello-app.dev.tap-canary` ClusterIP service to reach the green version. If the conformance tests are passing, Flagger starts the load tests and validates them with custom Prometheus queries. If the load test analysis is successful, Flagger promotes the new version to `hello-app.dev.tap-primary` and scales down the green version. Flagger extends a canary analysis through custom metrics and webhooks for running load tests, acceptance tests, or any other custom validation.

Flagger includes a load generation tool to ensure that the canary version of an application has enough traffic to generate metrics for analysis. Without an HPA (Horizontal Pod Autoscaler), Flagger does not dynamically scale up or down the new version based on traffic weight. This implies that the number of pods for the new version remains constant throughout deployment. Consequently, performance issues like high latency, errors, or timeouts can arise if the new version receives more traffic than it can handle. This situation can also impact the metrics and webhooks that Flagger uses to validate the new version, potentially leading to a rollback or promotion delay.

Workloads of type `Web` use Knative, which has its own custom autoscaler and doesn't use HPA by default, however you can configure the Knative to use it.

Use an existing image with Supply Chain Choreographer

This topic describes how you can use an existing image with Supply Chain Choreographer.

For apps that build container images in a predefined way, the supply chains in the Out of the Box packages enable you to specify a prebuilt image. This uses the same stages as any other workload.

Requirements for prebuilt images

Supply chains aim at Knative as the runtime for the container image you provide. Your app must adhere to the following Knative standards:

- **Container port listens on port 8080**

  The Knative service is created with the container port set to `8080` in the pod template spec Therefore, your container image must have a socket listening on `8080`.

  ```
  ports:
    - containerPort: 8080
      name: user-port
      protocol: TCP
  ```

- **Non-privileged user ID**

  By default, the container initiated as part of the pod is run as user 1000.

  ```
  securityContext:
    runAsUser: 1000
  ```

- **Arguments other than the image's default ENTRYPOINT**

  In most cases the container image runs using the `ENTRYPOINT` it was configured with. In the case of Dockerfiles, the combination of `ENTRYPOINT` and `CMD`.

  If you need extra configuration for your image, use `--env` flags with the `tanzu apps workload create` command or modify `spec.env` in your `workload.yaml` file.

- **Credentials for pulling the container image at runtime**

  The image you provide is not relocated to an internal container image registry. Any components associated with the image must have the necessary credentials to pull it. For the service accounts used for the workload and deliverable, you must attach a secret that contains the credentials to pull the container image.

  If the image is hosted in a registry that has certificates signed by a private certificate authority, the components of the supply chains, delivery, and the Kubernetes nodes in the run cluster must trust the certificate.

Configure your workload to use a prebuilt image

To select a prebuilt image, set the `spec.image` field in your `workload.yaml` file with the name of the container image that contains the app to deploy by running:

```
tanzu apps workload create WORKLOAD-NAME \
  --app APP-NAME \
  --type TYPE \
  --image IMAGE
```

Where:

- `WORKLOAD-NAME` is the name you choose for your workload.

- `APP-NAME` is the name of your app.
- `TYPE` is the type of your app.
- `IMAGE` is the container image that contains the app you want to deploy.

For example, if you have an image named `IMAGE`, you can create a workload with the flag mentioned earlier:

```
tanzu apps workload create tanzu-java-web-app \
  --app tanzu-java-web-app \
  --type web \
  --image IMAGE
```

Expected output:

```
Create workload:
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1
      3 + |kind: Workload
      4 + |metadata:
      5 + |  labels:
      6 + |    app.kubernetes.io/part-of: hello-world
      7 + |    apps.tanzu.vmware.com/workload-type: web
      8 + |  name: tanzu-java-web-app
      9 + |  namespace: default
     10 + |spec:
     11 + |  image: IMAGE
```

When you run `tanzu apps workload create` command with the `--image` field, the source resolution and build phases of the supply chain are skipped.

Examples

The following examples show ways that you can build container images for a Java-based app and complete the supply chains to a running service.

Using a Dockerfile

Using a Dockerfile is the most common way of building container images. You can select a base image, on top of which certain operations must occur, such as compiling code, and mutate the contents of the file system to a final container image that has a build of your app and any required runtime dependencies.

Here you use the `maven` base image for compiling your app code, and then the minimal distroless `java17-debian11` image for providing a JRE that can run your app when it is built.

After building the image, you push it to a container image registry, and then reference it in the workload.

1. Create a Dockerfile that describes how to build your app and make it available as a container image:

   ```
   ARG BUILDER_IMAGE=maven
   ARG RUNTIME_IMAGE=gcr.io/distroless/java17-debian11

   FROM $BUILDER_IMAGE AS build

           ADD . .
           RUN unset MAVEN_CONFIG && ./mvnw clean package -B -DskipTests
   ```

```
FROM $RUNTIME_IMAGE AS runtime

        COPY --from=build /target/demo-0.0.1-SNAPSHOT.jar /demo.jar
        CMD [ "/demo.jar" ]
```

2. Push the container image to a container image registry by running:

```
docker build -t IMAGE .
docker push IMAGE
```

3. Create a workload by running:

```
tanzu apps workload create tanzu-java-web-app \
  --type web \
  --app tanzu-java-web-app \
  --image IMAGE
```

Expected output:

```
Create workload:
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1
      3 + |kind: Workload
      4 + |metadata:
      5 + |  labels:
      6 + |    app.kubernetes.io/part-of: hello-world
      7 + |    apps.tanzu.vmware.com/workload-type: web
      8 + |  name: tanzu-java-web-app
      9 + |  namespace: default
     10 + |spec:
     11 + |  image: IMAGE
```

4. Run the following workload:

```
tanzu apps workload get tanzu-java-web-app
```

Expected output:

```
# tanzu-java-web-app: Ready
---
lastTransitionTime: "2022-04-06T19:32:46Z"
message: ""
reason: Ready
status: "True"
type: Ready

Workload pods
NAME                                                  STATUS      RESTARTS   A

tanzu-java-web-app   Ready   http://tanzu-java-web-app.default.example.com
```

Using Spring Boot's `build-image` Maven target

You can use Spring Boot's `build-image` target to build a container image that runs your app. The `build-image` target must use a Dockerfile.

For example, using the same sample repository as mentioned before (https://github.com/vmware-tanzu/application-accelerator-samples/tree/main/tanzu-java-web-app):

1. Build the image by running the following command from the root of the repository:

   ```
   IMAGE=ghcr.io/kontinue/hello-world:tanzu-java-web-app
   ./mvnw spring-boot:build-image -Dspring-boot.build-image.imageName=$IMAGE
   ```

   Expected output:

   ```
   [INFO] Scanning for projects...
   [INFO]
   [INFO] --------------------------< com.example:demo >--------------------------
   [INFO] Building demo 0.0.1-SNAPSHOT
   [INFO] --------------------------------[ jar ]---------------------------------
   [INFO]
   ...
   [INFO]
   [INFO] Successfully built image 'ghcr.io/kontinue/hello-world:tanzu-java-web-ap
   p'
   [INFO]
   [INFO] ------------------------------------------------------------------------
   [INFO] BUILD SUCCESS
   [INFO] ------------------------------------------------------------------------
   [INFO] Total time:  39.257 s
   [INFO] Finished at: 2022-04-06T19:40:16Z
   [INFO] ------------------------------------------------------------------------
   ```

2. Push the image you built to the container image registry by running:

   ```
   IMAGE=ghcr.io/kontinue/hello-world:tanzu-java-web-app
   docker push $IMAGE
   ```

   Expected output:

   ```
   The push refers to repository [ghcr.io/kontinue/hello-world]
   1dc94a70dbaa: Preparing
   ...
   9d6787a516e7: Pushed
   tanzu-java-web-app: digest: sha256:7140722ea396af69fb3d0ad12e9b4419bc3e67d9c5d8
   a2f6a1421decc4828ace size: 4497
   ```

After you push the container image, you see the same results as building the image using a Dockerfile.

For more information about building container images for a Spring Boot app, see Spring Boot with Docker

About Out of the Box Supply Chains

In Tanzu Application Platform, the `ootb-supply-chain-basic`, `ootb-supply-chain-testing`, and `ootb-supply-chain-testing-scanning` packages each receive a new supply chain that provides a prebuilt container image for your app.

```
ootb-supply-chain-basic

    (cluster)  basic-image-to-url   ClusterSupplyChain            (!) new
    ^          source-to-url        ClusterSupplyChain
```

```
ootb-supply-chain-testing

    (cluster)  testing-image-to-url  ClusterSupplyChain           (!) new
    ^          source-test-to-url    ClusterSupplyChain

ootb-supply-chain-testing-scanning

    (cluster)  scanning-image-scan-to-url    ClusterSupplyChain   (!) new
    ^          source-test-scan-to-url       ClusterSupplyChain
```

To leverage the supply chains that expect a prebuilt image, you must set the `spec.image` field in the workload to the name of the container image that contains the app to deploy.

The new supply chains use a Cartographer feature that lets VMware increase the specificity of supply chain selection by using the `matchFields` selector rule.

The selection takes place as follows:

- *ootb-supply-chain-basic*
    - From source: label `apps.tanzu.vmware.com/workload-type: web`
    - Prebuilt image: label `apps.tanzu.vmware.com/workload-type: web` **and** set `spec.image` in the `workload.yaml`
- *ootb-supply-chain-testing*
    - From source: labels `apps.tanzu.vmware.com/workload-type: web` and `apps.tanzu.vmware.com/has-tests: true`
    - Prebuilt image: label `apps.tanzu.vmware.com/workload-type: web` **and** set `spec.image` in the `workload.yaml`
- *ootb-supply-chain-testing-scanning*
    - From source: labels `apps.tanzu.vmware.com/workload-type: web` and `apps.tanzu.vmware.com/has-tests: true`
    - Prebuilt image: label `apps.tanzu.vmware.com/workload-type: web` **and** set `spec.image` in the `workload.yaml`

Workloads that already work with the supply chains before Tanzu Application Platform v1.1 continue to work with the same supply chain. Workloads that bring a prebuilt container image must set `spec.image` in the `workload.yaml`.

Understanding the supply chain for a prebuilt image

An `ImageRepository` object is created to keep track of new images pushed under that name. `ImageRepository` makes the image available to further resources in the supply chain, providing the final digest of the latest image.

Whenever a new image is pushed to the workload's image location, the `ImageRepository` detects the change. The image is then available to further resources by updating its `imagerepository.status.artifact.revision` with an absolute reference to that image.

For example, if you create a workload using an image named `hello-world`, tagged `tanzu-java-web-app` hosted under `ghcr.io` in the `kontinue` repository:

```
tanzu apps workload create tanzu-java-web-app \
  --app tanzu-java-web-app \
  --type web \
  --image ghcr.io/kontinue/hello-world:tanzu-java-web-app
```

After a couple seconds, you see the `ImageRepository` object created to keep track of images named `ghcr.io/kontinue/hello-world:tanzu-java-web-app`:

```
Workload/tanzu-java-web-app
├─ImageRepository/tanzu-java-web-app
├─PodIntent/tanzu-java-web-app
├─ConfigMap/tanzu-java-web-app
└─Runnable/tanzu-java-web-app-config-writer
  └─TaskRun/tanzu-java-web-app-config-writer-p2lzv
    └─Pod/tanzu-java-web-app-config-writer-p2lzv-pod
```

If you inspect the status in `status.resources` in the `workload.yaml`, you see the `image-provider` resource promoting the image it found to further resources:

```
apiVersion: carto.run/v1alpha1
kind: Workload
spec:
  image: ghcr.io/kontinue/hello-world:tanzu-java-web-app
status:
  resources:
    - name: image-provider
      outputs:
        # output being made available to further resources in the supply chain
        # (in this case, the latest image it found under that name).
        #
        - name: image
          lastTransitionTime: "2022-04-01T15:05:01Z"
          preview: ghcr.io/kontinue/hello-world:tanzu-java-web-app@sha256:9fb930a...

      # reference to the object managed by the supply chain for this
      # resource
      #
      stampedRef:
        apiVersion: source.apps.tanzu.vmware.com/v1alpha1
        kind: ImageRepository
        name: tanzu-java-web-app
        namespace: workload

      # reference to the template that defined how this object should look
      # like
      #
      templateRef:
        apiVersion: carto.run/v1alpha1
        kind: ClusterImageTemplate
        name: image-provider-template
```

The image found by the `ImageRepository` object is carried through the supply chain to the final configuration. This is pushed to either a Git repository or image registry so that it is deployed in a run cluster.

Note

The image name matches the image name supplied in the `spec.image` field in the `workload.yaml`, but also includes the digest of the latest image found under the tag. If a new image is pushed to the same tag, you see the `ImageRepository` resolving the name to a different digest corresponding to the new image pushed.

Use Git authentication with Supply Chain Choreographer

This topic describes how you can use Git authentication with Supply Chain Choreographer.

You can either fetch or push source code from or to a repository that requires credentials. You must provide credentials through a Kubernetes secret object referenced by the intended Kubernetes object created for performing the action.

The following sections provide details about how to appropriately set up Kubernetes secrets for carrying those credentials forward to the proper resources.

Important

For HTTP, HTTPS, and SSH, do not use the same server for multiple secrets to avoid a Tekton error.

Pulling Source Code

For the supply chain to pull source code it must reference a secret with Git credentials. This secret must exist in the same namespace as the workload.

```
apiVersion: v1
kind: Secret
metadata:
   name: NAME-OF-THE-SECRET
   namespace: SOME-NAMESPACE
spec: ...
```

You must provide the name of this secret to the supply chain, either as a tap-value or as a workload parameter.

tap-value example:

```
ootb_supply_chain_basic:
   source:
      credentials_secret: NAME-OF-THE-SECRET
```

Workload parameter value:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  namespace: SOME-NAMESPACE
spec:
  params:
    - name: source_credentials_secret
      value: NAME-OF-THE-SECRET
```

Pushing Build Configuration

For the supply chain to push build configuration to a Gitops repository, the supply chain must reference a service account and this service account must in turn reference a secret with Git credentials.

The secret can be different from the secret used for pulling source code, with different credentials to a different repository.

For example, a secret:

```
apiVersion: v1
kind: Secret
metadata:
```

```
   name: NAME-OF-A-SECRET
   namespace: SOME-NAMESPACE
   annotations:
     tekton.dev/git-0: GIT-SERVER        # ! required. example: https://github.com
spec: ...
```

referenced by a service account:

```
apiVersion: v1
kind: ServiceAccount
metadata:
  name: SOME-SA-NAME
  namespace: SOME-NAMESPACE
secrets:
  - name: registry-credentials
  - name: tap-registry
  - name: NAME-OF-A-SECRET
imagePullSecrets:
  - name: registry-credentials
  - name: tap-registry
```

You must provide the name of this service account to the supply chain, either as a tap-value or as a workload parameter.

tap-value example:

```
ootb_supply_chain_basic:
   service_account: SOME-SA-NAME
```

Workload parameter example:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  namespace: SOME-NAMESPACE
spec:
  params:
    - name: serviceAccount
      value: SOME-SA-NAME
```

Note

If you've used Namespace Provisioner to set up your Developer Namespace where your workload is created, use the `namespace_provisioner.default_parameters.supply_chain_service_account.secrets` property in your `tap-values.yaml`. For example:

```
```yaml
namespace_provisioner:
  default_parameters:
    supply_chain_service_account:
      secrets:
      - GIT-SECRET-NAME
```
```

Namespace Provisioner manages the service account and manual edits to it do not persist.

Pulling Build Configuration

The delivery must pull the build configuration that was pushed by the supply chain. It must reference a secret with Git credentials (similar to how the supply chain pulls source code). This secret must exist in the same namespace as the deliverable. The credentials in this secret must be valid for the repository to which the supply chain pushed configuration.

```
apiVersion: v1
kind: Secret
metadata:
   name: NAME-OF-A-SECRET
   namespace: A-NAMESPACE
spec: ...
```

You must provide the name of this secret, either as a tap-value or as a deliverable parameter.

tap-value example:

```
ootb_delivery_basic:
   source:
      credentials_secret: NAME-OF-A-SECRET
```

Deliverable parameter example:

```
apiVersion: carto.run/v1alpha1
kind: Deliverable
metadata:
  namespace: A-NAMESPACE
spec:
  params:
    - name: source_credentials_secret
      value: NAME-OF-A-SECRET
```

HTTP

For any action upon an HTTP or HTTPS based repository, create a Kubernetes secret object of type `kubernetes.io/basic-auth` as follows:

```
apiVersion: v1
kind: Secret
metadata:
  name: SECRET-NAME
  annotations:
    tekton.dev/git-0: GIT-SERVER        # ! required
type: kubernetes.io/basic-auth          # ! required
stringData:
  username: GIT-USERNAME
  password: GIT-PASSWORD
```

For example, assuming you have a repository called `kontinue/hello-world` on GitHub that requires authentication, and you have an access token with the privileges of reading the contents of the repository, you can create the secret as follows:

```
apiVersion: v1
kind: Secret
metadata:
  name: git-secret
  annotations:
    tekton.dev/git-0: https://github.com
type: kubernetes.io/basic-auth
stringData:
```

```
  username: GITHUB-USERNAME
  password: GITHUB-ACCESS-TOKEN
```

Note

In this example, you use an access token because GitHub deprecates basic authentication with plain user name and password. For more information, see Creating a personal access token on GitHub.

HTTPS with a Custom CA Certificate

In addition to the shared.ca_cert_data field, you must add the certificate to the secret used to access the Git repository. The only platform tested with custom CA certificates is GitLab.

You set up the secret similarly to the section above, but the `caFile` field specifies a certificate authority.

```
apiVersion: v1
kind: Secret
metadata:
 name: SECRET-NAME
 annotations:
   tekton.dev/git-0: GIT-SERVER        # ! required
type: kubernetes.io/basic-auth          # ! required
stringData:
 username: GIT-USERNAME
 password: GIT-PASSWORD
 caFile: |
  -----BEGIN CERTIFICATE-----
  ...
  -----END CERTIFICATE-----
```

SSH

Aside from using HTTP or HTTPS as a transport, the supply chains also allow you to use SSH.

Important

To use the pull request feature, you must use HTTP or HTTPS authentication with an access token.

1. To provide the credentials for any Git operations with SSH, create the Kubernetes secret as follows:

   ```
   apiVersion: v1
   kind: Secret
   metadata:
     name: GIT-SECRET-NAME
     annotations:
       tekton.dev/git-0: GIT-SERVER
   type: kubernetes.io/ssh-auth          # ! required
   stringData:
     ssh-privatekey: SSH-PRIVATE-KEY     # private key with push-permissions
     identity: SSH-PRIVATE-KEY           # private key with pull permissions
     identity.pub: SSH-PUBLIC-KEY        # public of the `identity` private key
     known_hosts: GIT-SERVER-PUBLIC-KEYS # Git server public keys
   ```

2. Generate a new SSH keypair: `identity` and `identity.pub`.

```
ssh-keygen -t ecdsa -b 521 -C "" -f "identity" -N ""
```

3. Go to your Git provider and add the `identity.pub` as a deployment key for the repository of interest or add to an account that has access to it. For example, for GitHub, visit `https://github.com/<repository>/settings/keys/new`.

Note

Keys of type SHA-1/RSA are recently deprecated by GitHub.

4. Gather public keys from the provider, for example, GitHub:

```
ssh-keyscan github.com > ./known_hosts
```

5. Create the Kubernetes secret by using the contents of the files in the first step:

```
apiVersion: v1
kind: Secret
metadata:
  name: GIT-SECRET-NAME
  annotations: {tekton.dev/git-0: GIT-SERVER}
type: kubernetes.io/ssh-auth
stringData:
  ssh-privatekey: SSH-PRIVATE-KEY
  identity: SSH-PRIVATE-KEY
  identity.pub: SSH-PUBLIC-KEY
  known_hosts: GIT-SERVER-PUBLIC-KEYS
```

For example, edit the credentials:

```
apiVersion: v1
kind: Secret
metadata:
  name: git-ssh
  annotations: {tekton.dev/git-0: github.com}
type: kubernetes.io/ssh-auth
stringData:
  ssh-privatekey: |
    -----BEGIN OPENSSH PRIVATE KEY-----
    AAAA
    ....
    ....
    -----END OPENSSH PRIVATE KEY-----
  known_hosts: |
    <known hosts entrys for git provider>
  identity: |
    -----BEGIN OPENSSH PRIVATE KEY-----
    AAAA
    ....
    ....
    -----END OPENSSH PRIVATE KEY-----
  identity.pub: ssh-ed25519 AAAABBBCCCCDDDDeeeeFFFF user@example.com
```

More information about Git

For information about Git, see Git Reference.

Using Azure DevOps as a Git provider with your supply chains

This topic describes how you can Azure DevOps as a Git provider with your Supply Chain Choreographer supply chains.

Overview

There are two uses for Git in a supply chain:

- As a source of code to build and deploy applications
- As a repository of configuration created by the build cluster which is deployed on a run or production cluster

Azure DevOps differs from other Git providers in the following ways:

- Azure DevOps requires Git clients to support multi-ack.
- Azure DevOps repository paths differ from other Git providers.

For information about how Azure DevOps is different from other Git providers, see Gitops write path templates.

The operator requires special configuration to integrate Azure DevOps repositories into a supply chain.

Azure authentication

You can use Azure authentication with Supply Chain Choreographer.

For information about configuring secrets to authenticate with your Azure DevOps Git repository, see Use Git authentication with Supply Chain Choreographer.

Azure http and https authentication requires:

```
username: "_token"
password: AZURE-USER-TOKEN
```

Where `AZURE-USER-TOKEN` is your Azure personal access token. See Azure Devops Personal Access Tokens in the Microsoft documentation.

Using Azure DevOps as a repository for committed code

Developers can use Azure DevOps to commit source code to a repository that the supply chain pulls.

Azure DevOps example

The following example uses the Azure DevOps source repository:

`https://dev.azure.com/my-company/app/_git/app`

You can configure the supply chain by using `tap-values`:

```
ootb_supply_chain_testing_scanning:
  git_implementation: go-git
```

or by using workload parameter:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  ...
spec:
  params:
    - name: gitImplementation
      value: go-git
```

Using Azure DevOps as a GitOps repository

The supply chain commits Kubernetes configuration to a Git repository. This configuration is then applied to another cluster. This is the GitOps promotion pattern.

You must construct a path and configure your Git implementation to read and write to an Azure DevOps repository.

GitOps write path example

The following example uses the Azure DevOps Git repository:

`https://dev.azure.com/vmware-tanzu/tap/_git/tap`

Set the `gitops_server_kind` workload parameters to `azure`.

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  ...
spec:
  params:
    - name: gitops_server_kind
      value: azure
    ...
```

Set other GitOps values in either tap-values or in the workload parameters.

- By using tap-values:

  ```
  ootb_supply_chain_testing_scanning:
    gitops:
      server_address: https://dev.azure.com
      repository_owner: vmware-tanzu/tap
      repository_name: tap
  ```

- By using the workload parameters:

  ```
  apiVersion: carto.run/v1alpha1
  kind: Workload
  metadata:
    ...
  spec:
    params:
      - name: gitops_server_address
        value: https://dev.azure.com
      - name: gitops_repository_owner
        value: vmware-tanzu/tap
      - name: gitops_repository_name
        value: tap
      ...
  ```

Gitops write path templates

Azure DevOps and Git use different URL structures.

For example, the Git clone URL of an Azure DevOps repository is structured as:

`https://dev.azure.com/<org_name>/<project_name>/_git/<repository_name>`

GitHub uses the following address structure:

`https://github.com/<org_name>/<repository_name>`

In Azure DevOps, a project can have multiple repositories, but the project name and repository name are often the same.

The config-writer and config-writer-and-pull-requester templates accept three parameters to build the path of the repository. For Azure DevOps, configure them as follows:

- gitops_server_address: `https://dev.azure.com`
- gitops_repository_owner: `<org_name>/<project_name>`
- gitops_repository_name: `<repository_name>`

Configure the template parameters as follows:

- `gitops.server_address` tap-value during the Out of the Box Supply Chains package installation or `gitops_server_address` configured as a workload parameter.
- `gitops.repository_owner` tap-value during the Out of the Box Supply Chains package installation or `gitops_repository_owner` configured as a workload parameter.
- `gitops.repository_name` tap-value during the Out of the Box Supply Chains package installation or `gitops_repository_name` configured as a workload parameter.

To properly contruct the write path, the template parameter `gitops_server_kind` must be configured as `azure`.

Configure`gitops_server_kind` as a workload parameter.

Note

When you use pull requests with GitOps, you can set the type of server with the tap-value `gitops.pull_request.server_kind`. See GitOps versus RegistryOps.

For information about configuring the GitOps write operations, see GitOps versus RegistryOps.

Using GitLab as a Git provider with your supply chains

This topic describes how to use GitLab as a Git provider with your Supply Chain Choreographer supply chains.

Overview

There are two uses for Git in a supply chain:

- As a source of code to build and deploy applications
- As a repository of configuration created by the build cluster which is deployed on a run or production cluster

Using GitLab as a repository for committed code

This section tells you how developers can use GitLab to commit source code to a repository that the supply chain pulls.

GitLab example

The following example uses the GitLab source repository:

`https://gitlab.example.com/my-org/repository.git`

You can configure the supply chain by using `tap-values.yaml`:

```
ootb_supply_chain_testing_scanning:
  git_implementation: go-git
```

or by using a workload parameter:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  ...
spec:
  params:
    - name: gitImplementation
      value: go-git
```

Using GitLab as a GitOps repository

The supply chain commits Kubernetes configuration to a Git repository. This configuration is then applied to another cluster. This is the GitOps promotion process.

You must construct a path and configure your Git implementation to read and write to an GitLab repository.

GitOps write path example

The following example uses the GitLab Git repository:

`https://gitlab.example.com/my-org/repository.git`

1. Set the `gitops_server_kind` workload parameters to `gitlab`.

   ```
   apiVersion: carto.run/v1alpha1
   kind: Workload
   metadata:
     ...
   spec:
     params:
       - name: gitops_server_kind
         value: gitlab
       ...
   ```

2. Set other GitOps values in either `tap-values.yaml` or in the workload parameters.

   By using `tap-values.yaml`:

   ```
   ootb_supply_chain_testing_scanning:
     gitops:
       server_address: https://gitlab.example.com
       repository_owner: my-org
       repository_name: repository
   ```

   By using the workload parameters:

   ```
   apiVersion: carto.run/v1alpha1
   kind: Workload
   metadata:
   ```

```
    ...
  spec:
    params:
      - name: gitops_server_address
        value: https://gitlab.example.com
      - name: gitops_repository_owner
        value: my-org
      - name: gitops_repository_name
        value: repository
      ...
```

GitLab read example

The following example uses the GitLab repository:

`https://gitlab.example.com/my-org/repository.git`

You can configure the delivery `tap-values.yaml`:

```
ootb_delivery_basic:
  git_implementation: go-git
```

or the deliverable parameter:

```
apiVersion: carto.run/v1alpha1
kind: Deliverable
metadata:
  ...
spec:
  params:
    - name: gitImplementation
      value: go-git
```

GitLab over HTTPS with a custom CA certificate

When using HTTPS with a custom certificate authority, you must configure the Git secret both in `tap-values.yaml` and the Git secret used by the GitRepository.

1. Set the shared.ca_cert_data in `tap-values.yaml`. You must set the Git secret in the `caFile` field.

   ```
   apiVersion: v1
   kind: Secret
   metadata:
     name: SECRET-NAME
     annotations:
       tekton.dev/git-0: GIT-SERVER        # ! required
   type: kubernetes.io/basic-auth          # ! required
   stringData:
     username: GIT-USERNAME
     password: GIT-PASSWORD
     caFile: |
     -----BEGIN CERTIFICATE-----
     ...
     -----END CERTIFICATE-----
   ```

2. Associate the secret with the `ServiceAccount`.

   ```
   apiVersion: v1
   kind: ServiceAccount
   metadata:
   name: default
   secrets:
   ```

```
- name: registry-credentials
- name: tap-registry
- name: GIT-SECRET-NAME
imagePullSecrets:
- name: registry-credentials
- name: tap-registry
```

For information about authentication, see Git Authentication.

Author your supply chains

The Out of the Box Supply Chain, Delivery Basic, and Templates Supply Chain Choreographer packages give you Kubernetes objects that cover a reference path to production. Because VMware recognizes that you have your own needs, these objects are customizable, including individual templates for each resource, whole supply chains, or delivery objects.

Depending on how you installed Tanzu Application Platform, there are different ways to customize the Out of the Box Supply Chains. The following sections describe the ways supply chains and templates are authored within the context of profile-based Tanzu Application Platform installations.

Providing your own supply chain

To create a new supply chain and make it available for workloads, ensure that the supply chain does not conflict with those installed on the cluster, as those objects are cluster-scoped.

If this is your first time creating a supply chain, follow the tutorials from the Cartographer documentation.

Any supply chain installed in a Tanzu Application Platform cluster might encounter two possible cases of collisions:

- **object name**: Supply chains are cluster scoped, such as any Cartographer resource prefixed with `Cluster`. So the name of the custom supply chain must be different from the ones provided by the Out of the Box packages.

  Either create a supply chain whose name is different, or remove the installation of the corresponding `ootb-supply-chain-*` from the Tanzu Application Platform.

- **workload selection**: A workload is reconciled against a particular supply chain based on a set of selection rules as defined by the supply chains. If the rules for the supply chain to match a workload are ambiguous, the workload does not make any progress.

  Either create a supply chain whose selection rules are different from the ones the Out of the Box Supply Chain packages use, or remove the installation of the corresponding `ootb-supply-chain-*` from Tanzu Application Platform.

  See Selectors.

For Tanzu Application Platform 1.2, the following selection rules are in place for the supply chains of the corresponding packages:

- *ootb-supply-chain-basic*
  - ClusterSupplyChain/**basic-image-to-url**
    - label `apps.tanzu.vmware.com/workload-type: web`
    - `workload.spec.image` text box set
  - ClusterSupplyChain/**source-to-url**
    - label `apps.tanzu.vmware.com/workload-type: web`
  - ClusterSupplyChain/**basic-image-to-url-package (experimental)**

        - label `apps.tanzu.vmware.com/workload-type: server`
        - label `apps.tanzu.vmware.com/carvel-package-workflow: true`
    - ClusterSupplyChain/**source-to-url-package (experimental)**
        - label `apps.tanzu.vmware.com/workload-type: server`
        - label `apps.tanzu.vmware.com/carvel-package-workflow: true`
- *ootb-supply-chain-testing*
    - ClusterSupplyChain/**testing-image-to-url**
        - label `apps.tanzu.vmware.com/workload-type: web`
        - `workload.spec.image` text box set
    - ClusterSupplyChain/**source-test-to-url**
        - label `apps.tanzu.vmware.com/workload-type: web`
        - label `apps.tanzu.vmware.com/has-test: true`
- *ootb-supply-chain-testing-scanning*
    - ClusterSupplyChain/**scanning-image-scan-to-url**
        - label `apps.tanzu.vmware.com/workload-type: web`
        - `workload.spec.image` text box set
    - ClusterSupplyChain/**source-test-scan-to-url**
        - label `apps.tanzu.vmware.com/workload-type: web`
        - label `apps.tanzu.vmware.com/has-test: true`

For details about how to edit an existing supply chain, see Modifying an Out of the Box Supply Chain section.

You can exclude a supply chain package from the installation to prevent the conflicts mentioned earlier, by using the `excluded_packages` property in `tap-values.yaml`. For example:

```
# add to exclued_packages `ootb-*` packages you DON'T want to install
# excluded_packages:
  - ootb-supply-chain-basic.apps.tanzu.vmware.com
  - ootb-supply-chain-testing.apps.tanzu.vmware.com
  - ootb-supply-chain-testing-scanning.apps.tanzu.vmware.com
# comment out remove the `supply_chain` property
#
# supply_chain: ""
```

Providing your own templates

Similar to supply chains, Cartographer templates (`Cluster*Template` resources) are cluster-scoped, so you must ensure that the new templates submitted to the cluster do not conflict with those installed by the `ootb-templates` package.

The following set of objects are provided by `ootb-templates`:

- ClusterConfigTemplate/**config-template**
- ClusterConfigTemplate/**convention-template**
- ClusterDeploymentTemplate/**app-deploy**
- ClusterImageTemplate/**image-provider-template**
- ClusterImageTemplate/**image-scanner-template**
- ClusterImageTemplate/**kpack-template**

- Task/**kaniko-build**
- ClusterImageTemplate/**kaniko-template**
- ClusterRole/**ootb-templates-app-viewer**
- ClusterRole/**ootb-templates-deliverable**
- ClusterRole/**ootb-templates-workload**
- ClusterRunTemplate/**tekton-source-pipelinerun**
- ClusterSourceTemplate/**delivery-source-template**
- ClusterSourceTemplate/**source-scanner-template**
- ClusterSourceTemplate/**source-template**
- ClusterSourceTemplate/**testing-pipeline**
- Task/**git-writer**
- Task/**image-writer**
- ClusterTemplate/**config-writer-template**
- ClusterTemplate/**deliverable-template**
- Task/**carvel-package (experimental)**
- ClusterConfigTemplate/**carvel-package (experimental)**
- ClusterTemplate/**package-config-writer-and-pull-requester-template (experimental)**
- ClusterTemplate/**package-config-writer-template (experimental)**

Before submitting your own, either ensure that the name and resource has no conflicts with those installed by `ootb-templates`, or exclude from the installation the template you want to override by using the `excluded_templates` property of `ootb-templates`.

For example, perhaps you want to override the `ClusterConfigTemplate` named `config-template` to provide your own with the same name, so that you don't need to edit the supply chain. In `tap-values.yaml`, you can exclude template provided by Tanzu Application Platform:

```
ootb_templates:
  excluded_templates:
    - 'config-writer'
```

For details about how to edit an existing template, see Modifying an Out of the Box Supply template section.

Modifying an Out of the Box Supply Chain

To change the shape of a supply chain or the template that it points to, do the following:

1. Copy one of the reference supply chains.
2. Remove the old supply chain. See preventing Tanzu Application Platform supply chains from being installed.
3. Edit the supply chain object.
4. Submit the modified supply chain to the cluster.

Example

In this example, you have a new `ClusterImageTemplate` object named `foo` that you want use for building container images instead of the out of the box object that makes use of Kpack. The supply

chain that you want to apply the modification to is `source-to-url` provided by the `ootb-supply-chain-basic` package.

1. Find the image that contains the supply chain definition:

```
kubectl get app ootb-supply-chain-basic \
  -n tap-install \
  -o jsonpath={.spec.fetch[0].imgpkgBundle.image}
```

```
registry.tanzu.vmware.com/tanzu-application-platform/tap-packages@sha256:f2ad40
1bb3e850940...
```

2. Pull the contents of the bundle into a directory named `ootb-supply-chain-basic`:

```
imgpkg pull \
  -b registry.tanzu.vmware.com/tanzu-application-platform/tap-packages@sha256:f
2ad401bb3e850940... \
  -o ootb-supply-chain-basic
```

```
Pulling bundle 'registry.tanzu.vmware.com/tanzu-...
  Extracting layer 'sha256:542f2bb8eb946fe9d2c8a...

Locating image lock file images...
The bundle repo (registry.tanzu.vmware.com/tanzu...

Succeeded
```

3. Inspect the files obtained:

```
tree ./ootb-supply-chain-basic/
```

```
./ootb-supply-chain-basic/
├── config
│   ├── supply-chain-image.yaml
│   └── supply-chain.yaml
└── values.yaml
```

4. Edit the supply chain that you want to exchange the template with another:

```
--- a/supply-chain.yaml
+++ b/supply-chain.yaml
@@ -52,7 +52,7 @@ spec:
   - name: image-builder
     templateRef:
       kind: ClusterImageTemplate
-      name: kpack-template
+      name: foo
     params:
       - name: serviceAccount
         value: #@ data.values.service_account
```

5. Submit the supply chain to Kubernetes:

   The supply chain definition found in the bundle expects the values you provided by using `tap-values.yaml` to be interpolated by using YTT before they are submitted to Kubernetes. So before applying the modified supply chain to the cluster, use YTT to interpolate those values. After that, run:

```
ytt \
  --ignore-unknown-comments \
  --file ./ootb-supply-chain-basic/config \
```

```
  --data-value registry.server=REGISTRY-SERVER \
  --data-value registry.repository=REGISTRY-REPOSITORY |
  kubectl apply -f-
```

Important

The modified supply chain does not outlive the destruction of the cluster. VMware recommends that you save it, for example, in a Git repository to install on every cluster where you expect the supply chain to exist.

Modifying an Out of the Box Supply template

The Out of the Box Templates package (`ootb-templates`) includes all of the templates and shared Tekton tasks used by the supply chains shipped by using `ootb-supply-chain-*` packages. Any template that you want to edit, for example, to change details about the resources that are created based on them, is part of this package.

The workflow for updating a template is as follows:

1. Copy one of the reference templates from `ootb-templates`.
2. Exclude that template from the set of objects provided by `ootb-templates`. For more information, see `excluded_templates` in Providing your Own Templates.
3. Edit the template.
4. Submit the modified template to the cluster.

Note

You don’t need to change anything related to supply chains, because you’re preserving the name of the object referenced by the supply chain.

Example

In this example, you want to update the `ClusterImageTemplate` object called `kpack-template`, which provides a template for creating `kpack/Image`s to hardcode an environment variable.

1. Exclude the `kpack-template` from the set of templates that `ootb-templates` installs by upating `tap-values.yaml`:

   ```
   ootb_templates:
   excluded_templates: ['kpack-template']
   ```

2. Find the image that contains the templates:

   ```
   kubectl get app ootb-templates \
     -n tap-install \
     -o jsonpath={.spec.fetch[0].imgpkgBundle.image}
   ```

   ```
   registry.tanzu.vmware.com/tanzu-application-platform/tap-packages@sha256:a5e177
   f38d7287f2ca7ee2afd67ff178645d8f1b1e47af4f192a5ddd6404825e
   ```

3. Pull the contents of the bundle into a directory named `ootb-templates`:

   ```
   imgpkg pull \
     -b registry.tanzu.vmware.com/tanzu-application-platform/tap-packages@sha256:a
   ```

```
5e177f38d7.. \
  -o ootb-templates
```

```
Pulling bundle 'registry.tanzu.vmware.com/tanzu-...
  Extracting layer 'sha256:a5e177f38d7...

Locating image lock file images...
The bundle repo (registry.tanzu.vmware.com/tanzu...

Succeeded
```

4. Confirm that you downloaded all the templates:

```
tree ./ootb-templates
```

```
./ootb-templates
├── config
│   ├── cluster-roles.yaml
│   ├── config-template.yaml
│   ├── kpack-template.yaml         # ! the one we want to modify
...
│   └── testing-pipeline.yaml
└── values.yaml
```

5. Change the property you want to change:

```
--- a/config/kpack-template.yaml
+++ b/config/kpack-template.yaml
@@ -65,6 +65,8 @@ spec:
         subPath: #@ data.values.workload.spec.source.subPath
       build:
         env:
+        - name: FOO
+          value: BAR
         - name: BP_OCI_SOURCE
           value: #@ data.values.source.revision
         #@ if/end param("live-update"):
```

6. Submit the template.

The name of the template is preserved but the contents are changed. So after the template is submitted, the supply chains are all embedded to the build of the application container images that have `FOO` environment variable.

Live modification of supply chains and templates

Preceding sections covered how to update supply chains or templates installed in a cluster. This section shows how you can experiment by making small changes in a live setup with `kubectl edit`.

When you install Tanzu Application Platform by using profiles, a `PackageInstall` object is created. This in turn creates a set of children `PackageInstall` objects for installing the individual components that make up the platform.

```
PackageInstall/tap
└─App/tap
  ├─ PackageInstall/cert-manager
  ├─ PackageInstall/cartographer
  ├─ ...
  └─ PackageInstall/tekton-pipelines
```

Because the installation is based on Kubernetes primitives, `PackageInstall` tries to achieve the state where all packages are installed.

This is great but presents challenges for modifying the contents of some of the objects that the installation submits to the cluster. Namely, such modifications cause the original definition persisting instead of the changes.

For this reason, before you perform any customization to the Out of the Box packages, you must pause the top-level `PackageInstall/tap` object. Run:

```
kubectl edit -n tap-install packageinstall tap
```

```
apiVersion: packaging.carvel.dev/v1alpha1
kind: PackageInstall
metadata:
  name: tap
  namespace: tap-install
spec:
  paused: true                    # ! set this field to `paused: true`.
  packageRef:
    refName: tap.tanzu.vmware.com
    versionSelection:
# ...
```

With the installation of Tanzu Application Platform paused, all of the installed components are still there, but changes to those children `PackageInstall` objects are not overwritten.

Now you can pause the `PackageInstall` objects that relate to the templates or supply chains you want to edit.

For example:

- To edit templates: `kubectl edit -n tap-install packageinstall ootb-templates`
- To edit the basic supply chains: `kubectl edit -n tap-install packageinstall ootb-supply-chain-basic`

setting `packageinstall.spec.paused: true`.

With the installations paused, further live changes to templates or supply chains are persisted until you revert the `PackageInstall`s to not being paused. To persist the changes, follow the steps outlined in the earlier sections.

Adding custom behavior to Supply Chains

Most behaviors in supply chains are supplied by Kubernetes controllers. For example, Cloud Native Buildpacks are created by the kpack controller when a kpack Image object is created. Sometimes there is need for behavior and no controller for it exists. In these instances, you might want to write a script that uses a CLI tool, or interact with an external API. To do this, you can bring the behavior to the supply chain by using Tekton.

You can look at the kaniko image-building as an example. You create a Tekton Task `kaniko-build` with instructions for how to build a Docker image using kaniko given a set of parameters. The Task has a set of steps. Each step refers to a container image and a set of instructions to run on the image. For example, it can be a Linux image against which a set of bash instructions are run. The Task is installed on the cluster in the `tap-tasks` namespace.

You create the ClusterImageTemplate `kaniko-template` to create Tekton TaskRuns. TaskRuns are immutable, so you add the `lifecycle: tekton` field to the template's specifications. This ensures two things:

- When inputs to the template change, rather than updating the TaskRun, a new TaskRun is created.
- Only the values from the most recently created TaskRun that is successful are propagated forward in the supply chain.

To learn more about the `lifecycle: tekton` field, see the Cartographer tutorial Lifecycle: Templating Objects That Cannot Update. To learn more about Tekton, see the Tekton documentation.

Tekton Tasks on a cluster with Pod Security Admission

Kubernetes administrators can enable the Pod Security Admission controller to restrict the behavior of pods in a clear consistent fashion. For more information, see the Kubernetes documentation. If this is the case on a cluster, the Tekton Tasks must be altered to adhere to the security context.

Include a PSA-compliant `stepTemplate`

The task specification must include a `stepTemplate` field with the following properties defined:

```
stepTemplate:
  securityContext:
    allowPrivilegeEscalation: false
    runAsUser: 1000
    capabilities:
      drop:
        - ALL
    seccompProfile:
      type: "RuntimeDefault"
    runAsNonRoot: true
```

For more information about `stepTemplate`, see the Tekton documentation.

Write to available directories

To be PSA-compliant, `stepTemplate` enforces that it is run as a non-root user. Task authors must ensure that there is no attempt to write to protected directories.

For example, a user might want to run a Go test and for their Task to use the Golang image.

In that image, the default value for the `HOME` environment variable is `/root`. This means that when running a command such as `go test`, binaries are created in a subdirectory of the root directory. However, the user does not have permission to create binaries in a subdirectory of the root directory.

To address this example, the task author can include a step `env` to override the default value:

```
    steps:
    - image: golang
      name: test
      env:
      - name: HOME
        value: /go
```

Knowing which directories are safe depends on the image you use. In this example, the `/go` directory exists and is not protected on the `golang` image, but the directory does not exist on an alpine image.

Reference guides for Supply Chain Choreographer for Tanzu

This topic describes the reference guides you can use for Supply Chain Choreographer for Tanzu.

Reference guides

The following reference guides apply to Supply Chain Choreographer for Tanzu:

- Tanzu Build Service Integration
- Use GitOps or RegistryOps with Supply Chain Choreographer
- Delivery reference for Supply Chain Choreographer
- Delivery reference for Supply Chain Choreographer
- ClusterRunTemplate reference for Supply Chain Choreographer
- Template reference for Supply Chain Choreographer
- Supply chains for Supply Chain Choreographer
- Workload Reference for Supply Chain Choreographer
- Events reference for Supply Chain Choreographer

Events reference for Supply Chain Choreographer

This topic describes each event you can view with Supply Chain Choreographer.

Events are emitted when Choreographer edits resources or notices a change in their output or healthy state. Don't treat events like logs, however they can offer valuable insight into what's happening in a supply chain over time. For example, very high occurrences of events in a short period of time might be a sign of slow application-level processing due to many page faults and a lack of storage resources.

Events are published on Workload, Deliverable, and Runnable resources. You can view them manually using:

```
kubectl describe workload.carto.run <workload-name> -n <workload-ns>
kubectl describe runnable.carto.run <runnable-name> -n <runnable-ns>
kubectl describe deliverable.carto.run <deliverable-name> -n <deliverable-ns>
```

Events

The following sections define the different events.

StampedObjectApplied

This event is emitted every time Choreographer creates or updates a resource. The created or updated resource is referenced in the event message.

Example messages:

```
Created object [gitrepositories.source.toolkit.fluxcd.io/my-project]
Updated object [apps.kappctrl.k14s.io/my-project-app]
```

StampedObjectRemoved

This event is emitted every time Choreographer deletes a resource. This currently only occurs when Runnable resources expire. The deleted object is referenced in the event message.

Example message:

```
Deleted object [task.tekton.dev/my-project-a737bdf]
```

ResourceOutputChanged

This event is emitted every time Choreographer recognizes a new output from a resource.

Example message:

```
[source-provider] found a new output in [imagerepositories.source.apps.tanzu.vmware.com/app]
```

ResourceHealthyStatusChanged

This event is emitted every time Choreographer recognizes that the healthy status of a resource has changed.

Example message:

```
[image-provider] found healthy status in [images.kpack.io/app] changed to [True]
[source-provider] found healthy status in [[gitrepositories.source.toolkit.fluxcd.io/my-project]] changed to [False]
```

Workload Reference for Supply Chain Choreographer

This topic describes the fields you can use for Supply Chain Choreographer workloads.

Standard Fields

Cartographer workloads have standard fields leveraged by supply chains. See Cartographer's Reference Documentation in the Cartographer documentation.

Labels

Workload labels affect which supply chain is selected. For information about which template is defined for a particular reference, see Selectors in the Cartographer documentation. Individual templates can also use workload labels.

OOTB Supply Chains use the following workload labels:

- `apps.tanzu.vmware.com/has-tests` by Source-Test-to-URL and Source-Test-Scan-to-URL.
- `apps.tanzu.vmware.com/workload-type` by all supply chains.
- `apis.apps.tanzu.vmware.com/register-api` by the Api-Descriptors Template.
- `apps.tanzu.vmware.com/carvel-package-workflow` by source-to-url-package (experimental) and basic-image-to-url-package (experimental).

Parameters

The OOTB templates are configured with parameters from the supply chain or workload. For information about Cartographer parameters, including precedence rules, see Parameters in the Cartographer documentation.

What parameters are relevant depends on the supply chain that selects the workload, for two reasons:

1. The OOTB supply chains refer to overlapping sets of templates. A workload selected by the Source-to-URL supply chain can provide a `scanning_image_template` parameter, but the supply chain does not refer to a template that leverages that parameter.
2. You can write Supply Chains to provide a parameter value to a template and prevent the workload from overriding the value. See Further Information in the Cartographer documentation.

The following list of parameters are respected by some OOTB supply chains. Each provides the templates that respect the parameter. The reference for the template details which supply chains include the template.

- gitImplementation: source-template
- source_credentials_secret: source-template
- gitops_credentials_secret: deliverable-template
- gitops_ssh_secret: source-template, deliverable-template, external-deliverable-template
- serviceAccount: source-template, image-provider-template, kpack-template, kaniko-template, convention-template, config-writer-template, config-writer-and-pull-requester-template, deliverable-template, external-deliverable-template
- maven: source-template
- testing_pipeline_matching_labels: testing-pipeline
- testing_pipeline_params: testing-pipeline
- scanning_source_template: source-scanner-template
- scanning_source_policy: source-scanner-template
- clusterBuilder: kpack-template
- buildServiceBindings: kpack-template
- live-update: kpack-template, convention-template
- dockerfile: kaniko-template
- docker_build_context: kaniko-template
- docker_build_extra_args: kaniko-template
- scanning_image_template: image-scanner-template
- scanning_image_policy: image-scanner-template
- annotations: convention-template, service-bindings, api-descriptors
- debug: convention-template
- ports: server-template
- api-descriptors: api-descriptors
- gitops_branch: config-writer-template, config-writer-and-pull-requester-template, deliverable-template, external-deliverable-template
- gitops_user_name: config-writer-template, config-writer-and-pull-requester-template
- gitops_user_email: config-writer-template, config-writer-and-pull-requester-template
- gitops_commit_message: config-writer-template, config-writer-and-pull-requester-template

- gitops_repository: config-writer-template, deliverable-template, external-deliverable-template
- gitops_repository_prefix: config-writer-template, deliverable-template, external-deliverable-template
- gitops_server_address: config-writer-template, config-writer-and-pull-requester-template, deliverable-template, external-deliverable-template
- gitops_repository_owner: config-writer-template, config-writer-and-pull-requester-template, deliverable-template, external-deliverable-template
- gitops_repository_name: config-writer-template, config-writer-and-pull-requester-template, deliverable-template, external-deliverable-template
- gitops_commit_branch: config-writer-and-pull-requester-template
- gitops_pull_request_title: config-writer-and-pull-requester-template
- gitops_pull_request_body: config-writer-and-pull-requester-template
- gitops_server_kind: config-writer-and-pull-requester-template
- carvel_package_gitops_subpath (experimental): carvel-package, package-config-writer-template, package-config-writer-and-pull-requester-template
- carvel_package_name_suffix (experimental): carvel-package, package-config-writer-template, package-config-writer-and-pull-requester-template
- carvel_package_openapiv3_enabled (experimental): carvel-package

Service Account

To create the templated objects, Cartographer needs a reference to a service account with permissions to manage resources. This service account might be provided in the workload's `.spec.serviceAccountName` field or in the supply chain's `spec.serviceAccountRef` field. See Service Account and Workload and Supply Chain Custom Resources in the Cartographer documentation. When using the Tanzu CLI to create a workload, specify this service account's name with the `--service-account` flag.

After the templated objects are created, they often need a service account with permissions to do work. In the OOTB Templates and Supply Chains, the parameter `serviceAccount` must reference the service account for these objects. When using the Tanzu CLI to create a workload, specify this service account's name with `--param serviceAccount=...`.

Supply chains for Supply Chain Choreographer

This topic describes the parameters for supply chains that you can use with Supply Chain Choreographer.

Tanzu Application Platform includes a number of supply chains packages, each of which installs two ClusterSupplyChains. You can only install one supply chain package at a time.

The supply chains provide some parameters to the referenced templates. The parameters provided by the workload might override the parameters in this topic.

Source-to-URL

Purpose

- Fetches application source code

- Builds it into an image
- Writes the Kubernetes configuration necessary to deploy the application
- Commits that configuration to either a Git repository or a container image registry

Resources

This section describes the templates and their parameters.

source-provider

Refers to source-template.

Parameters provided:

- `serviceAccount` from tap-value `service_account`. Overridable by workload.
- `source_credentials_secret` from tap-value `source.credentials_secret`. Overridable by workload.

image-provider

Refers to kaniko-template when the workload provides a parameter `dockerfile`. Refers to kpack-template otherwise.

Parameters provided:

- `serviceAccount` from tap-value `service_account`. Overridable by workload.
- `registry` from tap-value `registry`. NOT overridable by workload.
- `clusterBuilder` from tap-value `cluster_builder`. Overridable by workload.
- `dockerfile` value `./Dockerfile`. Overridable by workload.
- `docker_build_context` value `./`. Overridable by workload.
- `docker_build_extra_args` value `[]`. Overridable by workload.

Common resources

- Config-Provider
- App-Config
- Service-Bindings
- Api-Descriptors
- Config-Writer
- Deliverable

Parameters provided to all resources

- `maven_repository_url` from tap-value `maven.repository.url`. NOT overridable by workload.
- `maven_repository_secret_name` from tap-value `maven.repository.secret_name`. NOT overridable by workload.
- See Params provided by all Supply Chains to all Resources

Package

Out of the Box Supply Chain Basic

More information

See Install Out of the Box Supply Chain Basic for information about setting tap-values at installation time.

Source-Test-to-URL

- Fetches application source code
- Runs user defined tests against the code
- Builds the code into an image
- Writes the Kubernetes configuration necessary to deploy the application
- Commits that configuration to either a Git repository or a container image registry

Resources

source-provider

Refers to source-template.

Parameters provided:

- `serviceAccount` from tap-value `service_account`. Overridable by workload.
- `source_credentials_secret` from tap-value `source.credentials_secret`. Overridable by workload.

source-tester

Refers to testing-pipeline.

No parameters are provided by the supply-chain.

image-provider

Refers to kaniko-template when the workload provides a parameter `dockerfile`. Refers to kpack-template otherwise.

Parameters provided:

- `serviceAccount` from tap-value `service_account`. Overridable by workload.
- `registry` from tap-value `registry`. NOT overridable by workload.
- `clusterBuilder` from tap-value `cluster_builder`. Overridable by workload.
- `dockerfile` value `./Dockerfile`. Overridable by workload.
- `docker_build_context` value `./`. Overridable by workload.
- `docker_build_extra_args` value `[]`. Overridable by workload.

Common resources

- Config-Provider
- App-Config
- Service-Bindings
- Api-Descriptors
- Config-Writer

- Deliverable

Parameters provided to all resources

- `maven_repository_url` from tap-value `maven.repository.url`. NOT overridable by workload.
- `maven_repository_secret_name` from tap-value `maven.repository.secret_name`. NOT overridable by workload.
- See Params provided by all Supply Chains to all Resources.

Package

Out of the Box Supply Chain Testing

More information

See Install Out of the Box Supply Chain with Testing for information about setting tap-values at installation time.

Source-Test-Scan-to-URL

- Fetches application source code
- Runs user defined tests against the code
- Scans the code for vulnerabilities
- Builds the code into an image
- Scans the image for vulnerabilities
- Writes the Kubernetes configuration necessary to deploy the application
- Commits that configuration to either a Git repository or an image registry

Resources

source-provider

Refers to source-template.

Parameters provided:

- `serviceAccount` from tap-value `service_account`. Overridable by workload.
- `source_credentials_secret` from tap-value `source.credentials_secret`. Overridable by workload.

source-tester

Refers to testing-pipeline.

No parameters are provided by the supply-chain.

source-scanner

Refers to source-scanner-template.

Parameters provided:

- `scanning_source_policy` from tap-value `scanning.source.policy`. Overridable by workload.

- `scanning_source_template` from tap-value `scanning.source.template`. Overridable by workload.

image-provider

Refers to kaniko-template when the workload provides a parameter `dockerfile`. Refers to kpack-template otherwise.

Parameters provided:

- `serviceAccount` from tap-value `service_account`. Overridable by workload.
- `registry` from tap-value `registry`. NOT overridable by workload.
- `clusterBuilder` from tap-value `cluster_builder`. Overridable by workload.
- `dockerfile` value `./Dockerfile`. Overridable by workload.
- `docker_build_context` value `./`. Overridable by workload.
- `docker_build_extra_args` value `[]`. Overridable by workload.

image-scanner

Refers to image-scanner-template.

Parameters provided:

- `scanning_image_policy` from tap-value `scanning.image.policy`. Overridable by workload.
- `scanning_image_template` from tap-value `scanning.image.template`. Overridable by workload.

Common resources

- Config-Provider
- App-Config
- Service-Bindings
- Api-Descriptors
- Config-Writer
- Deliverable

Parameters provided to all resources

- `maven_repository_url` from tap-value `maven.repository.url`. NOT overridable by workload.
- `maven_repository_secret_name` from tap-value `maven.repository.secret_name`. NOT overridable by workload.
- See Params provided by all Supply Chains to all Resources

Package

Out of the Box Supply Chain Testing Scanning

More information

See Install Out of the Box Supply Chain with Testing and Scanning for information about setting tap-values at installation time.

Basic-Image-to-URL

- Fetches a prebuilt image.
- Writes the Kubernetes configuration necessary to deploy the application.
- Commits that configuration to either a Git repository or an image registry.

Resources

image-provider

Refers to image-provider-template.

Parameters provided:

- `serviceAccount` from tap-value `service_account`. Overridable by workload.

Common resources

- Config-Provider
- App-Config
- Service-Bindings
- Api-Descriptors
- Config-Writer
- Deliverable

Parameters provided to all resources

- See Params provided by all Supply Chains to all Resources

Package

Out of the Box Supply Chain Basic

More information

See Install Out of the Box Supply Chain Basic for information about setting tap-values at installation time.

Testing-Image-to-URL

- Fetches a prebuilt image.
- Writes the Kubernetes configuration necessary to deploy the application.
- Commits that configuration to either a Git repository or an image registry.

Resources

image-provider

Refers to image-provider-template.

Parameters provided:

- `serviceAccount` from tap-value `service_account`. Overridable by workload.

Common resources

- Config-Provider
- App-Config
- Service-Bindings
- Api-Descriptors
- Config-Writer
- Deliverable

Parameters provided to all resources

- See Params provided by all Supply Chains to all Resources

Package

Out of the Box Supply Chain Testing

More information

See Install Out of the Box Supply Chain with Testing for information about setting tap-values at installation time.

Scanning-image-scan-to-URL

- Fetches a prebuilt image.
- Scans the image for vulnerabilities.
- Writes the Kubernetes configuration necessary to deploy the application.
- Commits the configuration to either a Git repository or an image registry.

Resources

image-provider

Refers to image-provider-template.

Parameters provided:

- `serviceAccount` from tap-value `service_account`. Overridable by workload.

image-scanner

Refers to image-scanner-template.

Parameters provided:

- `scanning_image_policy` from tap-value `scanning.image.policy`. Overridable by workload.
- `scanning_image_template` from tap-value `scanning.image.template`. Overridable by workload.

Common resources

- Config-Provider
- App-Config

- Service-Bindings
- Api-Descriptors
- Config-Writer
- Deliverable

Parameters provided to all resources

- See Params provided by all Supply Chains to all Resources

Package

Out of the Box Supply Chain Testing Scanning

More information

See Install Out of the Box Supply Chain with Testing and Scanning for information about setting tap-values at installation time.

Source-to-URL-Package (experimental)

Purpose

- Fetches the application source code.
- Builds the source code into an image.
- Bundles the Kubernetes configuration necessary to deploy the application into a Carvel Package.
- Commits the Package to a Git Repository.

Resources

This section describes the templates and their parameters.

source-provider

Refers to source-template.

Parameters provided:

- `serviceAccount` from tap-value `service_account`. Overridable by workload.
- `source_credentials_secret` from tap-value `source.credentials_secret`. Overridable by workload.

image-provider

Refers to kaniko-template when the workload provides a parameter `dockerfile`. Refers to kpack-template otherwise.

Parameters provided:

- `serviceAccount` from tap-value `service_account`. Overridable by workload.
- `registry` from tap-value `registry`. NOT overridable by workload.
- `clusterBuilder` from tap-value `cluster_builder`. Overridable by workload.
- `dockerfile` value `./Dockerfile`. Overridable by workload.

- `docker_build_context` value `./`. Overridable by workload.
- `docker_build_extra_args` value `[]`. Overridable by workload.

carvel-package

Refers to carvel-package.

Parameters provided:

- `serviceAccount` from tap-value `service_account`. Overridable by workload.
- `registry` from tap-value `registry`. NOT overridable by workload.

package-config-writer

Refers to the package-config-writer-and-pull-requester-template when the tap-value `gitops.commit_strategy` is `pull_request`. Otherwise, this resource refers to the package-config-writer-template.

Parameters provided:

- `serviceAccount` from tap-value `service_account`. Overridable by workload.
- `registry` from tap-value `registry`. NOT overridable by workload.

Common resources

- Config-Provider
- App-Config
- Service-Bindings
- Api-Descriptors

Parameters provided to all resources

- `maven_repository_url` from tap-value `maven.repository.url`. NOT overridable by workload.
- `maven_repository_secret_name` from tap-value `maven.repository.secret_name`. NOT overridable by workload.
- `carvel_package_gitops_subpath` from tap-value `carvel_package.gitops_subpath`. Overridable by workload.
- `carvel_package_name_suffix` from tap-value `carvel_package.name_suffix`. Overridable by workload.
- See Params provided by all Supply Chains to all Resources

Package

Out of the Box Supply Chain Basic

More information

See Install Out of the Box Supply Chain Basic for information about setting tap-values at installation time.

Basic-Image-to-URL-Package (experimental)

- Fetches a prebuilt image.

- Bundles the Kubernetes configuration necessary to deploy the application into a Carvel Package.
- Commits the Package to a Git Repository.

Resources

image-provider

Refers to image-provider-template.

Parameters provided:

- `serviceAccount` from tap-value `service_account`. Overridable by workload.

carvel-package

Refers to carvel-package.

Parameters provided:

- `serviceAccount` from tap-value `service_account`. Overridable by workload.
- `registry` from tap-value `registry`. NOT overridable by workload.

package-config-writer

Refers to the package-config-writer-and-pull-requester-template when the tap-value `gitops.commit_strategy` is `pull_request`. Otherwise, this resource refers to the package-config-writer-template

Parameters provided:

- `serviceAccount` from tap-value `service_account`. Overridable by workload.
- `registry` from tap-value `registry`. NOT overridable by workload.

Common resources

- Config-Provider
- App-Config
- Service-Bindings
- Api-Descriptors
- Config-Writer
- Deliverable

Parameters provided to all resources

- `carvel_package_gitops_subpath` from tap-value `carvel_package.gitops_subpath`. Overridable by workload.
- `carvel_package_name_suffix` from tap-value `carvel_package.name_suffix`. Overridable by workload.
- See Params provided by all Supply Chains to all Resources

Package

Out of the Box Supply Chain Basic

More information

See Install Out of the Box Supply Chain Basic for information about setting tap-values at installation time.

Resources common to all OOTB supply chains

config-provider

Refers to convention-template.

Parameters provided:

- `serviceAccount` from tap-value `service_account`. Overridable by workload.

app-config

The tap-values field `supported_workloads` defines which templates are referred to by this resource. Default configuration is:

```
supported_workloads:
- type: web
  cluster_config_template_name: config-template
- type: server
  cluster_config_template_name: server-template
- type: worker
  cluster_config_template_name: worker-template
```

The workload's `apps.tanzu.vmware.com/workload-type` label determines which template is used at this step. For example, when the workload has a label `apps.tanzu.vmware.com/workload-type:web`, the supply chain references `config-template`.

No parameters are provided by the supply-chain.

service-bindings

Refers to the service-binding template.

No parameters are provided by the supply-chain.

api-descriptors

Refers to the api-descriptors template.

No parameters are provided by the supply-chain.

config-writer

Refers to the config-writer-and-pull-requester-template when the tap-value `gitops.commit_strategy` is `pull_request`. Otherwise, this resource refers to the config-writer-template

Parameters provided:

- `serviceAccount` from tap-value `service_account`. Overridable by workload.
- `registry` from tap-value `registry`. NOT overridable by workload.

deliverable

Refers to the external-deliverable-template when the tap-value `external_delivery` evaluates to `true`. Otherwise the resource refers to the deliverable-template.

Parameters provided:

- `registry` from tap-value `registry`. NOT overridable by workload.

Parameters provided by all supply chains to all resources

All of the following parameters are overridable by the workload.

- `gitops_branch` from tap-value `gitops.branch`
- `gitops_user_name` from tap-value `gitops.username`
- `gitops_user_email` from tap-value `gitops.email`
- `gitops_commit_message` from tap-value `gitops.commit_message`
- `gitops_ssh_secret` from tap-value `gitops.ssh_secret`
- `gitops_credentials_secret` from tap-value `gitops.credentials_secret`
- `gitops_repository_prefix` from tap-value `gitops.repository_prefix` when present.
- `gitops_server_address` from tap-value `gitops.server_address` when present.
- `gitops_repository_owner` from tap-value `gitops.repository_owner` when present.
- `gitops_repository_name` from tap-value `gitops.repository_name` when present.
- `gitops_server_kind` from tap-value `gitops.pull_request.server_kind` when present.
- `gitops_commit_branch` from tap-value `gitops.pull_request.commit_branch` when present.
- `gitops_pull_request_title` from tap-value `gitops.pull_request.pull_request_title` when present.
- `gitops_pull_request_body` from tap-value `gitops.pull_request.pull_request_body` when present.

Template reference for Supply Chain Choreographer

This topic describes the objects from templates that you can use with Supply Chain Choreographer.

All the objects referenced in this topic are Cartographer Templates packaged in Out of the Box Templates.

This topic describes:

- The purpose of the templates
- The one or more objects that the templates create
- The supply chains that include the templates
- The parameters that the templates use

source-template

Purpose

Creates an object to fetch source code and make that code available to other objects in the supply chain. See Building from Source.

Used by

- Source-to-URL in the `source-provider` step.
- Source-Test-to-URL in the `source-provider` step.

- Source-Test-Scan-to-URL in the `source-provider` step.
- Source-to-URL-Package (experimental) in the `source-provider` step.

Creates

The source-template creates one of three objects, either:

- GitRepository. Created if the workload has `.spec.source.git` defined.
- MavenArtifact. Created if the template is provided a value for the parameter `maven`.
- ImageRepository. Created if the workload has `.spec.source.image` defined.

GitRepository

`GitRepository` makes source code from a particular commit available as a tarball in the cluster. Other resources in the supply chain can then access that code.

Parameters

Template reference for Supply Chain Choreographer

Parameter name	Meaning	Example
`gitImplementation`	The library used to fetch source code.	`- name: gitImplementation value: go-git`
`source_credentials_secret`	Name of the secret used to provide credentials for the Git repository. The secret with this name must exist in the same namespace as the `Workload`. The credentials must be sufficient to read the repository. See Git authentication.	`- name: source_credentials_secret value: git-credentials`
`gitops_ssh_secret`	Deprecated Only used if provided and source_credentials_secret is not provided. Name of the secret used to provide credentials for the Git repository. The secret with this name must exist in the same namespace as the `Workload`. The credentials must be sufficient to read the repository. See Git authentication.	`- name: gitops_ssh_secret value: git-credentials`

More information

For an example using the Tanzu CLI to create a Workload using GitHub as the provider of source code, see Create a workload from GitHub repository.

For information about GitRepository objects, see GitRepository.

ImageRepository

`ImageRepository` makes the contents of a container image available as a tarball on the cluster.

Parameters

Parameter name	Meaning	Example
`serviceAccount`	Name of the service account, providing credentials to `ImageRepository` for fetching container images. The service account must exist in the same namespace as the Workload.	`- name: serviceAccount value: default`

Note

When using the Tanzu CLI to configure this `serviceAccount` parameter, use `--param serviceAccount=...`. The similarly named `--service-account` flag sets a different value: the `spec.serviceAccountName` key in the Workload object.

More information

For information about the ImageRepository resource, see the ImageRepository reference documentation.

For information about how to use the Tanzu CLI to create a workload leveraging ImageRepository, see Create a workload from local source code.

MavenArtifact

`MavenArtifact` makes a pre-built Java artifact available to as a tarball on the cluster.

While the `source-template` leverages the workload's `.spec.source` field when creating a `GitRepository` or `ImageRepository` object, the creation of the `MavenArtifact` relies only on parameters in the Workload.

Parameters

Parameter name	Meaning	Example

`maven`	Points to the Maven artifact to fetch and the polling interval.	`- name: maven`
		`value:`
		`artifactId: springboot-initial`
		`groupId: com.example`
		`version: RELEASE`
		`classifier: sources # optional`
		`type: jar # optional`
		`artifactRetryTimeout: 1m0s # optional`

`maven_repository_url`	Specifies the Maven repository from which to fetch	`- name: maven_repository_url` `value: https://repo1.maven.org/maven2/`
`maven_repository_secret_name`	Specifies the secret containing credentials necessary to fetch from the Maven repository. The secret named must exist in the same workspace as the workload.	`- name: maven_repository_secret_name` `value: auth-secret`

More information

For information about the custom resource, see MavenArtifact reference docs.

For information about how to use the custom resource with the Tanzu Apps CLI plug-in, see Create a workload from a Maven repository artifact.

testing-pipeline

Purpose

Tests the source code provided in the supply chain. Testing depends on a user provided Tekton Pipeline. Parameters for this template allow for selection of the proper Pipeline and for specification of additional values to pass to the Pipeline.

Used by

- Source-Test-to-URL in the source-tester step.
- Source-Test-Scan-to-URL in the source-tester step.

These are used as the `source-tester` resource.

Creates

`testing-pipeline`creates a Runnable object. This Runnable provides inputs to the ClusterRunTemplate named tekton-source-pipelinerun.

Parameters

Parameter name	Meaning	Example

`testing_pipeline_matching_labels`	Set of labels to use when searching for Tekton Pipeline objects in the same namespace as the Workload. By default, a Pipeline labeled as `apps.tanzu.vmware.com/pipeline: test` is selected.	`- name: testing_pipeline_matching_labels`
		`value:`
		`apps.tanzu.vmware.com/pipeline: test`
		`my.company/language: golang`

`testing_pipeline_params`	Set of parameters to pass to the Tekton Pipeline. To this set of parameters, the template always adds the source URL and revision as `source-url` and `source-revision`.	`- name: testing_pipeline_params`
		`value:`
		`- name: verbose`
		`value: true`
		`- name: foo`
		`value: bar`

More information

For information about the ClusterRunTemplate that pairs with the Runnable, read tekton-source-pipelinerun

For information about the Tekton Pipeline that the user must create, read the OOTB Supply Chain Testing documentation of the Pipeline

source-scanner-template

Purpose

Scans the source code for vulnerabilities.

Used by

- Source-Test-Scan-to-URL in the source-scanner step.

This is used as the `source-scanner` resource.

Creates

SourceScan

Parameters

Parameter name	Meaning	Example
`scanning_source_template`	Name of the ScanTemplate object to use for running the scans. The ScanTemplate must be in the same namespace as the Workload.	`- name: scanning_source_template value: private-source-scan-template`
`scanning_source_policy`	Name of the ScanPolicy object to use when evaluating the scan results of a source scan. The ScanPolicy must be in the same namespace as the Workload.	`- name: scanning_source_policy value: allowlist-policy`

More information

For information about how to set up the Workload namespace with the ScanPolicy and ScanTemplate required for this resource, see Out of the Box Supply Chain with Testing and Scanning.

For information about the SourceScan custom resource, see SourceScan reference.

For information about how the artifacts found during scanning are catalogued, see Supply Chain Security Tools for Tanzu – Store.

image-provider-template

Purpose

Fetches a container image of a prebuilt application, specified in the workload's `.spec.image` field. This makes the content-addressable name, (e.g. the image name containing the digest) available to other resources in the supply chain.

Used by

- Basic-Image-to-URL in the image-provider step.
- Testing-Image-to-URL in the image-provider step.
- Scanning-Image-Scan-to-URL in the image-provider step.
- Basic-Image-to-URL-Package (experimental) in the image-provider step.

These are used as the `image-provider` resource.

Creates

ImageRepository.source.apps.tanzu.vmware.com

Parameters

Parameter name	Meaning	Example
`serviceAccount`	Name of the service account providing credentials for the target image registry. The service account must exist in the same namespace as the Workload.	`- name: serviceAccount value: default`

Note

When using the Tanzu CLI to configure this `serviceAccount` parameter, use `--param serviceAccount=...`. The similarly named `--service-account` flag sets a different value: the `spec.serviceAccountName` key in the Workload object.

More information

For information about the ImageRepository resource, see ImageRepository reference docs.

For information about prebuilt images, see Using a prebuilt image.

kpack-template

Purpose

Builds an container image from source code using cloud native buildpacks.

Used by

- Source-to-URL in the image-provider step.
- Source-Test-to-URL in the image-provider step.
- Source-Test-Scan-to-URL in the image-provider step.
- Source-to-URL-Package (experimental) in the image-provider step.

These are used as the `image-provider` resource when the workload parameter `dockerfile` is not defined.

Creates

Image.kpack.io

Parameters

Parameter name	Meaning	Example
`serviceAccount`	Name of the service account providing credentials for the configured image registry. `Image` uses these credentials to push built container images to the registry. The service account must exist in the same namespace as the Workload.	`- name: serviceAccount value: default`

Parameter name	Meaning	Example
`clusterBuilder`	Name of the Kpack Cluster Builder to use.	`- name: clusterBuilder value: nodejs-cluster-builder`
`buildServiceBindings`	Definition of a list of service bindings to make use at build time. For example, providing credentials for fetching dependencies from repositories that require credentials.	`- name: buildServiceBindings value: - name: settings-xml kind: Secret apiVersion: v1`
`live-update`	Enable the use of Tilt's live-update function.	`- name: live-update value: "true"`

Note

When using the Tanzu CLI to configure this `serviceAccount` parameter, use `--param serviceAccount=...`. The similarly named `--service-account` flag sets a different value: the `spec.serviceAccountName` key in the Workload object.

More information

For information about the integration with Tanzu Build Service, see Tanzu Build Service Integration.

For information about `live-update`, see Developer Conventions and Overview of Tanzu Developer Tools for IntelliJ.

For information about using Kpack builders with `clusterBuilder`, see Builders.

For information about `buildServiceBindings`, see Service Bindings.

kaniko-template

Purpose

Build an image for source code that includes a Dockerfile.

Used by

- Source-to-URL in the image-provider step.
- Source-Test-to-URL in the image-provider step.

- Source-Test-Scan-to-URL in the image-provider step.
- Source-to-URL-Package (experimental) in the image-provider step.

These are used as the `image-provider` resource when the workload parameter `dockerfile` is defined.

Creates

A taskrun.tekton.dev provides configuration to the Tekton Task `kaniko-build` which builds an image with kaniko.

This template uses the lifecycle: tekton flag to create new immutable objects rather than updating the previous object.

Parameters

Parameter name	Meaning	Example
`dockerfile`	relative path to the Dockerfile file in the build context	`./Dockerfile`
`docker_build_context`	relative path to the directory where the build context is	`.`
`docker_build_extra_args`	List of flags to pass directly to kaniko,such as providing arguments to a build.	`- --build-arg=FOO=BAR`
`serviceAccount`	Name of the service account to use for providing Docker credentials. The service account must exist in the same namespace as the Workload. The service account must have a secret associated with the credentials. See Configuring authentication for Docker in the Tekton documentation.	`- name: serviceAccount value: default`
`registry`	Specification of the registry server and repository in which the built image is placed.	`- name: registry value: server: index.docker.io repository: web-team`

More information

For information about how to use Dockerfile-based builds and limits associated with the function, see Dockerfile-based builds.

For information about `lifecycle:tekton`, read Cartographer Lifecycle.

image-scanner-template

Purpose

Scans the container image for vulnerabilities, persists the results in a store, and prevents the image from moving forward if CVEs are found which are not compliant with its referenced ScanPolicy.

Used by

- Source-Test-Scan-to-URL in the image-scanner step.
- Scanning-Image-Scan-to-URL in the image-scanner step.

Creates

ImageScan.scanning.apps.tanzu.vmware.com

Parameters

Parameter name	Meaning	Example
`scanning_image_template`	Name of the ScanTemplate object for running the scans against a container image. The ScanTemplate must be in the same namespace as the Workload.	`- name: scanning_image_template value: private-image-scan-template`
`scanning_image_policy`	Name of the ScanPolicy object for evaluating the scan results of an image scan. The ScanPolicy must be in the same namespace as the Workload.	`- name: scanning_image_policy value: allowlist-policy`

More information

For information about the ImageScan custom resource, see ImageScan reference.

For information about how the artifacts found during scanning are catalogued, see Supply Chain Security Tools for Tanzu – Store.

convention-template

Purpose

Create the PodTemplateSpec for the Kubernetes configuration (e.g. the knative service or kubernetes deployment) which are applied to the cluster.

Used by

- Source-to-URL in the config-provider step.
- Basic-Image-to-URL in the config-provider step.
- Source-Test-to-URL in the config-provider step.
- Testing-Image-to-URL in the config-provider step.
- Source-Test-Scan-to-URL in the config-provider step.
- Scanning-Image-Scan-to-URL in the config-provider step.

- Source-to-URL-Package (experimental) in the config-provider step.
- Basic-Image-to-URL-Package (experimental) in the config-provider step.

Creates

Creates a PodIntent object. The PodIntent leverages conventions installed on the cluster. The PodIntent object is responsible for generating a PodTemplateSpec. The PodTemplateSpec is used in app configs, such as knative services and deployments, to represent the shape of the pods to run the application in containers.

Parameters

Parameter name	Meaning	Example
`serviceAccount`	Name of the serviceAccount providing necessary credentials to `PodIntent`. The serviceAccount must be in the same namespace as the Workload. The serviceAccount is set as the `serviceAccountName` in the podtemplatespec. The credentials associated with the serviceAccount must allow fetching the container image used to inspect the metadata passed to convention servers.	`- name: serviceAccount` `value: default`

`annotations`	Extra set of annotations to pass down to the PodTemplateSpec.	`- name: annotations`
		`value:`
		`name: my-application`
		`version: v1.2.3`
		`team: store`

`debug`	Put the workload in debug mode.	`- name: debug` `value: "true"`
`live-update`	Enable live-updating of the code (for innerloop development).	`- name: live-update` `value: "true"`

Note

When using the Tanzu CLI to configure this `serviceAccount` parameter, use `--param serviceAccount=...`. The similarly named `--service-account` flag sets a different value: the `spec.serviceAccountName` key in the Workload object.

More information

For information about `PodTemplateSpec`, see PodTemplateSpec in the Kubernetes documentation.

For information about conventions, see Cartographer Conventions.

For information about the two convention servers enabled by default in Tanzu Application Platform installations, see Developer Conventions and Spring Boot conventions.

config-template

Purpose

For workloads with the label `apps.tanzu.vmware.com/workload-type: web`, define a knative service.

Used by

- Source-to-URL in the app-config step.
- Basic-Image-to-URL in the app-config step.
- Source-Test-to-URL in the app-config step.
- Testing-Image-to-URL in the app-config step.
- Source-Test-Scan-to-URL in the app-config step.
- Scanning-Image-Scan-to-URL in the app-config step.

Creates

A ConfigMap, in which the data field has a key `delivery.yaml` whose value is the definition of a knative service.

Parameters

None

More information

See workload types for more details about the three different types of workloads.

worker-template

Purpose

For workloads with the label `apps.tanzu.vmware.com/workload-type: worker`, define a Kubernetes Deployment.

Used by

- Source-to-URL in the app-config step.
- Basic-Image-to-URL in the app-config step.

- Source-Test-to-URL in the app-config step.
- Testing-Image-to-URL in the app-config step.
- Source-Test-Scan-to-URL in the app-config step.
- Scanning-Image-Scan-to-URL in the app-config step.

Creates

A ConfigMap, in which the data field has a key `delivery.yaml` whose value is the definition of a Kubernetes Deployment.

Parameters

None

More information

For information about the three different types of workloads, see workload types.

server-template

Purpose

For workloads with the label `apps.tanzu.vmware.com/workload-type: server`, define a Kubernetes Deployment and a Kubernetes Service.

Used by

- Source-to-URL in the app-config step.
- Basic-Image-to-URL in the app-config step.
- Source-Test-to-URL in the app-config step.
- Testing-Image-to-URL in the app-config step.
- Source-Test-Scan-to-URL in the app-config step.
- Scanning-Image-Scan-to-URL in the app-config step.
- Source-to-URL-Package (experimental) in the app-config step.
- Basic-Image-to-URL-Package (experimental) in the app-config step.

Creates

A ConfigMap, in which the data field has a key `delivery.yaml` whose value is the definitions of a Kubernetes Deployment and a Kubernetes Service to expose the pods.

Parameters

Parameter name	Meaning	Example

`ports`	Set of network ports to expose from the application to the Kubernetes cluster.	`- name: ports`
		`value:`
		`- containerPort: 2025`
		`name: smtp`
		`port: 25`

More information

For information about the three different types of workloads, see workload types.

For information about the ports parameter, see server-specific Workload parameters.

service-bindings

Purpose

Adds ServiceBindings to the set of Kubernetes configuration files.

Used by

- Source-to-URL in the service-bindings step.
- Basic-Image-to-URL in the service-bindings step.
- Source-Test-to-URL in the service-bindings step.
- Testing-Image-to-URL in the service-bindings step.
- Source-Test-Scan-to-URL in the service-bindings step.
- Scanning-Image-Scan-to-URL in the service-bindings step.
- Source-to-URL-Package (experimental) in the service-bindings step.
- Basic-Image-to-URL-Package (experimental) in the service-bindings step.

Creates

A ConfigMap. This template consumes input of multiple deployment YAML files and enriches the input with ResourceClaims and ServiceBindings if the workload contains serviceClaims.

Parameters

Parameter name	Meaning	Example

`annotations`	Extra set of annotations to pass down to the ServiceBinding and ResourceClaim objects.	`- name: annotations`
		`value:`
		`name: my-application`
		`version: v1.2.3`
		`team: store`

More information

For an example of using `--service-ref`, see the Tanzu CLI Command Reference documentation.

For an overview of the function, see Consume services on Tanzu Application Platform.

api-descriptors

Purpose

The `api-descriptor` resource takes care of adding an APIDescriptor to the set of Kubernetes objects to deploy such that API auto registration takes place.

Used by

- Source-to-URL in the api-descriptors step.
- Basic-Image-to-URL in the api-descriptors step.
- Source-Test-to-URL in the api-descriptors step.
- Testing-Image-to-URL in the api-descriptors step.
- Source-Test-Scan-to-URL in the api-descriptors step.
- Scanning-Image-Scan-to-URL in the api-descriptors step.
- Source-to-URL-Package (experimental) in the api-descriptors step.
- Basic-Image-to-URL-Package (experimental) in the api-descriptors step.

Creates

A ConfigMap. This template consumes input of multiple YAML files and enriches the input with an APIDescriptor if the workload has a label `apis.apps.tanzu.vmware.com/register-api` == to `true`.

Parameters

Parameter name	Meaning	Example

`annotations`	Extra set of annotations to pass down to the APIDescriptor object.	`- name: annotations`
		`value:`
		`name: my-application`
		`version: v1.2.3`
		`team: store`

`api_descriptor`	Information used to fill the state that you want of the APIDescriptor object (its spec).	`- name: api_descriptor`
		`value:`
		`type: openapi`
		`location:`
		`baseURL: http://petclinic-hard-coded.my-apps.tapdemo.vmware.com/`
		`path: "/v3/api`
		`owner: team-petclinic`
		`system: pet-clinics`
		`description: "example"`

More information

For information about API auto registration, see Use API Auto Registration.

config-writer-template

Purpose

Persist in an external system, such as a registry or git repository, the Kubernetes configuration passed to the template.

Used by

- Source-to-URL in the config-writer step.
- Basic-Image-to-URL in the config-writer step.
- Source-Test-to-URL in the config-writer step.
- Testing-Image-to-URL in the config-writer step.
- Source-Test-Scan-to-URL in the config-writer step.
- Scanning-Image-Scan-to-URL in the config-writer step.

Creates

A runnable which creates a Tekton TaskRun that refers either to the Tekton Task `git-writer` or the Tekton Task `image-writer`.

Parameters

Parameter name	Meaning	Example
`serviceAccount`	Name of the service account which provides the credentials to the registry or repository. The service account must exist in the same namespace as the Workload.	`- name: serviceAccount` `value: default`
`gitops_branch`	Name of the branch to push the configuration to.	`- name: gitops_branch` `value: main`
`gitops_user_name`	User name to use in the commits.	`- name: gitops_user_name` `value: "Alice Lee"`
`gitops_user_email`	User email address to use in the commits.	`- name: gitops_user_email` `value: alice@example.com`

Parameter name	Meaning	Example
`gitops_commit_message`	Message to write as the body of the commits produced for pushing configuration to the Git repository.	`- name: gitops_commit_message` `value: "ci bump"`
`gitops_repository`	The full repository URL to which the configuration is committed. **DEPRECATED**	`- name: gitops_repository` `value: "https://github.com/vmware-tanzu/cartographer"`
`gitops_repository_prefix`	The prefix of the repository URL. **DEPRECATED**	`- name: gitops_repository` `value: "https://github.com/vmware-tanzu/"`
`gitops_server_address`	The server URL of the Git repository to which configuration is applied.	`- name: gitops_server_address` `value: "https://github.com/"`
`gitops_repository_owner`	The owner/organization to which the repository belongs.	`- name: gitops_repository_owner` `value: vmware-tanzu`
`gitops_repository_name`	The name of the repository.	`- name: gitops_repository_name` `value: cartographer`

`registry`	Specification of the registry server and repository in which the configuration is placed.	`- name: registry`
		`value:`
		`server: index.docker.io`
		`repository: web-team`
		`ca_cert_data:`
		`-----BEGIN CERTIFICATE-----`
		`MIIFXzCCA0egAwIBAgIJAJYm37SFocjlMA0GCSqGSIb3DQEBDQUAMEY...`
		`-----END CERTIFICATE-----`

More information

For information about operating this template, see Gitops vs RegistryOps and the config-writer-and-pull-requester-template.

config-writer-and-pull-requester-template

Purpose

Persist the passed in Kubernetes configuration to a branch in a repository and open a pull request to another branch. This process allows for manual review of configuration before deployment to a cluster.

Used by

- Source-to-URL in the config-writer step.
- Basic-Image-to-URL in the config-writer step.
- Source-Test-to-URL in the config-writer step.
- Testing-Image-to-URL in the config-writer step.
- Source-Test-Scan-to-URL in the config-writer step.
- Scanning-Image-Scan-to-URL in the config-writer step.

Creates

A Tekton TaskRun refers to the Tekton Task `commit-and-pr`.

Parameters

Parameter name	Meaning	Example
`serviceAccount`	Name of the service account which provides the credentials to the registry or repository. The service account must exist in the same namespace as the Workload.	`- name: serviceAccount` `value: default`
`gitops_commit_branch`	Name of the branch to which configuration is pushed.	`- name: gitops_commit_branch` `value: feature`
`gitops_branch`	Name of the branch to which a pull request is opened.	`- name: gitops_branch` `value: main`
`gitops_user_name`	User name to use in the commits.	`- name: gitops_user_name` `value: "Alice Lee"`

Parameter name	Meaning	Example
`gitops_user_email`	User email address to use in the commits.	`- name: gitops_user_email` `value: alice@example.com`
`gitops_commit_message`	Message to write as the body of the commits produced for pushing configuration to the Git repository.	`- name: gitops_commit_message` `value: "ci bump"`
`gitops_pull_request_title`	Title of the pull request to be opened.	`- name: gitops_pull_request_title` `value: "ready for review"`
`gitops_pull_request_body`	Body of the pull request to be opened.	`- name: gitops_pull_request_body` `value: "generated by supply chain"`
`gitops_server_address`	The server URL of the Git repository to which configuration is applied.	`- name: gitops_server_address` `value: "https://github.com/"`
`gitops_repository_owner`	The owner/organization to which the repository belongs.	`- name: gitops_repository_owner` `value: vmware-tanzu`
`gitops_repository_name`	The name of the repository.	`- name: gitops_repository_name` `value: cartographer`
`gitops_server_kind`	The kind of Git provider	`- name: gitops_server_kind` `value: gitlab`

Parameter name	Meaning	Example

`ca_cert_data`	The string contents of the ssl certificate of the git server	`- name: ca_cert_data`
		`value:`
		`-----BEGIN CERTIFICATE-----`
		`MIIFXzCCA0egAwIBAgIJAJYm37SFocjlMA0GCSqGSIb3DQEBDQUAMEY...`
		`-----END CERTIFICATE-----`

More information

For information about the operation of this template, see Gitops vs RegistryOps and the config-writer-template.

deliverable-template

Purpose

Create a deliverable which pairs with a Delivery to deploy Kubernetes configuration on the cluster.

Used by

- Source-to-URL in the deliverable step.
- Basic-Image-to-URL in the deliverable step.
- Source-Test-to-URL in the deliverable step.
- Testing-Image-to-URL in the deliverable step.
- Source-Test-Scan-to-URL in the deliverable step.
- Scanning-Image-Scan-to-URL in the deliverable step.

Creates

A Deliverable preconfigured with reference to a repository or registry from which to fetch Kubernetes configuration.

Parameters

Parameter name	Meaning	Example
`serviceAccount`	Name of the service account providing the necessary permissions for the Delivery to create children objects. Populates the Deliverable's serviceAccount parameter. The service account must be in the same namespace as the Deliverable.	`- name: serviceAccount` `value: default`

Parameter name	Meaning	Example
`gitops_credentials_secret`	Name of the secret where credentials exist for fetching the configuration from a Git repository. Populates the Deliverable's `source_credentials_secret` parameter (The Workload's GitOps repository is the Deliverable's source reposiotor). The secret must be in the same namespace as the Deliverable.	`- name: gitops_credentials_secret` `value: git-secret`
`gitops_ssh_secret`	Deprecated. Use gitops_credentials_secret instead. Name of the secret where credentials exist for fetching the configuration from a Git repository. Populates the Deliverable's gitops_ssh_secret parameter. The secret must be in the same namespace as the Deliverable.	`- name: gitops_ssh_secret` `value: git-secret`
`gitops_branch`	Name of the branch from which to fetch the configuration.	`- name: gitops_branch` `value: main`
`gitops_repository`	The full repository URL to which the configuration is fetched. **DEPRECATED**	`- name: gitops_repository` `value: "https://github.com/vmware-tanzu/cartographer"`
`gitops_repository_prefix`	The prefix of the repository URL. **DEPRECATED**	`- name: gitops_repository` `value: "https://github.com/vmware-tanzu/"`
`gitops_server_address`	The server URL of the Git repository from which configuration is fetched.	`- name: gitops_server_address` `value: "https://github.com/"`
`gitops_repository_owner`	The owner/organization to which the repository belongs.	`- name: gitops_repository_owner` `value: vmware-tanzu`

Parameter name	Meaning	Example
`gitops_repository_name`	The name of the repository.	`- name: gitops_repository_name` `value: cartographer`

`registry`	Specification of the registry server and repository from which the configuration is fetched.	`- name: registry`
		`value:`
		`server: index.docker.io`
		`repository: web-team`
		`ca_cert_data:`
		`-----BEGIN CERTIFICATE-----`
		`MIIFXzCCA0egAwIBAgIJAJYm37SFocjlMA0GCSqGSIb3DQEBDQUAMEY...`
		`-----END CERTIFICATE-----`

Note

When using the Tanzu CLI to configure this `serviceAccount` parameter, use `--param serviceAccount=...`. The similarly named `--service-account` flag sets a different value: the `spec.serviceAccountName` key in the Workload object.

More information

For information about the ClusterDelivery shipped with `ootb-delivery-basic`, see Out of the Box Delivery Basic.

external-deliverable-template

Purpose

Create a definition of a deliverable which a user can manually applied to an external kubernetes cluster. When a properly configured Delivery is installed on that external cluster, the Deliverable will pair with the Delivery to deploy Kubernetes configuration on the cluster. For example, the OOTB Delivery.

Used by

- Source-to-URL in the deliverable step.
- Basic-Image-to-URL in the deliverable step.
- Source-Test-to-URL in the deliverable step.

- Testing-Image-to-URL in the deliverable step.
- Source-Test-Scan-to-URL in the deliverable step.
- Scanning-Image-Scan-to-URL in the deliverable step.

Creates

A configmap in which the `.data` field has a key `deliverable` for which the value is the YAML definition of a Deliverable.

Parameters

Parameter name	Meaning	Example
`serviceAccount`	Name of the service account providing the necessary permissions for the Delivery to create children objects. Populates the Deliverable's serviceAccount parameter. The service account must be in the same namespace as the Deliverable.	`- name: serviceAccount` `value: default`
`gitops_ssh_secret`	Name of the secret where credentials exist for fetching the configuration from a Git repository. Populates the Deliverable's gitops_ssh_secret parameter. The secret must be in the same namespace as the Deliverable.	`- name: gitops_ssh_secret` `value: ssh-secret`
`gitops_branch`	Name of the branch from which to fetch the configuration.	`- name: gitops_branch` `value: main`
`gitops_repository`	The full repository URL to which the configuration is fetched. **DEPRECATED**	`- name: gitops_repository` `value: "https://github.com/vmware-tanzu/cartographer"`
`gitops_repository_prefix`	The prefix of the repository URL. **DEPRECATED**	`- name: gitops_repository` `value: "https://github.com/vmware-tanzu/"`
`gitops_server_address`	The server URL of the Git repository from which configuration is fetched.	`- name: gitops_server_address` `value: "https://github.com/"`

Parameter name	Meaning	Example
`gitops_repository_owner`	The owner/organization to which the repository belongs.	`- name: gitops_repository_owner` `value: vmware-tanzu`
`gitops_repository_name`	The name of the repository.	`- name: gitops_repository_name` `value: cartographer`

`registry`	Specification of the registry server and repository from which the configuration is fetched.	`- name: registry`
		`value:`
		`server: index.docker.io`
		`repository: web-team`
		`ca_cert_data:`
		`-----BEGIN CERTIFICATE-----`
		`MIIFXzCCA0egAwIBAgIJAJYm37SFocjlMA0GCSqGSIb3DQEBDQUAMEY...`
		`-----END CERTIFICATE-----`

More information

For information about the ClusterDelivery shipped with `ootb-delivery-basic`, see Out of the Box Delivery Basic.

For information about using the Deliverable object in a multicluster environment, see Getting started with multicluster Tanzu Application Platform.

delivery-source-template

Purpose

Continuously fetches Kubernetes configuration files from a Git repository or container image registry and makes them available on the cluster.

Used by

- Delivery-Basic

Creates

The source-template creates one of three objects, either: - GitRepository. Created if the deliverable has `.spec.source.git` defined. - ImageRepository. Created if the deliverable has

`.spec.source.image` defined.

GitRepository

`GitRepository` makes source code from a particular commit available as a tarball in the cluster. Other resources in the supply chain can then access that code.

Parameters

Parameter name	Meaning	Example
`gitImplementation`	The library used to fetch source code.	`- name: gitImplementation value: go-git`
`source_credentials_secret`	Name of the secret used to provide credentials for the Git repository. The secret with this name must exist in the same namespace as the `Deliverable`. The credentials must be sufficient to read the repository. See Git authentication.	`- name: source_credentials_secret value: git-credentials`

More information

For an example using the Tanzu CLI to create a Workload using GitHub as the provider of source code, see Create a workload from GitHub repository.

For information about GitRepository objects, see GitRepository.

ImageRepository

`ImageRepository` makes the contents of a container image available as a tarball on the cluster.

Parameters

Parameter name	Meaning	Example
`serviceAccount`	Name of the service account, providing credentials to `ImageRepository` for fetching container images. The service account must exist in the same namespace as the Deliverable.	`- name: serviceAccount value: default`

More information

For information about the ImageRepository resource, see ImageRepository reference docs.

app-deploy

Purpose

Applies Kubernetes configuration to the cluster.

Used by

- Delivery-Basic

Creates

A kapp App.

Parameters

Parameter name	Meaning	Example
`serviceAccount`	Name of the service account providing the necessary privileges for `App` to apply the Kubernetes objects to the cluster. The service account must be in the same namespace as the Deliverable.	`- name: serviceAccount` `value: default`
`gitops_sub_path` (deprecated)	Sub directory within the configuration bundle that is used for looking up the files to apply to the Kubernetes cluster. **DEPRECATED**	`- name: gitops_sub_path` `value: ./config`

Note

The `gitops_sub_path` parameter is deprecated. Use `deliverable.spec.source.subPath` instead.

More information

For details about RBAC and how `kapp-controller` makes use of the ServiceAccount provided through the Deliverable's `serviceAccount` parameter, see kapp-controller's Security Model.

carvel-package (experimental)

Purpose

Bundles Kubernetes configuration into a Carvel Package.

Used by

- Source-to-URL-Package (experimental) in the carvel-package step.
- Basic-Image-to-URL-Package (experimental) in the carvel-package step.

Creates

A taskrun.tekton.dev which provides configuration to the `carvel-package` Tekton Task which bundles Kubernetes configuration into a Carvel Package.

This template uses the lifecycle: tekton flag to create new immutable objects rather than updating the previous object.

Parameters

Parameter name	Meaning	Example
`serviceAccount`	Name of the service account to use for providing Docker credentials. The service account must exist in the same namespace as the Workload. The service account must have a secret associated with the credentials. See Configuring authentication for Docker in the Tekton documentation.	`- name: serviceAccount` `value: default`

`registry`	Specification of the registry server and repository in which the built image is placed.	`- name: registry`
		`value:`
		`server: index.docker.io`
		`repository: web-team`

`carvel_package_gitops_subpath`	Specifies the subpath to which Carvel Packages should be written.	`- name: carvel_package_gitops_subpath` `value: path/to/my/dir`
`carvel_package_name_suffix`	Specifies the suffix to append to the Carvel Package name. The format is WORKLOAD_NAME.WORKLOAD_NAMESPACE.carvel_package_name_suffix The full Carvel Package name must be a valid DNS subdomain name as defined in RFC 1123.	`- name: carvel_package_name_suffix` `value: vmware.com`

Parameter name	Meaning	Example

`carvel_package_parameters`	Specifies the custom Carvel Package parameters	`- name: carvel_package_parameters`
		`  value: |`
		`  - selector:`
		`  matchLabels:`
		`  apps.tanzu.vmware.com/workload-type: server`
		`  schema: |`
		`  #@data/values-schema`
		`  ---`
		`  #@schema/title "Workload name"`
		`  #@schema/example "tanzu-java-web-app"`
		`  #@schema/validation min_len=1`
		`  workload_name: ""`
		
		`  #@schema/title "Replicas"`
		`  replicas: 1`
		
		`  #@schema/title "Port"`
		`  port: 8080`
		
		`  #@schema/title "Hostname"`
		`  #@schema/example "app.tanzu.vmware.com"`
		`  hostname: ""`
		
		`  #@schema/title "Cluster Issuer"`
		`  cluster_issuer: "tap-ingress-selfsigned"`
		
		`  #@schema/nullable`
		`  http_route:`
		`  #@schema/default [{"protocol": "https", "name": "default-gateway"}]`
		`  gateways:`
		`  - protocol: ""`
		`  name: ""`
		`  overlays: |`
		`  #@ load("@`

Parameter name	Meaning	Example
		ytt:overlay", "overlay") #@ load("@ytt:data", "data") #@overlay/match by=overlay.subset({"apiVersion":"apps/v1", "kind": "Deployment"}) --- spec: #@overlay/match missing_ok=True replicas: #@ data.values.replicas #@ if data.values.http_route != None: --- apiVersion: gateway.networking.k8s.io/v1beta1 kind: HTTPRoute metadata: name: #@ data.values.workload_name + "-route" spec: parentRefs: #@ for/end gateway in data.values.http_route.gateways: - group: gateway.networking.k8s.io kind: Gateway name: #@ gateway.name sectionName: #@ gateway.protocol + "-" + data.values.workload_name rules: - backendRefs: - name: #@ data.values.workload_name port: #@ data.values.port #@ elif data.values.hostname != "": --- apiVersio

Parameter name	Meaning	Example
		n: networking.k8s.io/v1 kind: Ingress metadata: name: #@ data.values.workload_name annotations: cert-manager.io/cluster-issuer: #@ data.values.cluster_issuer ingress.kubernetes.io/force-ssl-redirect: "true" kubernetes.io/ingress.class: contour kapp.k14s.io/change-rule: "upsert after upserting Services" labels: app.kubernetes.io/component: "run" carto.run/workload-name: #@ data.values.workload_name spec: tls: - secretName: #@ data.values.workload_name hosts: - #@ data.values.hostname rules: - host: #@ data.values.hostname http: paths: - pathType: Prefix path: / backend: service: name: #@ data.values.workload_name port: number: #@ data.value

Parameter name	Meaning	Example
		s.port #@ end - selector: matchLabels: apps.tanzu.vmware.com/workload-type: web schema: | #@data/values-schema --- #@schema/validation min_len=1 workload_name: "" overlays: "" - selector: matchLabels: apps.tanzu.vmware.com/workload-type: worker schema: | #@data/values-schema --- #@schema/validation min_len=1 workload_name: "" replicas: 1 overlays: | #@ load("@ytt:overlay", "overlay") #@ load("@ytt:data", "data") #@overlay/match by=overlay.subset({"apiVersion":"apps/v1", "kind": "Deployment"}) --- spec: #@overlay/match missing_ok=True replicas: #@ data.values.replicas
`carvel_package_openapiv3_enabled`	Specifies whether the Carvel Package should include a generated OpenAPIv3 specification	- name: carvel_package_openapiv3_enabled value: true

More information

To read more about `lifecycle:tekton`, read Cartographer Lifecycle.

package-config-writer-template (experimental)

Purpose

Persist in an external git repository the Carvel Package Kubernetes configuration passed to the template.

Used by

- Source-to-URL-Package (experimental) in the config-writer step.
- Basic-Image-to-URL-Package (experimental) in the config-writer step.

Creates

A runnable which creates a Tekton TaskRun that refers either to the Tekton Task `git-writer`.

Parameters

Parameter name	Meaning	Example
`serviceAccount`	Name of the service account which provides the credentials to the registry or repository. The service account must exist in the same namespace as the Workload.	`- name: serviceAccount` `value: default`
`gitops_branch`	Name of the branch to push the configuration to.	`- name: gitops_branch` `value: main`
`gitops_user_name`	User name to use in the commits.	`- name: gitops_user_name` `value: "Alice Lee"`
`gitops_user_email`	User email address to use in the commits.	`- name: gitops_user_email` `value: alice@example.com`
`gitops_commit_message`	Message to write as the body of the commits produced for pushing configuration to the Git repository.	`- name: gitops_commit_message` `value: "ci bump"`

Parameter name	Meaning	Example
`gitops_repository`	The full repository URL to which the configuration is committed. **DEPRECATED**	`- name: gitops_repository` `value: "https://github.com/vmware-tanzu/cartographer"`
`gitops_repository_prefix`	The prefix of the repository URL. **DEPRECATED**	`- name: gitops_repository` `value: "https://github.com/vmware-tanzu/"`
`gitops_server_address`	The server URL of the Git repository to which configuration is applied.	`- name: gitops_server_address` `value: "https://github.com/"`
`gitops_repository_owner`	The owner/organization to which the repository belongs.	`- name: gitops_repository_owner` `value: vmware-tanzu`
`gitops_repository_name`	The name of the repository.	`- name: gitops_repository_name` `value: cartographer`

`registry`	Specification of the registry server and repository in which the configuration is placed.	`- name: registry`
		`value:`
		`server: index.docker.io`
		`repository: web-team`
		`ca_cert_data:`
		`-----BEGIN CERTIFICATE-----`
		`MIIFXzCCA0egAwIBAgIJAJYm37SFocjlMA0GCSqGSIb3DQEBDQUAMEY...`
		`-----END CERTIFICATE-----`

Parameter name	Meaning	Example
`carvel_package_gitops_subpath`	Specifies the subpath to which Carvel Packages should be written.	`- name: carvel_package_gitops_subpath` `value: path/to/my/dir`
`carvel_package_name_suffix`	Specifies the suffix to append to the Carvel Package name. The format is WORKLOAD_NAME.WORKLOAD_NAMESPACE.carvel_package_name_suffix The full Carvel Package name must be a valid DNS subdomain name as defined in RFC 1123.	`- name: carvel_package_name_suffix` `value: vmware.com`

More information

See Gitops vs RegistryOps for more information about the operation of this template and of the package-config-writer-and-pull-requester-template (experimental).

package-config-writer-and-pull-requester-template (experimental)

Purpose

Persist the passed in Carvel Package Kubernetes configuration to a branch in a repository and open a pull request to another branch. (This process allows for manual review of configuration before deployment to a cluster)

Used by

- Source-to-URL-Package (experimental) in the config-writer step.
- Basic-Image-to-URL-Package (experimental) in the config-writer step.

Creates

A Tekton TaskRun which refers to the Tekton Task `commit-and-pr`.

Parameters

Parameter name	Meaning	Example
`serviceAccount`	Name of the service account which provides the credentials to the registry or repository. The service account must exist in the same namespace as the Workload.	`- name: serviceAccount` `value: default`

`gitops_commit_branch`	Name of the branch to which configuration is pushed.	`- name: gitops_commit_branch` `value: feature`
`gitops_branch`	Name of the branch to which a pull request is opened.	`- name: gitops_branch` `value: main`
`gitops_user_name`	User name to use in the commits.	`- name: gitops_user_name` `value: "Alice Lee"`
`gitops_user_email`	User email address to use in the commits.	`- name: gitops_user_email` `value: alice@example.com`
`gitops_commit_message`	Message to write as the body of the commits produced for pushing configuration to the Git repository.	`- name: gitops_commit_message` `value: "ci bump"`
`gitops_pull_request_title`	Title of the pull request to be opened.	`- name: gitops_pull_request_title` `value: "ready for review"`
`gitops_pull_request_body`	Body of the pull request to be opened.	`- name: gitops_pull_request_body` `value: "generated by supply chain"`
`gitops_server_address`	The server URL of the Git repository to which configuration is applied.	`- name: gitops_server_address` `value: "https://github.com/"`
`gitops_repository_owner`	The owner/organization to which the repository belongs.	`- name: gitops_repository_owner` `value: vmware-tanzu`

`gitops_repository_name`	The name of the repository.	`- name: gitops_repository_name` `value: cartographer`
`gitops_server_kind`	The kind of Git provider	`- name: gitops_server_kind` `value: gitlab`
`carvel_package_gitops_subpath`	Specifies the subpath to which Carvel Packages should be written.	`- name: carvel_package_gitops_subpath` `value: path/to/my/dir`
`carvel_package_name_suffix`	Specifies the suffix to append to the Carvel Package name. The format is WORKLOAD_NAME.WORKLOAD_NAMESPACE.carvel_package_name_suffix The full Carvel Package name must be a valid DNS subdomain name as defined in RFC 1123.	`- name: carvel_package_name_suffix` `value: vmware.com`

`ca_cert_data`	The string contents of the ssl certificate of the git server	`- name: ca_cert_data`
		`value:`
		`-----BEGIN CERTIFICATE-----`
		`MIIFXzCCA0egAwIBAgIJAJYm37SFocjlMA0GCSqGSIb3DQEBDQUAMEY...`
		`-----END CERTIFICATE-----`

More information

See Gitops vs RegistryOps for more information about the operation of this template and of the package-config-writer-template (experimental).

ClusterRunTemplate reference for Supply Chain Choreographer

This topic lists the objects you can use with Supply Chain Choreographer. All the objects referenced in this topic are Cartographer ClusterRunTemplates packaged in Out of the Box Templates. This topic describes the one or more objects they create, the supply chains that include them, and the parameters they use.

tekton-source-pipelinerun

Purpose

Tests source code.

Used by

- testing-pipeline

Creates

This ClusterRunTemplate creates a Tekton PipelineRun referring to the user's Tekton Pipeline.

Inputs

ClusterRunTemplate reference for Supply Chain Choreographer

Input name	Meaning	Example

`tekton-params`	Set of parameters to pass to the Tekton Pipeline	`- name: source-url`
		`value: https://github.com/vmware-tanzu/cartographer.git`
		`- name: source-revision`
		`value: e4a53f49a92fc913d26f8cc23d59102a51a5e635`
		`- name: verbose`
		`value: true`
		`- name: foo`
		`value: bar`

More information

For information about the runnable created in the OOTB Testing and OOTB Testing and Scanning, see testing-pipeline.

For information about the Tekton Pipeline that the user must create, see Tekton/Pipeline.

Delivery reference for Supply Chain Choreographer

This topic describes the delivery parameters and templates you can use with Supply Chain Choreographer.

Tanzu Application Platform delivery package installs a single ClusterDelivery.

The delivery provides some parameters to the templates. The parameters provided by the deliverable might override some of the delivery parameters in this topic. For more information about how parameters work, including precedence rules, see the Cartographer documentation.

delivery-basic

Purpose

- Fetches Kubernetes configuration created by a supply chain.
- Deploys the configuration on the cluster.

Resources

The following resources describe the templates.

source-provider

Refers to delivery-source-template.

Parameters provided:

- `serviceAccount` from tap-value `service_account`. Overridable by deliverable.

Deployer

Refers to app-deploy template.

Parameter provided:

- `serviceAccount` from tap-value `service_account`. Overridable by deliverable.

Package

Refers to Out of the Box Delivery Basic.

More information

For information about setting `tap-values.yaml` at installation time, see Install Out of the Box Delivery Basic.

Use Git with Supply Chain Choreographer

This topic explains how you can use Git with Supply Chain Choreographer.

Overview

The out of the box supply chains and delivery use Git in three ways:

- To fetch the developers source code, using the template.
- To store complete Kubernetes configuration, the write side of GitOps, using template 1, template 2, template 3 (experimental), and template 4 (experimental).
- To fetch stored Kubernetes configuration, the read side of GitOps, from either the same or a different Kubernetes cluster, using the template.

Supported Git Repositories

Tanzu Application Platform supports three Git providers:

- GitHub
- GitLab
- Azure DevOps

Related Articles

Git Authentication walks through the objects, such as secrets and service accounts, you can create on a cluster to allow successful supply chain Git operations. This includes the configuring a custom CA certificate.

GitOps versus RegistryOps discusses the two methods of storing built Kubernetes configuration, either in a Git repository or a container image registry, and walks through the parameters that must be provided for each.

Configuration for Azure DevOps: discusses configuration necessary for working with this Git provider.

Use GitOps or RegistryOps with Supply Chain Choreographer

You can use GitOps or RegistryOps to manage your Kubernetes configuration with Supply Chain Choreographer.

Regardless of the supply chain that a workload goes through, in the end, some Kubernetes configuration is pushed to an external entity, either to a Git repository or to a container image registry.

For example:

```
Supply Chain

  -- fetch source
    -- test
      -- build
        -- scan
          -- apply-conventions
            -- push config        * either to Git or Registry
```

This topic dives into the specifics of that last phase of the supply chains by pushing configuration to a Git repository or a container image registry.

Note

For more information about providing source code either from a local directory or Git repository, see Building from Source.

GitOps

The GitOps approach differs from local iteration in that GitOps configures the supply chains to push the Kubernetes configuration to a remote Git repository. This allows users to compare configuration changes and promote those changes through environments by using GitOps principles.

Typically associated with an outerloop workflow, the GitOps approach is only activated if a collection of parameters are set:

- `gitops.server_address` during the Out of the Box Supply Chains package installation or `gitops_server_address` configured as a workload parameter.
- `gitops.repository_owner` during the Out of the Box Supply Chains package installation or `gitops_repository_owner` configured as a workload parameter.
- `gitops.repository_name` during the Out of the Box Supply Chains package installation or `gitops_repository_name` configured as a workload parameter.

With all three values set, Kubernetes configuration is written to the specified repository. If a value is set at installation and the corresponding workload parameter is also set, the value of the workload parameter is respected.

In the repository, files are located in the `./config/{workload-namespace}/{workload-name}` directory. This allows multiple workloads to commit configuration to the same repository.

Examples

`tap-values.yaml`

```
gitops:
  server_address:
  repository_owner:
  repository_name:
```

`workload`

```
  name: incrediApp
  namespace: awesomeTeam
  params:
    - name: gitops_server_address
      value: https://github.com/
    - name: gitops_repository_owner
      value: vmware-tanzu
    - name: gitops_repository_name
      value: cartographer
```

Resulting GitOps repository: `https://github.com/vmware-tanzu/cartographer`

Directory containing configuration: `./config/awesomeTeam/incrediApp`

`tap-values.yaml`:

```
gitops:
  server_address: https://github.com/
  repository_owner: vmware-tanzu
  repository_name: cartographer
```

`workload`:

```
  name: superApp
  namespace: awesomeTeam
```

Resulting GitOps repository: `https://github.com/vmware-tanzu/cartographer`

Directory containing configuration: `./config/awesomeTeam/superApp`

`tap-values.yaml`:

```
gitops:
  server_address: https://github.com/
  repository_owner: vmware-tanzu
```

`workload`:

```
  name: superApp
  namespace: awesomeTeam
  params:
     - name: gitops_repository_owner
       value: buildpacks-community
     - name: gitops_repository_name
       value: kpack
```

Resulting GitOps repository: `https://github.com/buildpacks-community/kpack`

Directory containing configuration: `./config/awesomeTeam/superApp`

`tap-values.yaml`:

```
gitops:
  server_address:
  repository_owner:
  repository_name:
```

`workload`:

```
  name: superApp
  namespace: awesomeTeam
  params:
     - name: gitops_repository_owner
       value: buildpacks-community
     - name: gitops_repository_name
       value: kpack
```

Resulting GitOps repository: Fails to resolve as some, but not all, of the three required values are provided.

Deprecated parameters

The following parameters are deprecated and no longer recommended for specifying GitOps repositories:

- `gitops.repository_prefix`: configured during the Out of the Box Supply Chains package installation.
- `gitops_repository`: configured as a workload parameter.

For example, assuming the installation of the supply chain packages through Tanzu Application Platform profiles and a `tap-values.yaml`:

```
ootb_supply_chain_basic:
  registry:
    server: REGISTRY-SERVER
    repository: REGISTRY-REPOSITORY

  gitops:
    repository_prefix: https://github.com/my-org/
```

Workloads in the cluster with the Kubernetes configuration produced throughout the supply chain are pushed to the repository whose name is formed by concatenating `gitops.repository_prefix` with the name of the workload. In this case, for example, `https://github.com/my-org/$(workload.metadata.name).git`.

```
Supply Chain
  param:
      - gitops_repository_prefix: GIT-REPO_PREFIX

workload-1:
  `git push` to GIT-REPO-PREFIX/workload-1.git

workload-2:
  `git push` to GIT-REPO-PREFIX/workload-2.git

...

workload-n:
  `git push` to GIT-REPO-PREFIX/workload-n.git
```

Alternatively, you can force a workload to publish the configuration in a Git repository by providing the `gitops_repository` parameter to the workload:

```
tanzu apps workload create tanzu-java-web-app \
  --app tanzu-java-web-app \
  --type web \
  --git-repo https://github.com/vmware-tanzu/application-accelerator-samples \
  --sub-path tanzu-java-web-app \
  --git-branch main \
  --param gitops_credentials_secret=GIT-SECRET-NAME \
  --param gitops_repository=https://github.com/my-org/config-repo
```

In this case, at the end of the supply chain, the configuration for this workload is published to the repository provided under the `gitops_repository` parameter.

If you use deprecated parameters, Kubernetes configuration is committed to the `./config` directory in the repository. This can lead to collisions if two workloads specify the same repository, or two workloads in different namespaces have the same name and the `gitops.repository_prefix` is set in `tap-values.yaml`.

If the deprecated values are set and any of the suggested GitOps values are set, the deprecated values are ignored.

Examples

`tap-values.yaml`:

```
gitops:
  repository_prefix: https://github.com/vmware-tanzu
```

`workload`:

```
  name: superApp
  namespace: awesomeTeam
```

Resulting GitOps repository: `https://github.com/vmware-tanzu/incrediApp`

Directory containing configuration: `./config`

`tap-values.yaml`:

```
gitops:
  server_address: https://github.com/
  repository_owner: vmware-tanzu
  repository_name: cartographer
```

`workload`:

```
  name: superApp
  namespace: awesomeTeam
  params:
    - name: gitops_repository
      value: https://github.com/buildpacks-community/kpack
```

Resulting GitOps repository: `https://github.com/vmware-tanzu/cartographer` The deprecated parameter `gitops_repository` is ignored.

Directory containing configuration: `./config/awesomeTeam/superApp`

`tap-values.yaml`:

```
gitops:
  repository_prefix: https://github.com/vmware-tanzu
```

`workload`:

```
  name: superApp
  namespace: awesomeTeam
  params:
    - name: gitops_repository_owner
      value: buildpacks-community
    - name: gitops_repository_name
      value: kpack
```

Resulting GitOps repository: Fails to resolve as some, but not all, of the three GitOps values are provided. The deprecated value `repository_prefix` is ignored because suggested values are present.

Pull requests

In the standard `git-ops` approach, configuration is pushed to a repository and is immediately applied to a cluster by any deliverable watching that repository. Operators might want to manually review configuration before applying it to the cluster. To do this, operators must specify a `pull_request` commit strategy. You can use this strategy with the following Git providers:

- GitHub
- GitLab
- Azure DevOps

Authentication

The pull request approach requires HTTP(S) authentication with a token.

The pull request function is not a part of the Git specification, but most Git server providers include it. You must authenticate with those providers using a token.

In the Kubernetes secret that holds the Git credentials, the password text box must contain a token. When generating a token, ensure that it has the proper scope:

- On GitHub, the token must have a Repo scope.
- On GitLab, the token must have an API scope.

To use the `pull_request` commit strategy, set the following parameters:

- `commit_strategy` == `pull_request` configured during the Out of the Box Supply Chains package installation.
- `gitops.pull_request.server_kind` configured during the Out of the Box Supply Chains package installation or `gitops_server_kind` configured as a workload parameter. Supported values are `github`, `gitlab`, and `azure`.
- `gitops.pull_request.commit_branch` configured during the Out of the Box Supply Chains package installation or `gitops_commit_branch` configured as a workload parameter.
- `gitops.pull_request.pull_request_title` configured during the Out of the Box Supply Chains package installation or `gitops_pull_request_title` configured as a workload parameter.
- `gitops.pull_request.pull_request_body` configured during the Out of the Box Supply Chains package installation or `gitops_pull_request_body` configured as a workload

parameter.

If a value is set at both installation and in a workload parameter, the workload parameter is respected.

The recommended value for `commit_branch` is an empty string. This generates a new branch for each commit based on a hash of the time when the commit is created. This prevents collisions between multiple workloads using a single Git repository.

For example, using the following Tanzu Application Platform values:

```
ootb_supply_chain_basic:
   gitops:
     server_address: https://github.com/
     repository_owner: vmware-tanzu
     repository_name: cartographer
     branch: main
     commit_strategy: pull_request
     pull_request:
       server_kind: github
       commit_branch: ""
       pull_request_title: ready for review
       pull_request_body: generated by supply chain
```

In a workload with the name `app` in the `dev` namespace, you find:

A commit to the `https://github.com/vmware-tanzu/cartographer` repository on a branch with a random name. For example, `MTY1MTYxMzE0NQo=`. There is a pull request open to merge this branch into the base branch `main`.

Authentication

Regardless of how the supply chains are configured, if the repository prefix or repository name is configured to push to Git, you must provide credentials for the remote provider by using a Kubernetes secret in the same namespace as the workload attached to the workload `ServiceAccount`.

Because the operation of pushing requires elevated permissions, credentials are required by both public and private repositories.

HTTP(S) Basic authentication or Token-based authentication

If the repository at which configuration is published uses `https://` or `http://` as the URL scheme, the Kubernetes secret must provide the credentials for that repository as follows:

```
apiVersion: v1
kind: Secret
metadata:
  name: GIT-SECRET-NAME #   - operators should write this name into the
                        #   `gitops.credentials_secret` property in `tap-values.yaml`
                        #   - developers can override by using the workload parameter
                        #     named `gitops_credentials_secret`.
  annotations:
    tekton.dev/git-0: GIT-SERVER        # ! required
type: kubernetes.io/basic-auth          # ! required
stringData:
  username: GIT-USERNAME
  password: GIT-PASSWORD
  # ! Optional, required if the git repository is signed by a certificate authority no
t in the system trust store
  caFile: |
    CADATA-BASE64
```

Both the Tekton annotation and the `basic-auth` secret type must be set. `GIT-SERVER` must be prefixed with the appropriate URL scheme and the Git server. For example, for `https://github.com/vmware-tanzu/cartographer`, `https://github.com` must be provided as the `GIT-SERVER`.

To use the pull request approach, the password text box must contain a token. See Pull Requests.

After the `Secret` is created, attach it to the `ServiceAccount` used by the workload. For example:

```
apiVersion: v1
kind: ServiceAccount
metadata:
  name: default
secrets:
  - name: registry-credentials
  - name: tap-registry
  - name: GIT-SECRET-NAME
imagePullSecrets:
  - name: registry-credentials
  - name: tap-registry
```

For more information about the credentials and setting up the Kubernetes secret, see Git Authentication's HTTP section.

SSH

If the repository to which configuration is published uses `https://` or `http://` as the URL scheme, the Kubernetes secret must provide the credentials for that repository as follows:

```
apiVersion: v1
kind: Secret
metadata:
  name: GIT-SECRET-NAME #   - operators should write this name into the
                        #   `gitops.credentials_secret` property in `tap-values.yaml`
                        #   - developers can override by using the workload parameter
                        #     named `gitops_credentials_secret`.
  annotations:
    tekton.dev/git-0: GIT-SERVER
type: kubernetes.io/ssh-auth
stringData:
  ssh-privatekey: SSH-PRIVATE-KEY     # private key with push-permissions
  identity: SSH-PRIVATE-KEY           # private key with pull permissions
  identity.pub: SSH-PUBLIC-KEY        # public of the `identity` private key
  known_hosts: GIT-SERVER-PUBLIC-KEYS # git server public keys
```

After the `Secret` is created, attach it to the `ServiceAccount` used by the workload. For example:

```
apiVersion: v1
kind: ServiceAccount
metadata:
  name: default
secrets:
  - name: registry-credentials
  - name: tap-registry
  - name: GIT-SECRET-NAME
imagePullSecrets:
  - name: registry-credentials
  - name: tap-registry
```

Note

If you've used Namespace Provisioner to set up your Developer Namespace where you workload is created, use the `namespace_provisioner.default_parameters.supply_chain_service_account.secrets` property in your `tap-values.yaml`. For example:

```yaml
namespace_provisioner:
  default_parameters:
    supply_chain_service_account:
      secrets:
      - GIT-SECRET-NAME
```

Namespace Provisioner manages the service account and manual edits to it do not persist.

For information about the credentials and setting up the Kubernetes secret, see Git Authentication's SSH section.

GitOps workload parameters

While installing `ootb-*`, operators can configure `gitops.repository_prefix` to indicate what prefix the supply chain must use when forming the name of the repository to push to the Kubernetes configurations produced by the supply chains.

To change the behavior to use GitOps, set the source of the source code to a Git repository. As the supply chain progresses, configuration is pushed to a repository named `$(gitops.repository_prefix) + $(workload.name)`.

For example, configure `gitops.repository_prefix` to `git@github.com/foo/` and create a workload as follows:

```
tanzu apps workload create tanzu-java-web-app \
  --git-branch main \
  --git-repo https://github.com/vmware-tanzu/application-accelerator-samples \
  --sub-path tanzu-java-web-app \
  --label app.kubernetes.io/part-of=tanzu-java-web-app \
  --type web
```

Expect to see the following output:

```
Create workload:
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1
      3 + |kind: Workload
      4 + |metadata:
      5 + |  labels:
      6 + |    apps.tanzu.vmware.com/workload-type: web
      7 + |    app.kubernetes.io/part-of: tanzu-java-web-app
      8 + |  name: tanzu-java-web-app
      9 + |  namespace: default
     10 + |spec:
     11 + |  source:
     12 + |    git:
     13 + |      ref:
     14 + |        branch: main
     15 + |      url: https://github.com/vmware-tanzu/application-accelerator-samples
     16 + |    subPath: tanzu-java-web-app
```

As a result, the Kubernetes configuration is pushed to `git@github.com/foo/tanzu-java-web-app.git`.

Regardless of the setup, developers can also manually override the repository where configuration is pushed to by tweaking the following parameters:

- `gitops_credentials_secret`: Name of the secret in the same namespace as the workload where SSH credentials exist for pushing the configuration produced by the supply chain to a Git repository. Example: `git-secret`
- `gitops_ssh_secret`: Deprecated: Name of the secret in the same namespace as the workload where SSH credentials exist for pushing the configuration produced by the supply chain to a Git repository. Example: `git-secret`
- `gitops_repository`: SSH URL of the Git repository to push the Kubernetes configuration produced by the supply chain to. Example: `ssh://git@foo.com/staging.git`
- `gitops_branch`: Name of the branch to push the configuration to. Example: `main`
- `gitops_commit_message`: Message to write as the body of the commits produced for pushing configuration to the Git repository. Example: `ci bump`
- `gitops_user_name`: User name to use in the commits. Example: `Alice Lee`
- `gitops_user_email`: User email address to use in the commits. Example: `alice@example.com`

RegistryOps

RegistryOps is typically used for inner loop flows where configuration is treated as an artifact from quick iterations by developers. In this scenario, at the end of the supply chain, configuration is pushed to a container image registry in the form of an imgpkg bundle. You can think of it as a container image whose sole purpose is to carry arbitrary files.

To enable this mode of operation, the supply chains must be configured **without** the following parameters being configured during the installation of the `ootb-` packages or overwritten by the workload by using the following parameters:

- `gitops_repository_prefix`
- `gitops_repository`

If none of the parameters are set, the configuration is pushed to the same container image registry as the application image. That is, to the registry configured under the `registry: {}` section of the `ootb-` values.

For example, assuming the installation of Tanzu Application Platform by using profiles, configure the `ootb-supply-chain*` package as follows:

```
ootb_supply_chain_basic:
  registry:
    server: REGISTRY-SERVER
    repository: REGISTRY_REPOSITORY
```

The Kubernetes configuration produced by the supply chain is pushed to an image named after `REGISTRY-SERVER/REGISTRY-REPOSITORY` including the workload name.

In this scenario, no extra credentials must be set up, because the secret containing the credentials for the container image registry were already configured during the setup of the workload namespace.

Overview of Supply Chain Security Tools for VMware Tanzu - Policy Controller

Supply Chain Security Tools - Policy Controller is a security tool that helps you ensure that the container images in their registry have not been tampered with. Policy Controller is a Kubernetes Admission Controller that allows you to apply policies to verify signatures on container images before being admitted to a cluster.

The Policy Controller:

- Verifies signatures on container images used by Kubernetes resources
- Enforces policies to allow or deny images being admitted a cluster
- Allows operators to define multiple policies in the cluster
- Allows operators to select which `namespaces` to enforce policies against
- Supports `cosign` signatures and keyless signing
- Supports storing public keys in a KMS

It enforces its policies against all resources that create `Pod`s as part of their life cycle:

- `Pod`
- `ReplicaSet`
- `Deployment`
- `Job`
- `StatefulSet`
- `DaemonSet`
- `CronJob`

Note

This component is the successor to `Supply Chain Security Tools - Sign`, which is deprecated. Support and maintenance for `Supply Chain Security Tools - Sign` continues. Monitor Release Notes for updates.

Supply Chain Security Tools - Policy Controller is based on Sigstore's Policy Controller and is compatible only with `cosign` signatures. See Cosign and Policy Controller in GitHub. For information about image signing and verification, see Sigstore open source community and the cosign project in GitHub.

The Policy Controller component is a policy enforcement tool only. It does not sign images. Operators can configure image signing for their containers in several ways, including:

- By using Tanzu Build Service
- By using kpack
- By integrating cosign into their build pipelines

Image signatures generated by `cosign` are stored in the same registry location as the image itself unless configured with the `COSIGN_REPOSITORY` environment variable. Policy Controller uses registry credentials provided in the admission request, Service Account, or `signaturePullSecrets` defined in the policy to connect to the registry to verify a signature.

Important

This component does not work with insecure registries.

To Install Supply Chain Security Tools - Policy Controller, see Install Supply Chain Security Tools - Policy Controller

Overview of Supply Chain Security Tools for VMware Tanzu - Policy Controller

Supply Chain Security Tools - Policy Controller is a security tool that helps you ensure that the container images in their registry have not been tampered with. Policy Controller is a Kubernetes Admission Controller that allows you to apply policies to verify signatures on container images before being admitted to a cluster.

The Policy Controller:

- Verifies signatures on container images used by Kubernetes resources
- Enforces policies to allow or deny images being admitted a cluster
- Allows operators to define multiple policies in the cluster
- Allows operators to select which `namespaces` to enforce policies against
- Supports `cosign` signatures and keyless signing
- Supports storing public keys in a KMS

It enforces its policies against all resources that create `Pod`s as part of their life cycle:

- `Pod`
- `ReplicaSet`
- `Deployment`
- `Job`
- `StatefulSet`
- `DaemonSet`
- `CronJob`

Note

This component is the successor to `Supply Chain Security Tools - Sign`, which is deprecated. Support and maintenance for `Supply Chain Security Tools - Sign` continues. Monitor Release Notes for updates.

Supply Chain Security Tools - Policy Controller is based on Sigstore's Policy Controller and is compatible only with `cosign` signatures. See Cosign and Policy Controller in GitHub. For information about image signing and verification, see Sigstore open source community and the cosign project in GitHub.

The Policy Controller component is a policy enforcement tool only. It does not sign images. Operators can configure image signing for their containers in several ways, including:

- By using Tanzu Build Service
- By using kpack
- By integrating cosign into their build pipelines

Image signatures generated by `cosign` are stored in the same registry location as the image itself unless configured with the `COSIGN_REPOSITORY` environment variable. Policy Controller uses registry credentials provided in the admission request, Service Account, or `signaturePullSecrets` defined in the policy to connect to the registry to verify a signature.

Important

This component does not work with insecure registries.

To Install Supply Chain Security Tools - Policy Controller, see Install Supply Chain Security Tools - Policy Controller

Install Supply Chain Security Tools - Policy Controller

You install Supply Chain Security Tools - Policy Controller as part of Tanzu Application Platform's Full, Iterate, and Run profiles. You can use the instructions in this topic to manually install SCST - Policy Controller.

Note

Follow the steps in this topic if you do not want to use a profile to install Supply Chain Security Tools - Policy Controller. For more information about profiles, see Components and installation profiles.

Prerequisites

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- A container image registry that supports TLS connections.

Important

This component does not work with not secure registries.

- For keyless authorities support, you must set `policy.tuf_enabled: true`. By default, the public official Sigstore The Update Framework (TUF) server is used. To target an alternative Sigstore stack, specify `policy.tuf_mirror` and `policy.tuf_root`.
- If you are installing in an air-gapped environment and require keyless authorities, you must deploy a Sigstore Stack on the cluster or be accessible from the air-gapped environment.
- During configuration, you provide a cosign public key to validate signed images. The Policy Controller only supports ECDSA public keys. An example cosign public key is provided that can validate an image from the public cosign registry. To provide your own key and images, follow the Cosign Quick Start Guide in GitHub.

Caution

This component rejects `pods` if they are not correctly configured. Test your configuration in a test environment before applying policies to your production cluster.

Install

To install Supply Chain Security Tools - Policy Controller:

1. List version information for the package by running:

```
tanzu package available list policy.apps.tanzu.vmware.com --namespace tap-insta
ll
```

   For example:

```
$ tanzu package available list policy.apps.tanzu.vmware.com --namespace tap-ins
tall
- Retrieving package versions for policy.apps.tanzu.vmware.com...
  NAME                           VERSION        RELEASED-AT
  policy.apps.tanzu.vmware.com  1.2.0          2023-10-01 20:00:00 -0400 EDT
```

2. (Optional) Make changes to the default installation settings by running:

```
tanzu package available get policy.apps.tanzu.vmware.com/VERSION --values-schem
a --namespace tap-install
```

   Where `VERSION` is the version number you discovered. For example, `1.2.0`.

   For example:

```
$ tanzu package available get policy.apps.tanzu.vmware.com/1.2.0 --values-schem
a --namespace tap-install
| Retrieving package details for policy.apps.tanzu.vmware.com/1.2.0...

KEY                         DEFAULT        TYPE     DESCRIPTION
custom_cas                  <nil>          array    List of custom CA contents t
hat should be included in the application container for registry communication.
                                                    An array of items containing
a ca_content field with the PEM-encoded contents of a certificate authority.
deployment_namespace        cosign-system  string   Deployment namespace specifi
es the namespace where this component should be deployed to.
                                                    If not specified, "cosign-sy
stem" is assumed.
fail_on_empty_authorities  true           boolean  Configure if a ClusterImageP
olicy will fail or allow empty authorities
limits_cpu                  200m           string   The CPU limit defines a hard
ceiling on how much CPU time
                                                    that the Policy Controller m
anager container can use.
                                                    https://kubernetes.io/docs/c
oncepts/configuration/manage-resources-containers/#meaning-of-cpu

no_match_policy             deny           string   The action when no policy ma
tches the admitting image digest. Valid values are "warn", "allow", or "deny".
quota.pod_number            6              string   The maximum number of Policy
Controller Pods allowed to be created with the priority class
                                                    system-cluster-critical. Thi
s value must be enclosed in quotes (""). If this value is not
                                                    specified then a default val
ue of 6 is used.
replicas                    1              integer  The number of replicas to be
created for the Policy Controller. This value must not be enclosed
                                                    in quotes. If this value is
not specified then a default value of 1 is used.
requests_memory             20Mi           string   The memory request defines t
he minium memory amount for the Policy Controller manager.
                                                    https://kubernetes.io/docs/c
oncepts/configuration/manage-resources-containers/#meaning-of-memory
```

```
tuf_root                                    string   The root.json file content o
f the TUF mirror

custom_ca_secrets          <nil>            array    List of custom CA secrets th
at should be included in the application container for registry communication.
                                                    An array of secret reference
s each containing a secret_name field with the secret name to be referenced
                                                    and a namespace field with t
he name of the namespace where the referred secret resides.
limits_memory              200Mi            string   The memory limit defines a h
ard ceiling on how much memory
                                                    that the Policy Controller m
anager container can use.
                                                    https://kubernetes.io/docs/c
oncepts/configuration/manage-resources-containers/#meaning-of-memory

requests_cpu               20m              string   The CPU request defines the
minimum CPU time for the Policy
                                                    Controller manager. During C
PU contention, CPU request is used as
                                                    a weighting where higher CPU
requests are allocated more CPU time.
                                                    https://kubernetes.io/docs/c
oncepts/configuration/manage-resources-containers/#meaning-of-cpu

tuf_mirror                                  string   TUF mirror address
```

3. Create a file named `scst-policy-values.yaml` and add the settings you want to customize:

    - `custom_ca_secrets`: If your container registries are secured by self-signed certificates, this setting controls which secrets are added to the application container as custom certificate authorities (CAs). `custom_ca_secrets` consists of an array of items. Each item contains two text boxes: the `secret_name` text box defines the name of the secret, and the `namespace` text box defines the name of the namespace where said secret is stored.

      For example:

      ```
      custom_ca_secrets:
      - secret_name: first-ca
        namespace: ca-namespace
      - secret_name: second-ca
        namespace: ca-namespace
      ```

      

      Note

      This setting is allowed even if `custom_cas` is defined.

    - `custom_cas`: This setting enables adding certificate content in PEM format. The certificate content is added to the application container as custom certificate authorities (CAs) to communicate with registries deployed with self-signed certificates. `custom_cas` consists of an array of items. Each item contains a single text box named `ca_content`. The value of this text box must be a PEM-formatted certificate authority. The certificate content must be defined as a YAML block, preceded by the literal indicator (`|`) to preserve line breaks and ensure that the certificates are interpreted correctly.

      For example:

```
custom_cas:
- ca_content: |
    ----- BEGIN CERTIFICATE -----
    first certificate content here...
    ----- END CERTIFICATE -----
- ca_content: |
    ----- BEGIN CERTIFICATE -----
    second certificate content here...
    ----- END CERTIFICATE -----
```

> **Note**
>
> This setting is allowed even if `custom_ca_secrets` is defined.

- `deployment_namespace`: This setting controls the namespace to which this component is deployed. When not specified, the namespace `cosign-system` is assumed. This component creates the specified namespace to deploy required resources. Select a namespace that is not used by any other components.
- `limits_cpu`: This setting controls the maximum CPU resource allocated to the Policy admission controller. The default value is “200m”. See Kubernetes documentation.
- `limits_memory`: This setting controls the maximum memory resource allocated to the Policy admission controller. The default value is “200Mi”. See Kubernetes documentation.
- `quota.pod_number`: This setting controls the maximum number of pods that are allowed in the deployment namespace with the `system-cluster-critical` priority class. This priority class is added to the pods to prevent preemption of this component’s pods in case of node pressure.

  The default value for this text box is `6`. If your use requires more than 6 pods, change this value to allow the number of replicas you intend to deploy.

  > **Note**
  >
  > VMware recommends to run this component with a critical priority level to prevent the cluster from rejecting all admission requests if the component’s `pod`s are evicted due to resource limits.

- `replicas`: This setting controls the default amount of replicas deployed by this component. The default value is `1`.

  For production environments: VMware recommends you increase the number of replicas to `3` to ensure that the availability of the component and better admission performance.
- `requests_cpu`: This setting controls the minimum CPU resource allocated to the Policy admission controller. During CPU contention, this value is used as a weighting where higher values indicate more CPU time is allocated. The default value is `20m`. See CPU resource units in the Kubernetes documentation.
- `requests_memory`: This setting controls the minimum memory resource allocated to the Policy admission controller. The default value is `20Mi`. See Memory resource units in the Kubernetes documentation.
- `tuf_enabled`: This setting defines whether the TUF initialization is done on startup. It is required for keyless verification support. The default value is `false`, which means

that keyless authorities of `ClusterImagePolicy` are not supported. Also, policy-controller does not have an external dependency on setup.

- `tuf_root`: The root.json file content of the TUF mirror.
- `tuf_mirror`: This setting defines the TUF mirror address which is used for doing the initialization.
- `no_match_policy`: The action when no policy matches the admitting image digest. Valid values are `"warn"`, `"allow"`, or `"deny"`. Default value is `"deny"`
- `fail_on_empty_authorities`: Failing or allowing empty authorities when adding a new `ClusterImagePolicy`. Default value is `true`.

4. Install the package:

```
tanzu package install policy-controller \
  --package policy.apps.tanzu.vmware.com \
  --version VERSION \
  --namespace tap-install \
  --values-file scst-policy-values.yaml
```

Where `VERSION` is the version number you discovered earlier. For example, `1.2.0`.

For example:

```
$ tanzu package install policy-controller \
    --package policy.apps.tanzu.vmware.com \
    --version 1.2.0 \
    --namespace tap-install \
    --values-file scst-policy-values.yaml

  Installing package 'policy.apps.tanzu.vmware.com'
  Getting package metadata for 'policy.apps.tanzu.vmware.com'
  Creating service account 'policy-controller-tap-install-sa'
  Creating cluster admin role 'policy-controller-tap-install-cluster-role'
  Creating cluster role binding 'policy-controller-tap-install-cluster-rolebind
ing'
  Creating package resource
  Waiting for 'PackageInstall' reconciliation for 'policy-controller'
  'PackageInstall' resource install status: Reconciling
  'PackageInstall' resource install status: ReconcileSucceeded
  'PackageInstall' resource successfully reconciled

  Added installed package 'policy-controller'
```

After you run the commands earlier the policy controller is running.

Policy Controller is now installed, but it does not enforce any policies by default. Policies must be explicitly configured on the cluster. To configure signature verification policies, see Configuring Supply Chain Security Tools - Policy.

Configure Supply Chain Security Tools - Policy

This topic describes how you can configure Supply Chain Security Tools - Policy. SCST - Policy requires extra configuration steps to verify your container images.

Admission of Images

An image is admitted after it is validated against a policy with matching image pattern, and where at least one valid signature is obtained from the authorities provided in a matched ClusterImagePolicy.

If more than one policy exists with a matching image pattern, *ALL* of the policies must have at least one passing authority for the image.

Including Namespaces

The Policy Controller only validates resources in namespaces that have chosen to opt-in. This is done by adding the label `policy.sigstore.dev/include: "true"` to the namespace resource.

```
kubectl label namespace my-secure-namespace policy.sigstore.dev/include=true
```

Caution

Without a Policy Controller ClusterImagePolicy applied, there are fallback behaviors where images are validated against the public Sigstore Rekor and Fulcio servers by using a keyless authority flow. Therefore, if the deploying image is signed publicly by a third-party using the keyless authority flow, the image is admitted as it can validate against the public Rekor and Fulcio. To avoid this behavior, develop, and apply a ClusterImagePolicy that applies to the images being deployed in the namespace.

Create a `ClusterImagePolicy` resource

The cluster image policy is a custom resource containing the following properties:

`images`

In a ClusterImagePolicy, `spec.images` specifies a list of glob matching patterns. These patterns are matched against the image digest in `PodSpec` for resources attempting deployment.

Policy Controller defines the following globs by default:

- If `*` is specified, the `glob` matching behavior is `index.docker.io/library/*`.
- If `*/*` is specified, the `glob` matching behavior is `index.docker.io/*/*`.

With these defaults, you require the `glob` pattern `**` to match against all images. If your image is hosted on Docker Hub, include `index.docker.io` as the host for the glob.

A sample ClusterImagePolicy which matches against all images using glob:

```
apiVersion: policy.sigstore.dev/v1beta1
kind: ClusterImagePolicy
metadata:
  name: image-policy
spec:
  images:
  - glob: "**"
```

`mode`

In a ClusterImagePolicy, `spec.mode` specifies the action of a policy:

- `enforce`: The default behavior. If the policy fails to validate the image, the policy fails.
- `warn`: If the policy fails to validate the image, validation error messages are converted to warnings and the policy passes.

A sample of a ClusterImagePolicy which has `warn` mode configured.

```
---
apiVersion: policy.sigstore.dev/v1beta1
kind: ClusterImagePolicy
metadata:
  name: POLICY-NAME
spec:
  mode: warn
```

Where `POLICY-NAME` is the name of the policy you want to configure your ClusterImagePolicy with.

When `enforce` mode is set, an image that fails validation is not admitted.

Sample output message:

```
error: failed to patch: admission webhook "policy.sigstore.dev" denied the request: va
lidation failed: failed policy: POLICY-NAME: spec.template.spec.containers[0].image
IMAGE-REFERENCE signature key validation failed for authority authority-0 for IMAGE-RE
FERENCE: GET IMAGE-SIGNATURE-REFERENCE: DENIED: denied; denied
failed policy: POLICY-NAME: spec.template.spec.containers[1].image
IMAGE-REFERENCE signature key validation failed for authority authority-0 for IMAGE-RE
FERENCE: GET IMAGE-SIGNATURE-REFERENCE: DENIED: denied; denied
```

When `warn` mode is set, an image that fails validation is admitted.

Sample output message:

```
Warning: failed policy: POLICY-NAME: spec.template.spec.containers[0].image
Warning: IMAGE-REFERENCE signature key validation failed for authority authority-0 for
IMAGE-REFERENCE: GET IMAGE-SIGNATURE-REFERENCE: DENIED: denied; denied
Warning: failed policy: POLICY-NAME: spec.template.spec.containers[1].image
Warning: IMAGE-REFERENCE signature key validation failed for authority authority-0 for
IMAGE-REFERENCE: GET IMAGE-SIGNATURE-REFERENCE: DENIED: denied; denied
```

If you don't want a `Warning` output message, you can configure a `static.action pass` authority to allow expected unsigned images. For example, you may want to allow unsigned images if your policy controller runs on a development environment, and you need to iterate quickly. For information about static action authorities, see Static Action.

match

You can use `match` to filter resources using group, version, kind, or labels in a selected namespace to enforce the defined policy. If the list of matching resources is empty, all core resources are used by default.

For example, you can filter all `v1 cronjobs` with the label `app: tap` in a namespace that is labeled for policy enforcement:

```
spec:
  match:
  - group: batch
    resource: cronjobs
    version: v1
    selector:
      matchLabels:
        app: tap
```

authorities

Authorities listed in the `authorities` block of the ClusterImagePolicy are `key` or `keyless` specifications.

`key`

Each `key` authority can contain a PEM-encoded ECDSA public key, a `secretRef`, or a `kms` path.

The policy resyncs with KMS referenced every 10 hours. Any updates to the secret in KMS is pulled in during the refresh. To force a resync, the policy must be deleted and recreated.

Important

Only ECDSA public keys are supported.

```
spec:
  authorities:
    - key:
        data: |
          -----BEGIN PUBLIC KEY-----
          ...
          -----END PUBLIC KEY-----
    - key:
        secretRef:
          name: secretName
    - key:
        kms: KMSPATH
```

Where `KMSPATH` is the name of the KMS path you want to configure in your key authority.

Note

The secret referenced in `key.secretRef.name` must be created in the `cosign-system` namespace or the namespace where the Policy Controller is installed. This secret must only contain one `data` entry with the public key.

`keyless`

Note

Keyless support is deactivated by default. See Install Supply Chain Security Tools - Policy Controller.

Each keyless authority can contain a Fulcio URL, a Rekor URL, a certificate, or an array of identities.

Identities are represented with a combination of `issuer` or `issuerRegExp` with `subject` or `subjectRegExp`.

- `issuer`: Defines the issuer for this identity.
- `issuerRegExp`: Specifies a regular expression to match the issuer for this identity.
- `subject`: Defines the subject for this identity.
- `subjectRegExp`: Specifies a regular expression to match the subject for this identity.

An example of keyless authority structure:

```
spec:
  authorities:
    - keyless:
        url: https://fulcio.example.com
```

```
        ca-cert:
          data: Certificate Data
        identities:
          - issuer: https://accounts.google.com
            subjectRegExp: .*@example.com
          - issuer: https://token.actions.githubusercontent.com
            subject: https://github.com/mycompany/*/.github/workflows/*@*
      ctlog:
        url: https://rekor.example.com
    - keyless:
        url: https://fulcio.example.com
        ca-cert:
          secretRef:
            name: secretName
        identities:
          - issuerRegExp: .*kubernetes.default.*
            subjectRegExp: .*kubernetes.io/namespaces/default/serviceaccounts/default
```

The authorities are evaluated using the `any of` operator to admit container images. For each pod, the Policy Controller iterates over the list of containers and init containers. For every policy that matches against the images, they must each have at least one valid signature obtained using the authorities specified. If an image does not match any policy, the Policy Controller does not admit the image.

`static.action`

ClusterImagePolicy authorities are configured to always `pass` or `fail` with `static.action`.

Sample `ClusterImagePolicy` with static action `fail`.

```
apiVersion: policy.sigstore.dev/v1beta1
kind: ClusterImagePolicy
metadata:
  name: POLICY-NAME
spec:
  authorities:
  - static:
      action: fail
```

Where `POLICY-NAME` is the name of the policy you want to configure your ClusterImagePolicy with.

A sample output of static action `fail`:

```
error: failed to patch: admission webhook "policy.sigstore.dev" denied the request: va
lidation failed: failed policy: POLICY-NAME: spec.template.spec.containers[0].image
IMAGE-REFERENCE disallowed by static policy
failed policy: POLICY-NAME: spec.template.spec.containers[1].image
IMAGE-REFERENCE disallowed by static policy
```

Images that are unsigned in a namespace with validation enabled are admitted with an authority with static action `pass`.

This applies when you are configuring a policy with `static.action pass` for `tap-packages` images. Another policy is then configured to validate signed images produced by Tanzu Build Service. This allows images from `tap-packages`, which are unsigned and required by the platform, to be admitted while still validating signed built images from Tanzu Build Service. See Configure your supply chain to sign and verify your image builds.

If `Warning` messages are desirable for admitted images where validation failed, you can configure a policy with `warn` mode and valid authorities. For information about ClusterImagePolicy modes, see Mode.

Provide credentials for the package

There are three ways the package reads credentials to authenticate to registries protected by authentication:

1. Reading `imagePullSecrets` directly from the resource being admitted. See Container image pull secrets in the Kubernetes documentation.
2. Reading `imagePullSecrets` from the service account the resource is running as. See Arranging for imagePullSecrets to be automatically attached in the Kubernetes documentation.
3. Reading a `secretRef` from the `ClusterImagePolicy` resource's `signaturePullSecrets` when specifying the cosign signature source.

Authentication can fail for the following scenarios:

- A not valid credential is specified in the `imagePullSecrets` of the resource or in the service account the resource runs as.
- A not valid credential is specified in the `ClusterImagePolicy` `signaturePullSecrets` text box.

Provide secrets for authentication in your policy

You can provide secrets for authentication as part of the policy configuration. The `oci` location is the image location or a remote location where signatures are configured to be stored during signing. The `signaturePullSecrets` is available in the `cosign-system` namespace or the namespace where the Policy Controller is installed.

By default, `imagePullSecrets` from the resource or service account is used while the default `oci` location is the image location.

See the following example:

```
spec:
  authorities:
    - key:
        data: |
          -----BEGIN PUBLIC KEY-----
          ...
          -----END PUBLIC KEY-----
      source:
        - oci: registry.example.com/project/signature-location
          signaturePullSecrets:
            - name: MY-SECRET
    - keyless:
        url: https://fulcio.example.com
      source:
        - oci: registry.example.com/project/signature-location
          signaturePullSecrets:
            - name: MY-SECRET
```

Where `MY-SECRET` is the name of the secret you want to use with your credentials.

VMware recommends using a set of credentials with the least amount of privilege that allows reading the signature stored in your registry.

Verify your configuration

A sample policy:

```
apiVersion: policy.sigstore.dev/v1beta1
kind: ClusterImagePolicy
metadata:
  name: image-policy
spec:
  images:
  - glob: "gcr.io/projectsigstore/cosign*"
  authorities:
  - name: official-cosign-key
    key:
      data: |
        -----BEGIN PUBLIC KEY-----
        MFkwEwYHKoZIzj0CAQYIKoZIzj0DAQcDQgAEhyQCx0E9wQWSFI9ULGwy3BuRklnt
        IqozONbbdbqz11hlRJy9c7SG+hdcFl9jE9uE/dwtuwU2MqU9T/cN0YkWww==
        -----END PUBLIC KEY-----
```

When using the sample policy, run these commands to verify your configuration:

1. Verify that the Policy Controller admits the signed image that validates with the configured public key. Run:

   ```
   kubectl run cosign \
     --image=gcr.io/projectsigstore/cosign:v1.2.1 \
     --dry-run=server
   ```

   For example:

   ```
   $ kubectl run cosign \
     --image=gcr.io/projectsigstore/cosign:v1.2.1 \
     --dry-run=server
   pod/cosign created (server dry run)
   ```

   If you are using vSphere with Tanzu or OpenShift, you must add some overrides:

   ```
   $ kubectl run cosign \
     --image=gcr.io/projectsigstore/cosign:v1.2.1 \
     --overrides='{"spec": {"securityContext": {"seccompProfile": {"type": "Runtim
   eDefault"}}, "containers": [{"name": "cosign", "securityContext": {"allowPrivil
   egeEscalation": false, "runAsNonRoot": true, "capabilities": {"drop": ["AL
   L"]}}}]}}' \
     --override-type strategic \
     --dry-run=server
   pod/cosign created (server dry run)
   ```

2. Verify that the Policy Controller rejects the unmatched image. Run:

   ```
   kubectl run busybox --image=busybox --dry-run=server
   ```

   For example:

   ```
   $ kubectl run busybox --image=busybox --dry-run=server
     Error from server (BadRequest): admission webhook "policy.sigstore.dev" denie
   d the request: validation failed: no matching policies: spec.containers[0].imag
   e
     index.docker.io/library/busybox@sha256:3614ca5eacf0a3a1bcc361c939202a974b4902
   b9334ff36eb29ffe9011aaad83
   ```

   In the output, it did not specify which authorities were used as there was no policy found that matched the image. Therefore, the image fails to validate for a signature and fails to deploy.

3. Verify that the Policy Controller rejects a matched image signed with a different key than the one configured. Run:

```
kubectl run cosign-fail \
  --image=gcr.io/projectsigstore/cosign:v0.3.0 \
  --dry-run=server
```

For example:

```
$ kubectl run cosign-fail \
    --image=gcr.io/projectsigstore/cosign:v0.3.0 \
    --dry-run=server
  Error from server (BadRequest): admission webhook "policy.sigstore.dev" denie
d the request: validation failed: failed policy: image-policy: spec.containers
[0].image
  gcr.io/projectsigstore/cosign@sha256:135d8c5e27bdc917f04b415fc947d7d5b1137f99
bb8fa00bffc3eca1856e9c52 failed to validate public keys with authority official
-cosign-key for gcr.io/projectsigstore/cosign@sha256:135d8c5e27bdc917f04b415fc9
47d7d5b1137f99bb8fa00bffc3eca1856e9c52: no matching signatures:
```

In the output, it specifies which authorities were used for validation when a policy was found that matched the image. In this case, the authority used was `official-cosign-key`. If no name is specified, it is defaulted to `authority-#`.

Overview of Supply Chain Security Tools - Scan

This topic gives you an overview of use cases, features, and CVEs for Supply Chain Security Tools (SCST) - Scan.

Overview

With Supply Chain Security Tools (SCST) - Scan, you can build and deploy secure, trusted software that complies with your corporate security requirements. SCST - Scan provides scanning and gatekeeping capabilities that Application and DevSecOps teams can incorporate early in their path to production. This is the best practice for reducing security risk and ensuring more efficient remediation.

Language support

For information about the languages and frameworks that are supported by Tanzu Application Platform components, see the Language and framework support in Tanzu Application Platform table.

Use cases

The following use cases apply to SCST - Scan:

- Scan source code repositories and images for known Common Vulnerabilities and Exposures (CVEs) as part of your software supply chain at build time.
- Scan container images produced by your supply chain and any running image in your Tanzu Application Platform clusters for newly reported vulnerabilities after the initial image build scan.
- Use one of the available scan integrations or create your own to use your existing vulnerability scanning platforms.
- Analyze supply chain scan results against user-defined policies.

- Store vulnerability scan results in SCST - Store for long-term archival and reporting.

SCST - Scan versions

There are two versions of SCST - Scan:

SCST - Scan 1.0

SCST - Scan 1.0 has been in the testing and scanning supply chain since it was introduced with Tanzu Application Platform v1.0. SCST - Scan 1.0 can scan a workload for vulnerabilities, submit the scan results to SCST - Store for long-term storage and reporting, and compare the results against a policy defined by the user. This is all included in a tightly coupled scan job that is executed as part of the testing and scanning supply chain.

This tight coupling of the capabilities made it difficult to develop and maintain integrations for the vast ecosystem of vulnerability scanning platforms. To simplify this integration process, VMware introduced SCST - Scan 2.0.

Although other scan integrations are available, the default configuration for SCST - Scan 1.0 is the open-source Anchore Grype.

SCST - Scan 2.0

SCST - Scan 2.0 was introduced in the Tanzu Application Platform v1.5 release as an Alpha and is now GA in Tanzu Application Platform v1.8. This iteration of SCST - Scan focuses on simplifying the integration experience by decoupling SCST - Store submission and policy from the scanning task. This allows integration to be simplified and more focused on the task of scanning workloads for vulnerabilities.

SCST - Scan 2.0 can scan container images after the initial creation of the workload. This allows you to have visibility in the security posture of images as new vulnerabilities are reported. For more information, see Recurring Scanning. This capability can be used with Scan 1.0 or Scan 2.0.

SCST - Scan 2.0 includes the default configuration to use open-source Aqua Security Trivy as the image scanner, and a Grype template is also included for backward compatibility. Examples of other integrations, and how to build your own integration with this simplified interface, are provided in documentation.

Determine which version to use

In Tanzu Application Platform v1.8, both SCST - Scan v1.0 and SCST - Scan v2.0 are supported. In a future release, SCST - Scan v1.0 will be deprecated and replaced with SCST - Scan v2.0. To help facilitate this transition, VMware is slowly making SCST - Scan 2.0 the default component. The default version varies depending on the environment Tanzu Application Platform is installed on:

Installation Environment	Default Component	Detail
Online Installation	SCST - Scan v1.0	SCST - Scan v1.0 remains the default with the option to opt in to Scan 2.0.
Offline Installation	SCST - Scan v2.0	SCST - Scan v2.0 is the default due to a simplified air-gapped experience with Trivy.
Azure Installation	SCST - Scan v1.0	SCST - Scan v1.0 remains the default with the option to opt in to Scan v2.0.
AWS Installation	SCST - Scan v1.0	SCST - Scan v1.0 remains the default with the option to opt in to SCST - Scan v2.0.

If you require a policy to block a workload in a supply chain based on detected vulnerabilities, use SCST - Scan v1.0.

If you want to create a scan integration for a scan tool that does not exist, use SCST - Scan v2.0 as the process is greatly simplified. For more information, see Bring your own scanner with Supply Chain Security Tools - Scan 2.0.

If you are using the Tanzu Supply Chain component, use SCST - Scan v2.0 as only SCST - Scan v2.0 is supported with Tanzu Supply Chain. For more information, see Overview of Tanzu Supply Chain.

Vulnerability Scanner limitations

Although vulnerability scanning is an important practice in DevSecOps and the benefits of it are widely recognized and accepted, some limits impact its efficacy. The following examples illustrate the limits that are prevalent in most scanners today:

Missed CVEs

One limit of all vulnerability scanners is that no one tool can find all CVEs, which means there is a risk that a missed CVE could be exploited. Some reasons for missed CVEs include:

- The scanner does not detect the vulnerability because it is a recently discovered vulnerability and the CVE databases are not updated yet.
- The scanner verifies different CVE sources based on the detected package type and OS.
- The scanner might not fully support a particular programming language, packaging system, or manifest format.
- The scanner might not implement binary analysis or fingerprinting.
- The detected component does not always include a canonical name and vendor, requiring the scanner to infer and attempt fuzzy matching.
- When vendors register impacted software with NVD, the provided information might not exactly match the values in the release artifacts.

False positives

Vulnerability scanners cannot always access the information to accurately identify whether a CVE exists. This often leads to an influx of false positives where the tool mistakenly flags something as a vulnerability. Unless you are specialized in security or are very familiar with a vulnerable component, assessing, and determining false positives is a challenging and time-consuming activity. Some reasons for a false positive flag include:

- A component is misidentified due to similar names.
- A sub-component is identified as the parent component.
- A component is correctly identified but the impacted function is not on a reachable code path.
- A component's impacted function is on a reachable code path but is not a concern due to the specific environment or configuration.
- The version of a component might be incorrectly flagged as impacted.
- The detected component does not always include a canonical name and vendor, requiring the scanner to infer and attempt fuzzy matching.

Mitigation measures

Although vulnerability scanning is not a perfect solution, it is an essential part of the process for keeping your organization secure. To maximize the benefits while minimizing the impact of the limits of vulnerability scanning, take the following steps to scan more continuously and comprehensively to identify and remediate zero-day vulnerabilities quickly:

- Scan early in the development cycle to ensure that you can address issues more efficiently. Tanzu Application Platform includes security practices such as source and container image vulnerability scanning earlier in the path to production for application teams.
- Scan any base images in use. Tanzu Application Platform image scanning can recognize and scan the OS packages from a base image.
- Scan running software in test, stage, and production environments at a regular cadence.
- Generate accurate provenance at any level so that scanners have a complete picture of the dependencies to scan. This is where a software bill of materials (SBoM) is used. To help you automate this process, VMware Tanzu Build Service, leveraging Cloud Native Buildpacks, generates an SBoM for buildpack-based projects. Because this SBoM is generated during the image-building stage, it is more accurate and complete than one generated earlier or later in the release life cycle. This is because it can highlight dependencies introduced at the time of build that might introduce the potential for compromise.
- Scan by using multiple scanners to maximize CVE coverage.
- Keep your dependencies up-to-date.
- To reduce the overall surface area of attack use smaller dependencies.
- Reduce the amount of third-party dependencies when possible.
- Use distroless base images when possible.
- Maintain a central record of false positives to ease CVE triaging and remediation efforts.

Vulnerability Scanner limitations

Although vulnerability scanning is an important practice in DevSecOps and the benefits of it are widely recognized and accepted, some limits impact its efficacy. The following examples illustrate the limits that are prevalent in most scanners today:

Missed CVEs

One limit of all vulnerability scanners is that no one tool can find all CVEs, which means there is a risk that a missed CVE could be exploited. Some reasons for missed CVEs include:

- The scanner does not detect the vulnerability because it is a recently discovered vulnerability and the CVE databases are not updated yet.
- The scanner verifies different CVE sources based on the detected package type and OS.
- The scanner might not fully support a particular programming language, packaging system, or manifest format.
- The scanner might not implement binary analysis or fingerprinting.
- The detected component does not always include a canonical name and vendor, requiring the scanner to infer and attempt fuzzy matching.
- When vendors register impacted software with NVD, the provided information might not exactly match the values in the release artifacts.

False positives

Vulnerability scanners cannot always access the information to accurately identify whether a CVE exists. This often leads to an influx of false positives where the tool mistakenly flags something as a vulnerability. Unless you are specialized in security or are very familiar with a vulnerable component, assessing, and determining false positives is a challenging and time-consuming activity. Some reasons for a false positive flag include:

- A component is misidentified due to similar names.
- A sub-component is identified as the parent component.

- A component is correctly identified but the impacted function is not on a reachable code path.
- A component's impacted function is on a reachable code path but is not a concern due to the specific environment or configuration.
- The version of a component might be incorrectly flagged as impacted.
- The detected component does not always include a canonical name and vendor, requiring the scanner to infer and attempt fuzzy matching.

Mitigation measures

Although vulnerability scanning is not a perfect solution, it is an essential part of the process for keeping your organization secure. To maximize the benefits while minimizing the impact of the limits of vulnerability scanning, take the following steps to scan more continuously and comprehensively to identify and remediate zero-day vulnerabilities quickly:

- Scan early in the development cycle to ensure that you can address issues more efficiently. Tanzu Application Platform includes security practices such as source and container image vulnerability scanning earlier in the path to production for application teams.
- Scan any base images in use. Tanzu Application Platform image scanning can recognize and scan the OS packages from a base image.
- Scan running software in test, stage, and production environments at a regular cadence.
- Generate accurate provenance at any level so that scanners have a complete picture of the dependencies to scan. This is where a software bill of materials (SBoM) is used. To help you automate this process, VMware Tanzu Build Service, leveraging Cloud Native Buildpacks, generates an SBoM for buildpack-based projects. Because this SBoM is generated during the image-building stage, it is more accurate and complete than one generated earlier or later in the release life cycle. This is because it can highlight dependencies introduced at the time of build that might introduce the potential for compromise.
- Scan by using multiple scanners to maximize CVE coverage.
- Keep your dependencies up-to-date.
- To reduce the overall surface area of attack use smaller dependencies.
- Reduce the amount of third-party dependencies when possible.
- Use distroless base images when possible.
- Maintain a central record of false positives to ease CVE triaging and remediation efforts.

Scan Types for Supply Chain Security Tools - Scan

This topic tells you what scan types you can use with Scan Types for Supply Chain Security Tools (SCST) - Scan. The out-of-box test and scan supply chain supports the source and container image scan types.

Source scan

The source scan step in the test and scan supply chain performs a Software Composition Analysis (SCA) scan to inspect the open source dependencies of an application for vulnerabilities. You perform this by inspecting the file that the language uses for dependency declaration. For example:

Language	Dependency File
Spring	`pom.xml`

Language	Dependency File
.Net	`deps.json`
Node.JS	`packages.json`
Python	`requirements.txt`

Rather than declare specific dependency versions, some languages such as Spring, Java, and .Net resolve dependency versions at build time. For these languages, performing a SCA scan on the declaration file stored in the source code does not produce meaningful results, often creating false positives or false negatives.

Due to this, in Tanzu Application Platform v1.6, the source scan step is moved to an opt-in step in the supply chain.

Adding Source Scan to the Test and Scan Supply Chain

To add source scanning to the out-of-the-box test and scan supply chain, you can apply an overlay in the install `tap-values.yaml` file. This overlay adds the required resources to the supply chain in the correct location to opt-in to source scanning.

For information about how overlays work with Tanzu Application Platform, see Customize your package installation.

To add source scanning to the default out-of-the-box test and scan supply chain:

1. Create a `secret.yml` file with a `Secret` that contains your ytt overlay. For example:

```
apiVersion: v1
kind: Secret
metadata:
 name: ootb-supply-chain-testing-scanning-add-source-scanner
 namespace: tap-install
 annotations:
   kapp.k14s.io/change-group: "tap-overlays"
type: Opaque
stringData:
 ootb-supply-chain-testing-scanning-add-source-scanner.yaml: |
   #@ load("@ytt:overlay", "overlay")
   #@overlay/match by=overlay.subset({"metadata":{"name":"source-test-scan-to-u
rl"}, "kind": "ClusterSupplyChain"})
   ---
   spec:
     resources:
       #@overlay/match by=overlay.index(2)
       #@overlay/insert before=True
           - name: source-scanner
             params:
             - default: scan-policy
               name: scanning_source_policy
             - default: blob-source-scan-template
               name: scanning_source_template
             sources:
             - name: source
               resource: source-tester
             templateRef:
               kind: ClusterSourceTemplate
               name: source-scanner-template
           #@overlay/match by="name"
           - name: image-provider
             sources:
             #@overlay/match by="name"
```

```
            - name: source
              resource: source-scanner
```

For information about ytt overlays, see the Carvel documentation.

2. Apply the `Secret` to your cluster:

```
kubectl apply -f secret.yml
```

3. Update your values file to include a `package_overlays` field:

```
package_overlays:
- name: ootb-supply-chain-testing-scanning
  secrets:
  - name: ootb-supply-chain-testing-scanning-add-source-scanner
```

4. Update Tanzu Application Platform:

```
tanzu package installed update tap -p tap.tanzu.vmware.com -v 1.9.1  --values-f
ile tap-values.yaml -n tap-install
```

For a multicluster installation, you must apply this to the build profile, because that is where the scan components run. For information about Tanzu Application Platform profiles, see Installing Tanzu Application Platform package and profiles.

Container image scan

A container image scan inspects the contents of a built container image for vulnerabilities. This scan is performed on the container image after it is uploaded to the container image registry and at periodic intervals after the initial upload. Many container registries, such as Harbor and Docker Hub include this capability.

Tanzu Application Platform enables scanning container images for vulnerabilities as part of your supply chain, allowing you to prevent deployment of a container image if vulnerabilities are discovered that exceed your security policy.

Overview of Supply Chain Security Tools - Scan 1.0

This topic gives you an overview of use cases, features, and CVEs for Supply Chain Security Tools (SCST) - Scan 1.0

Overview

With Supply Chain Security Tools - Scan, you can build and deploy secure, trusted software that complies with your corporate security requirements. Supply Chain Security Tools (SCST) - Scan provides scanning and gatekeeping capabilities that Application and DevSecOps teams can incorporate early in their path to production as it is a known industry best practice for reducing security risk and ensuring more efficient remediation.

Language support

For information about the languages and frameworks that are supported by Tanzu Application Platform components, see the Language and framework support in Tanzu Application Platform table.

Use cases

The following use cases apply to SCST - Scan:

- Use your scanner as a plug-in to scan source code repositories and images for known Common Vulnerabilities and Exposures (CVEs) before deploying to a cluster.
- Identify CVEs by continuously scanning each new code commit or each new image built.
- Analyze scan results against user-defined policies by using Open Policy Agent.
- Produce vulnerability scan results and post them to the SCST - Store from where they are queried.

SCST - Scan features

The following SCST - Scan features enable the Use cases:

- Kubernetes controllers to run scan TaskRuns.
- Custom Resource Definitions (CRDs) for Image and Source Scan.
- CRD for a scanner plug-in. Example is available by using Anchore's Syft and Grype.
- CRD for policy enforcement.
- Enhanced scanning coverage by analyzing the Cloud Native Buildpack SBoMs that Tanzu Build Service images provide.

A Note on Vulnerability Scanners

Although vulnerability scanning is an important practice in DevSecOps and the benefits of it are widely recognized and accepted, remember that there are limits present that impact its efficacy. The following examples illustrate the limits that are prevalent in most scanners today:

Missed CVEs

One limit of all vulnerability scanners is that there is no one tool that can find 100% of all CVEs, which means there is always a risk that a missed CVE can be exploited. Some reasons for missed CVEs include:

- The scanner does not detect the vulnerability because it is recently discovered and the CVE databases that the scanner checks against are not updated yet.
- Scanners verify different CVE sources based on the detected package type and OS.
- The scanner might not fully support a particular programming language, packaging system or manifest format.
- The scanner might not implement binary analysis or fingerprinting.
- The detected component does not always include a canonical name and vendor, requiring the scanner to infer and attempt fuzzy matching.
- When vendors register impacted software with NVD, the provided information might not exactly match the values in the release artifacts.

False positives

Vulnerability scanners cannot always access the information to accurately identify whether a CVE exists. This often leads to an influx of false positives where the tool mistakenly flags something as a vulnerability when it isn't. Unless a user is specialized in security or is deeply familiar with what is deemed to be a vulnerable component by the scanner, assessing and determining false positives becomes a challenging and time-consuming activity. Some reasons for a false positive flag include:

- A component might be misidentified due to similar names.
- A sub-component might be identified as the parent component.
- A component is correctly identified but the impacted function is not on a reachable code path.
- A component's impacted function is on a reachable code path but is not a concern due to the specific environment or configuration.
- The version of a component might be incorrectly flagged as impacted.
- The detected component does not always include a canonical name and vendor, requiring the scanner to infer and attempt fuzzy matching.

So what can you do to protect yourselves and your software?

Although vulnerability scanning is not a perfect solution, it is an essential part of the process for keeping your organization secure. You can take the following measures to maximize the benefits while minimizing the impact of the limits:

- Scan more continuously and comprehensively to identify and remediate zero-day vulnerabilities quicker. You can achieve comprehensive scanning by:
    - scanning earlier in the development cycle to ensure that you can address issues more efficiently and do not delay a release. Tanzu Application Platform includes security practices such as source and container image vulnerability scanning earlier in the path to production for application teams.
    - scanning any base images in use. Tanzu Application Platform image scanning can recognize and scan the OS packages from a base image.
    - scanning running software in test, stage, and production environments at a regular cadence.
    - generating accurate provenance at any level so that scanners have a complete picture of the dependencies to scan. This is where a software bill of materials (SBoM) comes into play. To help you automate this process, VMware Tanzu Build Service, leveraging Cloud Native Buildpacks, generates an SBoM for buildpack-based projects. Because this SBoM is generated during the image building stage, it is more accurate and complete than one generated earlier or later in the release life cycle. This is because it can highlight dependencies introduced at the time of build that might introduce potential for compromise.
- Scan by using multiple scanners to maximize CVE coverage.
- Practice keeping your dependencies up-to-date.
- Reduce overall surface area of attack by:
    - using smaller dependencies.
    - reducing the amount of third-party dependencies when possible.
    - using distroless base images when possible.
- Maintain a central record of false positives to ease CVE triaging and remediation efforts.

Install Supply Chain Security Tools - Scan

This topic describes how you can install Supply Chain Security Tools - Scan from the Tanzu Application Platform package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install SCST - Scan. For information about profiles, see Components and installation profiles.

Prerequisites

Before installing SCST - Scan:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- Install Supply Chain Security Tools - Store for scan results to persist. The integration with SCST - Store are handled in:
    - **Single Cluster:** The SCST - Store is present in the same cluster where SCST - Scan and the `ScanTemplates` are present.
    - **Multi-Cluster:** The SCST - Store is present in a different cluster (e.g.: view cluster) where the SCST - Scan and `ScanTemplates` are present.
    - **Integration Deactivated:** The SCST - Scan deployment is not required to communicate with SCST - Store.

  For information about SCST - Store, see Using the Supply Chain Security Tools - Store.

Note

If you are installing SCST - Scan in a cluster with restricted Kubernetes Pod Security Standards, you must update configurations for the Tekton Pipelines package. See Troubleshooting.

Configure properties

When you install the SCST - Scan (Scan controller), you can configure the following optional properties:

Key	Default	Type	Description	ScanTemplate Version
resources.limits.cpu	250m	integer/string	Limits describes the maximum amount of CPU resources allowed.	*n/a*
resources.limits.memory	256Mi	integer/string	Limits describes the maximum amount of memory resources allowed.	*n/a*
resources.requests.cpu	100m	integer/string	Requests describes the minimum amount of CPU resources required.	*n/a*
resources.requests.memory	128Mi	integer/string	Requests describes the minimum amount of memory resources required.	*n/a*
namespace	scan-link-system	string	Deployment namespace for the Scan Controller	*n/a*
retryScanJobsSecondsAfterError	60	integer	Seconds to wait before retrying errored scans	v1.3.1 and later
caCertData	""	string	The custom certificates trusted by the scans' connections	v1.4.0 and later

Key	Default	Type	Description	ScanTemplate Version
controller.pullSecret	“controller-secret-ref”	string	Reference to the secret used for pulling the controller image from private registry. Set to empty if deploying from a public registry.	v1.5.0 and later
docker.import	true	Boolean	Import `controller.pullSecret` from another namespace (requires secretgen-controller). Set to false if the secret is present.	v1.5.0 and later
deployedThroughTmc	false	Boolean	Flag to configure multicluter property collectors to configure Insight Metadata Store credentials	v1.7.0 and later
insertUserAndGroupID	true	Boolean	Flag to add default pod security context runAsUser and runAsGroup to the scan job	v1.7.0 and later
metadataStore.exports.namespace	metadata-store-secrets	string	Namespace for metadata store secrets and exports	v1.7.0 and later
metadataStore.exports.toNamespace	“*”	string	Destination namespace for exported secrets, or "*" to allow any namespace to import	v1.7.0 and later
metadataStore.exports.toNamespaces	- ""	array of strings	List of destination namespaces for exported secrets	v1.7.0 and later
metadataStore.exports.ca.secretName	store-ca-cert	string	Name to use for created CA Cert secret of the Insight Metadata Store	v1.7.0 and later
metadataStore.exports.ca.pem	""	string	PEM-encoded CA certificate of the Insight Metadata Store	v1.7.0 and later
metadataStore.exports.auth.secretName	store-auth-token	string	Name to use for created auth secret for the Insight Metadata Store	v1.7.0 and later
metadataStore.exports.auth.token	""	string	Service account auth token with read-write access to the Insight Metadata Store	v1.7.0 and later

When you install the SCST - Scan (Grype scanner), you can configure the following optional properties:

Key	Default	Type	Description	ScanTemplate Version
resources.requests.cpu	250m	integer/string	Requests describes the minimum amount of CPU resources required.	
resources.requests.memory	128Mi	integer/string	Requests describes the minimum amount of memory resources required.	
scanner.serviceAccount	grype-scanner	string	Name of scan pod’s service ServiceAccount	
scanner.serviceAccountAnnotations	nil	object	Annotations added to ServiceAccount	
targetImagePullSecret	*n/a*	string	Reference to the secret used for pulling images from private registry	

Key	Default	Type	Description	ScanTemplate Version
targetSourceSshSecret	*n/a*	string	Reference to the secret containing SSH credentials for cloning private repositories	
namespace	default	string	Deployment namespace for the Scan Templates	*n/a*
metadataStore.url	https://metadata-store-app.metadata-store.svc.cluster.local:8443	string	URL of the Insight Metadata Store	v1.2.0 and earlier
metadataStore.authSecret.name	*n/a*	string	Name of deployed secret with key auth_token	v1.2.0 and earlier
metadataStore.authSecret.importFromNamespace	*n/a*	string	Namespace from which to import the Insight Metadata Store auth_token	v1.2.0 and earlier
metadataStore.caSecret.importFromNamespace	metadata-store	string	Namespace from which to import the Insight Metadata Store CA Cert	v1.2.0 and earlier
metadataStore.caSecret.name	app-tls-cert	string	Name of deployed secret with key ca.crt holding the CA Cert of the Insight Metadata Store	v1.2.0 and earlier
metadataStore.clusterRole	metadata-store-read-write	string	Name of the deployed ClusterRole for read/write access to the Insight Metadata Store deployed in the same cluster	v1.2.0

Install

There are two options for installing Supply Chain Security Tools – Scan

Option 1: Install to multiple namespaces with the Namespace Provisioner

The Namespace Provisioner enables operators to securely automate the provisioning of multiple developer namespaces in a shared cluster. To install Supply Chain Security Tools – Scan by using the Namespace Provisioner, see Namespace Provisioner.

The Namespace Provisioner can also create scan policies across multiple developer namespaces. See Customize installation in the Namespace Provisioner documentation for configuration steps.

Option 2: Install manually to each individual namespace

The installation for Supply Chain Security Tools – Scan involves installing two packages:

- Scan controller
- Grype scanner

The Scan controller enables you to use a scanner, in this case, the Grype scanner. Ensure that both the Grype scanner and the Scan controller are installed.

To install SCST - Scan (Scan controller):

1. List version information for the package by running:

```
tanzu package available list scanning.apps.tanzu.vmware.com --namespace tap-ins
```

```
tall
```

For example:

```
$ tanzu package available list scanning.apps.tanzu.vmware.com --namespace tap-i
nstall
/ Retrieving package versions for scanning.apps.tanzu.vmware.com...
  NAME                            VERSION       RELEASED-AT
  scanning.apps.tanzu.vmware.com   1.1.0
```

2. (Optional) Make changes to the default installation settings:

   If you are using Grype Scanner `v1.5.1 and later` or other supported scanners included with Tanzu Application Platform `v1.5.1 and later`, and do not want to use the default SCST - Store integration, deactivate the integration by appending the following field to the `values.yaml` file:

   ```
   ---
   metadataStore:
     url: "" # Deactivate Supply Chain Security Tools - Store integration
   ```

   If you are using Grype Scanner `v1.5.0` or other supported scanners included with Tanzu Application Platform `v1.5.0`, and do not want to use the default SCST - Store integration, deactivate the integration by appending the following field to the `values.yaml` file:

   ```
   ---
   metadataStore: {} # Deactivate Supply Chain Security Tools - Store integration
   ```

   If you are using Grype Scanner `v1.2.0 and earlier`, or the Snyk Scanner, the following scanning configuration deactivates the embedded SCST - Store integration with a `scan-values.yaml` file.

   ```
   ---
   metadataStore:
     url: "" # Deactivate Supply Chain Security Tools - Store integration
   ```

   If your Grype Scanner version is earlier than v1.2.0, the scanning configuration must configure the store parameters. See v1.1 Install Supply Chain Security Tools - Scan.

   Run to retrieve other configurable settings and append the key-value pair to the previous `scan-values.yaml` file:

   ```
   tanzu package available get scanning.apps.tanzu.vmware.com/VERSION --values-sch
   ema -n tap-install
   ```

   Where `VERSION` is your package version number. For example, `1.1.0`.

3. Install the package by running:

   ```
   tanzu package install scan-controller \
     --package scanning.apps.tanzu.vmware.com \
     --version VERSION \
     --namespace tap-install \
     --values-file scan-values.yaml
   ```

   Where `VERSION` is your package version number. For example, `1.1.0`.

To install SCST - Scan (Grype scanner):

Note

To install Grype in multiple namespaces, use a namespace provisioner. See Namespace Provisioner.

1. List version information for the package by running:

```
tanzu package available list grype.scanning.apps.tanzu.vmware.com --namespace t
ap-install
```

For example:

```
$ tanzu package available list grype.scanning.apps.tanzu.vmware.com --namespace
tap-install
/ Retrieving package versions for grype.scanning.apps.tanzu.vmware.com...
  NAME                                  VERSION       RELEASED-AT
  grype.scanning.apps.tanzu.vmware.com  1.1.0
```

2. (Optional) Make changes to the default installation settings:

To define the configuration for the SCST - Store integration in the `grype-values.yaml` file for the Grype Scanner:

```
---
namespace: "DEV-NAMESPACE" # The developer namespace where the ScanTemplates ar
e going to be deployed
metadataStore:
  url: "METADATA-STORE-URL" # The base URL where the Store deployment can be re
ached
  caSecret:
    name: "CA-SECRET-NAME" # The name of the secret containing the ca.crt
    importFromNamespace: "SECRET-NAMESPACE" # The namespace where Store is depl
oyed (if single cluster) or where the connection secrets were created (if multi
-cluster)
  authSecret:
    name: "TOKEN-SECRET-NAME" # The name of the secret containing the auth toke
n to connect to Store
    importFromNamespace: "SECRET-NAMESPACE" # The namespace where the connectio
n secrets were created (if multi-cluster)
```

Note In a single cluster, the connection between the scanning pod and the metadata store happens inside the cluster and does not pass through ingress. This is automatically configured. You do not need to provide an ingress connection to the store. For information about troubleshooting issues with scanner to metadata store connection configuration, see Troubleshooting Scanner to MetadataStore Configuration.

Important

You must either define both the `METADATA-STORE-URL` and `CA-SECRET-NAME`, or not define them as they depend on each other.

Where:

- `DEV-NAMESPACE` is the namespace where you want to deploy the `ScanTemplates`. This is the namespace where the scanning feature runs.
- `METADATA-STORE-URL` is the base URL where the Supply Chain Security Tools (SCST) - Store deployment is reached, for example, `https://metadata-store-app.metadata-store.svc.cluster.local:8443`.

- `CA-SECRET-NAME` is the name of the secret containing the ca.crt to connect to the SCST - Store deployment.
- `SECRET-NAMESPACE` is the namespace where SCST - Store is deployed, if you are using a single cluster. If you are using multicluster, it is where the connection secrets were created.
- `TOKEN-SECRET-NAME` is the name of the secret containing the authentication token to connect to the SCST - Store deployment when installed in a different cluster, if you are using multicluster. If built images are pushed to the same registry as the Tanzu Application Platform images, this can reuse the `tap-registry` secret created in Add the Tanzu Application Platform package repository as described earlier.

Run to retrieve other configurable settings and append the key-value pair to the previous `grype-values.yaml` file:

```
tanzu package available get grype.scanning.apps.tanzu.vmware.com/VERSION --valu
es-schema -n tap-install
```

Where `VERSION` is your package version number. For example, `1.1.0`.

For example:

```
$ tanzu package available get grype.scanning.apps.tanzu.vmware.com/1.1.0 --valu
es-schema -n tap-install
| Retrieving package details for grype.scanning.apps.tanzu.vmware.com/1.1.0...
  KEY                         DEFAULT  TYPE    DESCRIPTION
  namespace                   default  string  Deployment namespace for the Scan
Templates
  resources.limits.cpu        1000m    <nil>   Limits describes the maximum amou
nt of cpu resources allowed.
  resources.requests.cpu      250m     <nil>   Requests describes the minimum am
ount of cpu resources required.
  resources.requests.memory   128Mi    <nil>   Requests describes the minimum am
ount of memory resources required.
  targetImagePullSecret       <EMPTY>  string  Reference to the secret used for
pulling images from private registry.
  targetSourceSshSecret       <EMPTY>  string  Reference to the secret containin
g SSH credentials for cloning private repositories.
```

Important

If `targetSourceSshSecret` is not set, the private source scan template is not installed.

3. Install the package by running:

```
tanzu package install grype-scanner \
  --package grype.scanning.apps.tanzu.vmware.com \
  --version VERSION \
  --namespace tap-install \
  --values-file grype-values.yaml
```

Where `VERSION` is your package version number. For example, `1.1.0`.

For example:

```
$ tanzu package install grype-scanner \
  --package grype.scanning.apps.tanzu.vmware.com \
  --version 1.1.0 \
  --namespace tap-install \
```

```
  --values-file grype-values.yaml
/ Installing package 'grype.scanning.apps.tanzu.vmware.com'
| Getting namespace 'tap-install'
| Getting package metadata for 'grype.scanning.apps.tanzu.vmware.com'
| Creating service account 'grype-scanner-tap-install-sa'
| Creating cluster admin role 'grype-scanner-tap-install-cluster-role'
| Creating cluster role binding 'grype-scanner-tap-install-cluster-rolebinding'
/ Creating package resource
- Package install status: Reconciling

 Added installed package 'grype-scanner' in namespace 'tap-install'
```

Upgrade Supply Chain Security Tools - Scan

This topic describes how you can upgrade Supply Chain Security Tools - Scan from the Tanzu Application Platform package repository.

You can perform a fresh install of SCST - Scan by following the instructions in Install Supply Chain Security Tools - Scan.

Prerequisites

Before you upgrade SCST - Scan, upgrade the Tanzu Application Platform by following the instructions in Upgrading Tanzu Application Platform.

General Upgrades for SCST - Scan

When you're upgrading to any version of SCST - Scan these are some factors to accomplish this task:

1. Inspect the Release Notes for the version you're upgrading to. There you can find any breaking changes for the installation.
2. Get the values schema for the package version you're upgrading to by running:

   ```
   tanzu package available get scanning.apps.tanzu.vmware.com/$VERSION --values-sc
   hema -n tap-install
   ```

   Where `$VERSION` is the new version. This gives you insights on the values you can configure in your `tap-values.yaml` for the new version.

Upgrade a scanner in all namespaces

This section describes how to upgrade a supported scanner in all namespaces. The procedure is different depending on the installation method:

1. Installation by using Namespace Provisioner
2. Manual installation

Installation by using Namespace Provisioner

All scanners installed by the Namespace Provisioner in all managed namespaces are upgraded automatically. For example, if you upgrade your installation of Tanzu Application Platform and the version of Grype is updated, all Grype scanners installed by the Namespace Provisioner for all managed namespaces are automatically upgraded.

Manual installation

1. If a scanner, such as Grype Scanner, was installed as part of Tanzu Application Platform by using the full profile, run to upgrade:

   ```
   tanzu package installed update tap -p tap.tanzu.vmware.com -v VERSION --values-file tap-values.yaml -n tap-install
   ```

   Where `VERSION` is your Tanzu Application Platform version.

2. If a scanner, such as Grype Scanner, was installed by using component installation you must manually run:

   ```
   tanzu package installed update grype -p grype.scanning.apps.tanzu.vmware.com -v GRYPE-VERSION --values-file grype-values.yaml -n NAMESPACE
   ```

   Where:

   - `GRYPE-VERSION` is the version of Grype that you are upgrading to.
   - `NAMESPACE` is the namespace in which Grype is installed in.

Upgrade to Version v1.2.0

To upgrade from a previous version of SCST - Scan to the version `v1.2.0`:

1. Change the `SecretExports` from SCST - Store.

   SCST - Scan needs information to connect to the SCST - Store deployment, you must change where these secrets are exported to enable the connection with the version `v1.2.0` of SCST - Scan.

   - **For a single cluster deployment:**

     1. Edit the `tap-values.yaml` file you used to deploy SCST - Store to export the CA certificate to your developer namespace.

        ```
        metadata_store:
            ns_for_export_app_cert: "DEV-NAMESPACE"
        ```

        

        Note

        The `ns_for_export_app_cert` supports one namespace at a time. If you have multiple namespaces you can replace this value with a `*`, but this exports the CA certificate to all namespaces. Consider whether this increased visibility presents a risk.

     2. Update Tanzu Application Platform to apply the changes:

        ```
        tanzu package installed update tap -f tap-values.yaml -n tap-install
        ```

   - **For a multicluster deployment:**

     You must reapply the SecretExport by changing the `toNamespace: scan-link-system` to `toNamespace: DEV-NAMESPACE`:

     ```
     ---
     apiVersion: secretgen.carvel.dev/v1alpha1
     kind: SecretExport
     metadata:
     ```

```
  name: store-ca-cert
  namespace: metadata-store-secrets
spec:
  toNamespace: "DEV-NAMESPACE"
---
apiVersion: secretgen.carvel.dev/v1alpha1
kind: SecretExport
metadata:
  name: store-auth-token
  namespace: metadata-store-secrets
spec:
  toNamespace: "DEV-NAMESPACE"
```

2. Update your `tap-values.yaml` file.

   The installation of the SCST - Scan and the Grype scanner have some changes. The connection to the SCST - Store component have moved to the Grype scanner package. To deactivate the connection from the SCST - Scan, which is still present for backwards compatibility, but is deprecated and is removed in `v1.3.0`.

```
# Deactivate scan controller embedded Supply Chain Security Tools - Store integ
ration
scanning:
  metadataStore:
    url: ""

# Install Grype Scanner v1.2.0
grype:
  namespace: "DEV-NAMESPACE" # The developer namespace where the ScanTemplates
are going to be deployed
  metadataStore:
    url: "METADATA-STORE-URL" # The base URL where the Store deployment can be
reached
    caSecret:
      name: "CA-SECRET-NAME" # The name of the secret containing the ca.crt
      importFromNamespace: "SECRET-NAMESPACE" # The namespace where Store is de
ployed (if single cluster) or where the connection secrets were created (if mul
ti-cluster)
    authSecret:
      name: "TOKEN-SECRET-NAME" # The name of the secret containing the auth to
ken to connect to Store
      importFromNamespace: "SECRET-NAMESPACE" # The namespace where the connect
ion secrets were created (if multi-cluster)
```

   For more insights on how to install Grype, see Install Supply Chain Security Tools - Scan (Grype Scanner).

   

   Note

   If a mix of Grype templates, such as earlier than v1.2.0 and v1.2.0 and later, are used, both `scanning` and `grype` must configure the parameters. The secret must also export to both scan-link-system and the developer namespace. Do this by exporting to `*` or by defining multiple secrets and exports. If Grype is installed to multiple namespaces there must be corresponding exports. See Install Supply Chain Security Tools - Scan (Grype Scanner).

3. Update Tanzu Application Platform to apply the changes:

```
tanzu package installed update tap -f tap-values.yaml -n tap-install
```

4. Update the `ScanPolicy` to include the latest structure changes for `v1.2.0`.

   To update to the latest valid Rego File in the `ScanPolicy`, Enforce compliance policy using Open Policy Agent. `v1.2.0` introduced some breaking changes in the Rego File structure used for the `ScanPolicies`. For more information, see the Release Notes.

5. Verify the upgrade.

   You can run any `ImageScan` or `SourceScan` in your `DEV-NAMESPACE` where the Grype Scanner was installed, and it finishes. Here is a sample you can try to run to detect if everything upgraded.

   1. Create the `verify-upgrade.yaml` file in your system with the following content:

```
---
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ScanPolicy
metadata:
  name: scan-policy
  labels:
    'app.kubernetes.io/part-of': 'enable-in-gui'
spec:
  regoFile: |
    package main

    # Accepted Values: "Critical", "High", "Medium", "Low", "Negligible",
"UnknownSeverity"
    notAllowedSeverities := ["Critical", "High", "UnknownSeverity"]
    ignoreCves := []

    contains(array, elem) = true {
      array[_] = elem
    } else = false { true }

    isSafe(match) {
      severities := { e | e := match.ratings.rating.severity } | { e | e
:= match.ratings.rating[_].severity }
      some i
      fails := contains(notAllowedSeverities, severities[i])
      not fails
    }

    isSafe(match) {
      ignore := contains(ignoreCves, match.id)
      ignore
    }

    deny[msg] {
      comps := { e | e := input.bom.components.component } | { e | e := i
nput.bom.components.component[_] }
      some i
      comp := comps[i]
      vulns := { e | e := comp.vulnerabilities.vulnerability } | { e | e
:= comp.vulnerabilities.vulnerability[_] }
      some j
      vuln := vulns[j]
      ratings := { e | e := vuln.ratings.rating.severity } | { e | e := v
uln.ratings.rating[_].severity }
      not isSafe(vuln)
      msg = sprintf("CVE %s %s %s", [comp.name, vuln.id, ratings])
    }
---
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ImageScan
metadata:
  name: sample-public-image-scan
```

```
spec:
  registry:
    image: "nginx:1.16"
  scanTemplate: public-image-scan-template
  scanPolicy: scan-policy
```

2. Deploy the resources:

```
kubectl apply -f verify-upgrade.yaml -n DEV-NAMESPACE
```

3. View the scan results:

```
kubectl describe imagescan sample-public-image-scan -n DEV-NAMESPACE
```

If it is successful, the `ImageScan` goes to the `Failed` phase and shows the results of the scan in the `Status`.

Install another scanner for Supply Chain Security Tools - Scan

This topic describes how you can install scanners to work with Supply Chain Security Tools - Scan from the Tanzu Application Platform package repository.

Follow the instructions in this topic to install a scanner other than the out of the box Grype Scanner with SCST - Scan.

Prerequisites

Before installing a new scanner, install Supply Chain Security Tools - Scan. It must be present on the same cluster. The prerequisites for Scan are also required.

Install

To install a new scanner, follow these steps:

1. Complete scanner specific prerequisites for the scanner you're trying to install. For example, creating an API token to connect to the scanner.
    - Snyk Scanner (Beta) is available for image scanning.
    - Carbon Black Scanner (Beta) is available for image scanning.
2. List the available packages to discover what scanners you can use by running:

```
tanzu package available list --namespace tap-install
```

For example:

```
$ tanzu package available list --namespace tap-install
/ Retrieving available packages...
  NAME                                                DISPLAY-NAME
SHORT-DESCRIPTION
  grype.scanning.apps.tanzu.vmware.com                Grype Scanner for Supply
Chain Security Tools - Scan                      Default scan templates using A
nchore Grype
  snyk.scanning.apps.tanzu.vmware.com                 Snyk for Supply Chain Se
curity Tools - Scan                               Default scan templates using
Snyk
  carbonblack.scanning.apps.tanzu.vmware.com          Carbon Black Scanner for
```

```
Supply Chain Security Tools - Scan               Default scan templates using C
arbon Black
```

3. List version information for the scanner package by running:

   ```
   tanzu package available list SCANNER-NAME --namespace tap-install
   ```

   For example:

   ```
   $ tanzu package available list snyk.scanning.apps.tanzu.vmware.com --namespace
   tap-install
   / Retrieving package versions for snyk.scanning.apps.tanzu.vmware.com...
     NAME                                VERSION           RELEASED-AT
     snyk.scanning.apps.tanzu.vmware.com   1.0.0-beta.2
   ```

4. (Optional) Confirm that the secret created in Step 1 for scanner specific prerequisites is created.

5. Create a `values.yaml` to apply custom configurations to the scanner:

   > **Note**
   >
   > This step might be required for some scanners but optional for others.

   To list the values you can configure for any scanner, run:

   ```
   tanzu package available get SCANNER-NAME/VERSION --values-schema -n tap-install
   ```

   Where:

   - `SCANNER-NAME` is the name of the scanner package you retrieved earlier.
   - `VERSION` is your package version number. For example, `snyk.scanning.apps.tanzu.vmware.com/1.0.0-beta.2`.

   For example:

   ```
   $ tanzu package available get snyk.scanning.apps.tanzu.vmware.com/1.0.0-beta.2
   --values-schema -n tap-install

   KEY                                          DEFAULT
   TYPE    DESCRIPTION
   metadataStore.authSecret.name
   string  Name of deployed Secret with key auth_token
   metadataStore.authSecret.importFromNamespace
   string  Namespace from which to import the Insight Metadata Store auth_token
   metadataStore.caSecret.importFromNamespace    metadata-store
   string  Namespace from which to import the Insight Metadata Store CA Cert
   metadataStore.caSecret.name                   app-tls-cert
   string  Name of deployed Secret with key ca.crt holding the CA Cert of the Insi
   ght Metadata Store
   metadataStore.clusterRole                     metadata-store-read-write
   string  Name of the deployed ClusterRole for read/write access to the Insight M
   etadata Store deployed in the same cluster
   metadataStore.url                             https://metadata-store-app.metada
   ta-store.svc.cluster.local:8443  string  Url of the Insight Metadata Store
   namespace                                     default
   string  Deployment namespace for the Scan Templates
   resources.requests.cpu                        250m
   <nil>   Requests describes the minimum amount of cpu resources required.
   resources.requests.memory                     128Mi
   <nil>   Requests describes the minimum amount of memory resources required.
   ```

```
resources.limits.cpu                            1000m
<nil>   Limits describes the maximum amount of cpu resources allowed.
snyk.tokenSecret.name
string  Reference to the secret containing a Snyk API Token as snyk_token.
targetImagePullSecret
string  Reference to the secret used for pulling images from private registry.
```

6. Define the `--values-file` flag to customize the default configuration:

   The `values.yaml` file you created earlier is referenced with the `--values-file` flag when running your Tanzu install command:

   ```
   tanzu package install REFERENCE-NAME \
     --package SCANNER-NAME \
     --version VERSION \
     --namespace tap-install \
     --values-file PATH-TO-VALUES-YAML
   ```

   Where:

   - `REFERENCE-NAME` is the name referenced by the installed package. For example, `grype-scanner`, `snyk-scanner`.
   - `SCANNER-NAME` is the name of the scanner package you retrieved earlier. For example, `snyk.scanning.apps.tanzu.vmware.com`.
   - `VERSION` is your package version number. For example, `1.0.0-beta.2`.
   - `PATH-TO-VALUES-YAML` is the path that points to the `values.yaml` file created earlier.

   For example:

   ```
   $ tanzu package install snyk-scanner \
     --package snyk.scanning.apps.tanzu.vmware.com \
     --version 1.1.0 \
     --namespace tap-install \
     --values-file values.yaml
   / Installing package 'snyk.scanning.apps.tanzu.vmware.com'
   | Getting namespace 'tap-install'
   | Getting package metadata for 'snyk.scanning.apps.tanzu.vmware.com'
   | Creating service account 'snyk-scanner-tap-install-sa'
   | Creating cluster admin role 'snyk-scanner-tap-install-cluster-role'
   | Creating cluster role binding 'snyk-scanner-tap-install-cluster-rolebinding'
   / Creating package resource
   - Package install status: Reconciling

    Added installed package 'snyk-scanner' in namespace 'tap-install'
   ```

Verify Installation

To verify the installation create an `ImageScan` or `SourceScan` referencing one of the newly added `ScanTemplates` for the scanner.

1. (Optional) Create a `ScanPolicy` formatted for the output specific to the scanner you are installing, to reference in the `ImageScan` or `SourceScan`.

   ```
   kubectl apply -n $DEV_NAMESPACE -f SCAN-POLICY-YAML
   ```

   

   Note

   As vulnerability scanners output different formats, the `ScanPolicies` can vary. For information about policies and samples, see Enforce compliance

policy using Open Policy Agent.

2. Retrieve available `ScanTemplates` from the namespace where the scanner is installed:

```
kubectl get scantemplates -n DEV-NAMESPACE
```

Where `DEV-NAMESPACE` is the developer namespace where the scanner is installed.

For example:

```
$ kubectl get scantemplates
NAME                                AGE
blob-source-scan-template           10d
private-image-scan-template         10d
public-image-scan-template          10d
public-source-scan-template         10d
snyk-private-image-scan-template    10d
snyk-public-image-scan-template     10d
```

3. Create the following ImageScan YAML:

Note

Some scanners do not support both `ImageScan` and `SourceScan`.

```
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ImageScan
metadata:
  name: sample-scanner-public-image-scan
spec:
  registry:
    image: "nginx:1.16"
  scanTemplate: SCAN-TEMPLATE
  scanPolicy: SCAN-POLICY # Optional
```

Where:

- `SCAN-TEMPLATE` is the name of the installed `ScanTemplate` in the `DEV-NAMESPACE` you retrieved earlier.
- `SCAN-POLICY` it's an optional reference to an existing `ScanPolicy` in the same `DEV-NAMESPACE`.

For example:

```
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ImageScan
metadata:
  name: sample-snyk-public-image-scan
spec:
  registry:
    image: "nginx:1.16"
  scanTemplate: snyk-public-image-scan-template
  scanPolicy: snyk-scan-policy
```

4. Create the following SourceScan YAML:

Note

Some scanners do not support both `ImageScan` and `SourceScan`.

```
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: SourceScan
metadata:
  name: sample-scanner-public-source-scan
spec:
  git:
    url: "https://github.com/houndci/hound.git"
    revision: "5805c650"
  scanTemplate: SCAN-TEMPLATE
  scanPolicy: SCAN-POLICY # Optional
```

Where:

- `SCAN-TEMPLATE` is the name of the installed `ScanTemplate` in the `DEV-NAMESPACE` you retrieved earlier.
- `SCAN-POLICY` is an optional reference to an existing `ScanPolicy` in the same `DEV-NAMESPACE`.

For example:

```
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: SourceScan
metadata:
  name: sample-grype-public-source-scan
spec:
  git:
    url: "https://github.com/houndci/hound.git"
    revision: "5805c650"
  scanTemplate: public-source-scan-template
  scanPolicy: scan-policy
```

5. Apply the ImageScan and SourceScan YAMLs:

   To run the scans, apply them to the cluster by running these commands:

   `ImageScan`:

   ```
   kubectl apply -f PATH-TO-IMAGE-SCAN-YAML -n DEV-NAMESPACE
   ```

   Where `PATH-TO-IMAGE-SCAN-YAML` is the path to the YAML file created earlier.

   `SourceScan`:

   ```
   kubectl apply -f PATH-TO-SOURCE-SCAN-YAML -n DEV-NAMESPACE
   ```

   Where `PATH-TO-SOURCE-SCAN-YAML` is the path to the YAML file created earlier.

   For example:

   ```
   $ kubectl apply -f imagescan.yaml -n my-apps
   imagescan.scanning.apps.tanzu.vmware.com/sample-snyk-public-image-scan created

   $ kubectl apply -f sourcescan.yaml -n my-apps
   sourcescan.scanning.apps.tanzu.vmware.com/sample-grype-public-source-scan creat
   ed
   ```

6. To verify the integration, get the scan to see if it completed by running:

   For `ImageScan`:

```
kubectl get imagescan IMAGE-SCAN-NAME -n DEV-NAMESPACE
```

Where `IMAGE-SCAN-NAME` is the name of the `ImageScan` as defined in the YAML file created earlier.

For `SourceScan`:

```
kubectl get sourcescan SOURCE-SCAN-NAME -n DEV-NAMESPACE
```

Where `SOURCE-SCAN-NAME` is the name of the `SourceScan` as defined in the YAML file created earlier.

For example:

```
$ kubectl get imagescan sample-snyk-public-image-scan -n my-apps
NAME                              PHASE       SCANNEDIMAGE   AGE   CRITICAL   HIG
H   MEDIUM   LOW   UNKNOWN   CVETOTAL
sample-snyk-public-image-scan   Completed   nginx:1.16     26h   0          114
58       314   0         486

$ kubectl get sourcescan sample-grype-public-source-scan -n my-apps
NAME                                                                          PHASE
SCANNEDREVISION   SCANNEDREPOSITORY                        AGE     CRITICAL   HIG
H   MEDIUM   LOW   UNKNOWN   CVETOTAL
sourcescan.scanning.apps.tanzu.vmware.com/grypesourcescan-sample-public   Compl
eted   5805c650          https://github.com/houndci/hound.git   8m34s   21
121    112      9     0         263
```

Note

If you define a `ScanPolicy` for the scans and the evaluation finds a violation, the `Phase` is `Failed` instead of `Completed`. In both cases the scan finished.

7. Clean up:

```
kubectl delete -f PATH-TO-SCAN-YAML -n DEV-NAMESPACE
```

Where `PATH-TO-SCAN-YAML` is the path to the YAML file created earlier.

Install scanner to multiple namespaces

To install a Scanner to multiple namespaces, VMware recommends using a namespace provisioner. See Namespace Provisioner

Configure Tanzu Application Platform Supply Chain to use new scanner

In order to scan your images with the new scanner installed in the Out of the Box Supply Chain with Testing and Scanning, you must update your Tanzu Application Platform installation.

Add the `ootb_supply_chain_testing_scanning.scanning` section to your `tap-values.yaml` and perform a Tanzu Application Platform update.

You can define which `ScanTemplates` is used for both `SourceScan` and `ImageScan`. The default values are the Grype Scanner `ScanTemplates`, but they are overwritten by any other `ScanTemplate` present in your `DEV-NAMESPACE`. The same applies to the `ScanPolicies` applied to each kind of scan.

```
ootb_supply_chain_testing_scanning:
  scanning:
    image:
      template: IMAGE-SCAN-TEMPLATE
      policy: IMAGE-SCAN-POLICY
    source:
      template: SOURCE-SCAN-TEMPLATE
      policy: SOURCE-SCAN-POLICY
```

Note

For the Supply Chain to work properly, the `SOURCE-SCAN-TEMPLATE` must support blob files and the `IMAGE-SCAN-TEMPLATE` must support private images.

For example:

```
ootb_supply_chain_testing_scanning:
  scanning:
    image:
      template: snyk-private-image-scan-template
      policy: snyk-scan-policy
    source:
      template: blob-source-scan-template
      policy: scan-policy
```

Uninstall Scanner

To replace the scanner in the Supply Chain, follow the steps mentioned in Configure TAP Supply Chain to Use New Scanner. After the scanner is no longer required by the Supply Chain, you can remove the package by running:

```
tanzu package installed delete REFERENCE-NAME \
    --namespace tap-install
```

Where `REFERENCE-NAME` is the name you identified the package with, when installing in the Install section. For example, `grype-scanner`, `snyk-scanner`.

For example:

```
$ tanzu package installed delete snyk-scanner \
    --namespace tap-install
```

Other Available Scanner Integrations

In addition to providing the above supported integrations, VMware encourages the broader community to support VMware in our goal of integrating with customers' preferred CVE scanners.

Additional integrations:

- Prisma Scanner (Alpha) is available for source and image scanning.
- Trivy Scanner (Alpha) is available for source and image scanning.

Prerequisites for Snyk Scanner for Supply Chain Security Tools - Scan (Beta)

This topic describes the prerequisites you must complete to install Supply Chain Security Tools - Scan (Snyk Scanner) from the Tanzu Application Platform package repository.

Important

Snyk's image scanning capability is in beta. Snyk might only return a partial list of CVEs when scanning Buildpack images.

Prepare the Snyk Scanner configuration

1. Obtain a Snyk API Token from the Snyk documentation.
2. Create a Snyk secret YAML file and insert the base64 encoded Snyk API token into the `snyk_token`:

   ```
   apiVersion: v1
   kind: Secret
   metadata:
     name: snyk-token-secret
     namespace: my-apps
   data:
     snyk_token: BASE64-SNYK-API-TOKEN
   ```

   Where `BASE64-SNYK-API-TOKEN` is the Snyk API Token obtained earlier.
3. Apply the Snyk secret YAML file by running:

   ```
   kubectl apply -f YAML-FILE
   ```

   Where `YAML-FILE` is the name of the Snyk secret YAML file you created.
4. Define the `--values-file` flag to customize the default configuration. You must define the following fields in the `values.yaml` file for the Snyk Scanner configuration. You can add fields as needed to activate or deactivate behaviors. You can append the values to this file as shown later in this topic. Create a `values.yaml` file by using the following configuration:

   ```
   ---
   namespace: DEV-NAMESPACE
   targetImagePullSecret: TARGET-REGISTRY-CREDENTIALS-SECRET
   snyk:
     tokenSecret:
       name: SNYK-TOKEN-SECRET
   ```

   Where:

   - `DEV-NAMESPACE` is your developer namespace.

     

     Note

     To use a namespace other than the default namespace, ensure that the namespace exists before you install. If the namespace does not exist, the scanner installation fails.

   - `TARGET-REGISTRY-CREDENTIALS-SECRET` is the name of the secret that contains the credentials to pull an image from a private registry for scanning.
   - `SNYK-TOKEN-SECRET` is the name of the secret you created that contains the `snyk_token` to connect to the Snyk API. This field is required.

The Snyk Scanner integration can work with or without the SCST - Store integration. The `values.yaml` file is slightly different for each configuration.

SCST - Store integration

Using SCST - Store Integration: To persist the results found by the Snyk Scanner, you can enable the SCST - Store integration by appending the fields to the `values.yaml` file.

The Grype and Snyk Scanner Integrations both enable the Metadata Store. To prevent conflicts, the configuration values are slightly different based on whether the Grype Scanner Integration is installed or not. If Tanzu Application Platform is installed using the Full Profile, the Grype Scanner Integration is installed, unless it is explicitly excluded.

- If the Grype Scanner Integration is installed in the same `dev-namespace` Snyk Scanner is installed:

```
#! ...
metadataStore:
  #! The url where the Store deployment is accessible.
  #! Default value is: "https://metadata-store-app.metadata-store.svc.cluster.l
ocal:8443"
  url: "STORE-URL"
  caSecret:
    #! The name of the secret that contains the ca.crt to connect to the Store
Deployment.
    #! Default value is: "app-tls-cert"
    name: "CA-SECRET-NAME"
    importFromNamespace: "" #! since both Snyk and Grype both enable store, one
must leave importFromNamespace blank
  #! authSecret is for multicluster configurations.
  authSecret:
    #! The name of the secret that contains the auth token to authenticate to t
he Store Deployment.
    name: "AUTH-SECRET-NAME"
    importFromNamespace: "" #! since both Snyk and Grype both enable store, one
must leave importFromNamespace blank
```

- If the Grype Scanner Integration is not installed in the same `dev-namespace` Snyk Scanner is installed:

```
#! ...
metadataStore:
  #! The url where the Store deployment is accessible.
  #! Default value is: "https://metadata-store-app.metadata-store.svc.cluster.l
ocal:8443"
  url: "STORE-URL"
  caSecret:
    #! The name of the secret that contains the ca.crt to connect to the Store
Deployment.
    #! Default value is: "app-tls-cert"
    name: "CA-SECRET-NAME"
    #! The namespace where the secrets for the Store Deployment live.
    #! Default value is: "metadata-store"
    importFromNamespace: "STORE-SECRETS-NAMESPACE"
  #! authSecret is for multicluster configurations.
  authSecret:
    #! The name of the secret that contains the auth token to authenticate to t
he Store Deployment.
    name: "AUTH-SECRET-NAME"
    #! The namespace where the secrets for the Store Deployment live.
    importFromNamespace: "STORE-SECRETS-NAMESPACE"
```

Without SCST - Store Integration: The SCST - Store integration is enabled by default. If you don't want to use this integration, deactivate the integration by appending the following field to the `values.yaml` file:

```
# ...
metadataStore:
   url: "" # Configuration is moved, so set this string to empty.
```

Sample ScanPolicy for Snyk in SPDX JSON format

1. Create a ScanPolicy YAML with a Rego file for scanner output in the SPDX JSON format. Here is a sample scan policy resource:

```
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ScanPolicy
metadata:
  name: snyk-scan-policy
  labels:
    'app.kubernetes.io/part-of': 'enable-in-gui'
spec:
  regoFile: |
    package main

    # Accepted Values: "Critical", "High", "Medium", "Low", "Negligible", "Unkn
ownSeverity"
    notAllowedSeverities := ["Critical", "High", "UnknownSeverity"]
    ignoreCves := []

    contains(array, elem) = true {
      array[_] = elem
    } else = false { true }

    isSafe(match) {
      fails := contains(notAllowedSeverities, match.relationships[_].ratedBy.ra
ting[_].severity)
      not fails
    }

    isSafe(match) {
      ignore := contains(ignoreCves, match.id)
      ignore
    }

    deny[msg] {
      vuln := input.vulnerabilities[_]
      ratings := vuln.relationships[_].ratedBy.rating[_].severity
      comp := vuln.relationships[_].affect.to[_]
      not isSafe(vuln)
      msg = sprintf("CVE %s %s %s", [comp, vuln.id, ratings])
    }
```

2. Apply the YAML file by running:

```
kubectl apply -n $DEV_NAMESPACE -f SCAN-POLICY-YAML
```

Note

The Snyk Scanner integration is only available for an image scan, not a source scan.

After all prerequisites are completed, follow the steps in Install another scanner for Supply Chain Security Tools - Scan to install the Snyk Scanner.

Prerequisites for Carbon Black Scanner for Supply Chain Security Tools - Scan (Beta)

This topic describes prerequisites you must complete to install Supply Chain Security Tools - Scan (Carbon Black Scanner) from the Tanzu Application Platform package repository. The Carbon Black Scanner integration is only available for an image scan, not a source scan.

Important

Carbon Black's image scanning capability is in beta. Carbon Black might only return a partial list of CVEs when scanning Buildpack images.

Prepare the Carbon Black Scanner configuration

To prepare the Carbon Black Scanner configuration before you install any scanners:

1. Obtain a Carbon Black API Token from Carbon Black Cloud.
2. Create a Carbon Black secret YAML file and insert the Carbon Black API configuration key. Obtain all values from your CBC console.

   ```
   apiVersion: v1
   kind: Secret
   metadata:
     name: CARBONBLACK-CONFIG-SECRET
     namespace: my-apps
   stringData:
     cbc_api_id: CBC-API-ID
     cbc_api_key: CBC-API-KEY
     cbc_org_key: CBC-ORG-KEY
     cbc_saas_url: CBC-SAAS-URL
   ```

   Where:

   - `CBC-API-ID` is the API ID obtained from CBC.
   - `CBC-API-KEY` is the API Key obtained from CBC.
   - `CBC-ORG-KEY` is the Org Key of your CBC organization.
   - `CBC-SAAS-URL` is the CBC Backend URL.
3. Apply the Carbon Black secret YAML file by running:

   ```
   kubectl apply -f YAML-FILE
   ```

   Where `YAML-FILE` is the name of the Carbon Black secret YAML file you created.
4. Define the `--values-file` flag to customize the default configuration. Create a `values.yaml` file by using the following configuration:

   You must define the following fields in the `values.yaml` file for the Carbon Black Scanner configuration. You can add fields as needed to enable or deactivate behaviors. You can append the values to this file as shown later in this topic.

   ```
   ---
   namespace: DEV-NAMESPACE
   ```

```
targetImagePullSecret: TARGET-REGISTRY-CREDENTIALS-SECRET
carbonBlack:
  configSecret:
    name: CARBONBLACK-CONFIG-SECRET
```

- `DEV-NAMESPACE` is your developer namespace.

  

  Important

  To use a namespace other than the default namespace, ensure that the namespace exists before you install. If the namespace does not exist, the scanner installation fails.

- `TARGET-REGISTRY-CREDENTIALS-SECRET` is the name of the secret that contains the credentials to pull an image from a private registry for scanning.
- `CARBONBLACK-CONFIG-SECRET` is the name of the secret you created that contains the Carbon Black configuration to connect to CBC. This field is required.

The Carbon Black Scanner integration can work with or without the SCST - Store integration. The `values.yaml` file is slightly different for each configuration.

SCST - Store integration

To Integrate:

1. Do one of the following procedures:
   - Use the Supply Chain Security Tools - Store
   - Without using the Supply Chain Security Tools - Store
2. Apply the YAML.

Using SCST - Store Integration

To persist the results found by the Carbon Black Scanner, you can enable the SCST - Store integration by appending the fields to the `values.yaml` file.

The Grype and Carbon Black Scanner Integrations both enable the Metadata Store. To prevent conflicts, the configuration values are slightly different based on whether the Grype Scanner Integration is installed or not. If Tanzu Application Platform was installed using the Full Profile, the Grype Scanner Integration was installed, unless it was explicitly excluded.

- If the Grype Scanner Integration is installed in the same `dev-namespace` Carbon Black Scanner is installed:

```
#! ...
metadataStore:
  #! The url where the Store deployment is accessible.
  #! Default value is: "https://metadata-store-app.metadata-store.svc.cluster.l
ocal:8443"
  url: "STORE-URL"
  caSecret:
    #! The name of the secret that contains the ca.crt to connect to the Store
Deployment.
    #! Default value is: "app-tls-cert"
    name: "CA-SECRET-NAME"
    importFromNamespace: "" #! since both Carbon Black and Grype both enable st
ore, one must leave importFromNamespace blank
  #! authSecret is for multicluster configurations.
  authSecret:
```

```
    #! The name of the secret that contains the auth token to authenticate to t
he Store Deployment.
    name: "AUTH-SECRET-NAME"
    importFromNamespace: "" #! since both Carbon Black and Grype both enable st
ore, one must leave importFromNamespace blank
```

- If the Grype Scanner Integration is not installed in the same `dev-namespace` Carbon Black Scanner is installed:

```
#! ...
metadataStore:
  #! The url where the Store deployment is accessible.
  #! Default value is: "https://metadata-store-app.metadata-store.svc.cluster.l
ocal:8443"
  url: "STORE-URL"
  caSecret:
    #! The name of the secret that contains the ca.crt to connect to the Store
Deployment.
    #! Default value is: "app-tls-cert"
    name: "CA-SECRET-NAME"
    #! The namespace where the secrets for the Store Deployment live.
    #! Default value is: "metadata-store"
    importFromNamespace: "STORE-SECRETS-NAMESPACE"
  #! authSecret is for multicluster configurations.
  authSecret:
    #! The name of the secret that contains the auth token to authenticate to t
he Store Deployment.
    name: "AUTH-SECRET-NAME"
    #! The namespace where the secrets for the Store Deployment live.
    importFromNamespace: "STORE-SECRETS-NAMESPACE"
```

Without SCST - Store Integration

The SCST - Store integration is enabled by default. If you don't want to use this integration, explicitly deactivate the integration by appending the following field to the `values.yaml` file:

```
# ...
metadataStore:
  url: "" # Disable Supply Chain Security Tools - Store integration
```

Sample ScanPolicy in CycloneDX format

1. Create a ScanPolicy YAML with a Rego file for scanner output in the CycloneDX format. For example:

```
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ScanPolicy
metadata:
  name: scan-policy
  labels:
    'app.kubernetes.io/part-of': 'enable-in-gui'
spec:
  regoFile: |
    package main

    # Accepted Values: "Critical", "High", "Medium", "Low", "Negligible", "Unkn
ownSeverity"
    notAllowedSeverities := ["Critical", "High", "UnknownSeverity"]
    ignoreCves := []

    contains(array, elem) = true {
      array[_] = elem
```

```
    } else = false { true }

    isSafe(match) {
      severities := { e | e := match.ratings.rating.severity } | { e | e := mat
ch.ratings.rating[_].severity }
      some i
      fails := contains(notAllowedSeverities, severities[i])
      not fails
    }

    isSafe(match) {
      ignore := contains(ignoreCves, match.id)
      ignore
    }

    deny[msg] {
      comps := { e | e := input.bom.components.component } | { e | e := input.b
om.components.component[_] }
      some i
      comp := comps[i]
      vulns := { e | e := comp.vulnerabilities.vulnerability } | { e | e := com
p.vulnerabilities.vulnerability[_] }
      some j
      vuln := vulns[j]
      ratings := { e | e := vuln.ratings.rating.severity } | { e | e := vuln.ra
tings.rating[_].severity }
      not isSafe(vuln)
      msg = sprintf("CVE %s %s %s", [comp.name, vuln.id, ratings])
    }
```

2. Apply the YAML:

```
kubectl apply -n $DEV_NAMESPACE -f SCAN-POLICY-YAML
```

After you complete all prerequisites, install the Carbon Black Scanner. See Install another scanner for Supply Chain Security Tools - Scan.

Prerequisites for Prisma Scanner for Supply Chain Security Tools - Scan (Alpha)

This topic describes prerequisites you must complete to install SCST - Scan (Prisma) from the VMware package repository.

Important

This integration is in Alpha, which means that it is still in active development by the Tanzu Practices Global Tech Team and might be subject to change at any point. Users might encounter unexpected behavior.

Verify the latest alpha package version

Run this command to output a list of available tags.

```
imgpkg tag list -i projects.registry.vmware.com/tanzu_practice/tap-scanners-package/pr
isma-repo-scanning-bundle | sort -V
```

Use the latest version returned in place of the sample version in this topic. For example, `0.1.5-alpha.13` in the following output.

```
imgpkg tag list -i projects.registry.vmware.com/tanzu_practice/tap-scanners-package/pr
isma-repo-scanning-bundle | sort -V
0.1.4-alpha.11
0.1.4-alpha.12
0.1.4-alpha.15
0.1.5-alpha.11
0.1.5-alpha.12
0.1.5-alpha.13
```

Relocate images to a registry

VMware recommends relocating the images from VMware Tanzu Network registry to your own container image registry before installing. The Prisma Scanner is in the Alpha development phase, and not packaged as part of Tanzu Application Platform. It is hosted on the VMware Project Repository instead of VMware Tanzu Network. If you relocated the Tanzu Application Platform images, you can also relocate the Prisma Scanner package. If you don't relocate the images, the Prisma Scanner installation depends on VMware Tanzu Network for continued operation, and VMware Tanzu Network offers no uptime guarantees. The option to skip relocation is documented for evaluation and proof-of-concept only.

For information about supported registries, see each registry's documentation.

To relocate images from the VMware Project Registry to your registry:

1. Set up environment variables for installation:

   ```
   export IMGPKG_REGISTRY_HOSTNAME_0=registry.tanzu.vmware.com
   export IMGPKG_REGISTRY_USERNAME_0=MY-TANZUNET-USERNAME
   export IMGPKG_REGISTRY_PASSWORD_0=MY-TANZUNET-PASSWORD
   export INSTALL_REGISTRY_USERNAME=MY-REGISTRY-USER
   export INSTALL_REGISTRY_PASSWORD=MY-REGISTRY-PASSWORD
   export INSTALL_REGISTRY_HOSTNAME=MY-REGISTRY
   export VERSION=VERSION-NUMBER
   export INSTALL_REPO=TARGET-REPOSITORY
   ```

   Where:

   - `MY-REGISTRY-USER` is the user with write access to MY-REGISTRY.
   - `MY-REGISTRY-PASSWORD` is the password for `MY-REGISTRY-USER`.
   - `MY-REGISTRY` is your own registry.
   - `VERSION` is your Prisma Scanner version. For example, `0.1.4-alpha.12`.
   - `TARGET-REPOSITORY` is your target repository, a directory or repository on `MY-REGISTRY` that serves as the location for the installation files for Prisma Scanner.

2. Install the Carvel tool imgpkg CLI. See Deploying Cluster Essentials.
3. Relocate images with the imgpkg CLI by running:

   ```
   imgpkg copy -b projects.registry.vmware.com/tanzu_practice/tap-scanners-packag
   e/prisma-repo-scanning-bundle:${VERSION} --to-repo ${INSTALL_REGISTRY_HOSTNAM
   E}/${INSTALL_REPO}/prisma-repo-scanning-bundle
   ```

Add the Prisma Scanner package repository

Tanzu CLI packages are available on repositories. Adding the Prisma Scanning package repository makes the Prisma Scanning bundle and its packages available for installation.

Note

VMware recommends, but does not require, relocating images to a registry for installation. This section assumes that you relocated images to a registry. See the earlier section to fill in the variables.

VMware recommends installing the Prisma Scanner objects in the existing `tap-install` namespace to keep the Prisma Scanner grouped logically with the other Tanzu Application Platform components.

1. Add the Prisma Scanner package repository to the cluster by running:

```
tanzu package repository add prisma-scanner-repository \
  --url ${INSTALL_REGISTRY_HOSTNAME}/${INSTALL_REPO}/prisma-repo-scanning-bundl
e:$VERSION \
  --namespace tap-install
```

2. Get the status of the Prisma Scanner package repository, and ensure that the status updates to `Reconcile succeeded` by running:

```
tanzu package repository get prisma-scanner-repository --namespace tap-install
```

For example:

```
$ tanzu package repository get prisma-scanning-repository --namespace tap-insta
ll
- Retrieving repository prisma-scanner-repository...
NAME:          prisma-scanner-repository
VERSION:       71091125
REPOSITORY:    projects.registry.vmware.com/tanzu_practice/tap-scanners-packag
e/prisma-repo-scanning-bundle
TAG:           0.1.4-alpha.12
STATUS:        Reconcile succeeded
REASON:
```

3. List the available packages by running:

```
tanzu package available list --namespace tap-install
```

For example:

```
$ tanzu package available list --namespace tap-install
/ Retrieving available packages...
  NAME                                                DISPLAY-NAME
SHORT-DESCRIPTION
  prisma.scanning.apps.tanzu.vmware.com               Prisma for Supply Chain
Security Tools - Scan                              Default scan templates using
Prisma
```

Prepare the Prisma Scanner configuration

Before installing the Prisma scanner, you must create the configuration and a Kubernetes secret that contains credentials to access Prisma Cloud.

Obtain Console URL and Access Keys and Token

The Prisma Scanner supports two methods of authentication:

1) Basic Authentication with API Key and Secret 2) Token Based Authentication

The steps to configure both are outlined to allow you to decide which option you use.

> **Note**
>
> The token method issued by Prisma Cloud has a expiration of 1 hour, so it requires frequent refreshing.

To obtain your Prisma Compute Console URL and Access Keys and Token. See Access keys in the Palo Alto Networks documentation.

> **Note**
>
> Generated tokens expire after an hour.

Access key and secret authentication

To create a Prisma secret, use the following instructions.

1. Create a Prisma secret YAML file and insert the base64 encoded Prisma API token into the `prisma_token`:

   ```
   apiVersion: v1
   kind: Secret
   metadata:
     name: PRISMA-ACCESS-KEY-SECRET
     namespace: APP-NAME
   data:
     username: BASE64-PRISMA-ACCESS-KEY-ID
     password: BASE64-PRISMA-ACCESS-KEY-PASSWORD
   ```

   Where:

   - `PRISMA-ACCESS-KEY-SECRET` is the name of your Prisma token secret.
   - `APP-NAME` is the namespace you want to use.
   - `BASE64-PRISMA-ACCESS-KEY-ID` is your base64 encoded Prisma Access Key ID.
   - `BASE64-PRISMA-ACCESS-KEY-PASSWORD` is your base64 encoded Prisma Access Key Password.

2. Apply the Prisma secret YAML file by running:

   ```
   kubectl apply -f YAML-FILE
   ```

   Where `YAML-FILE` is the name of the Prisma secret YAML file you created.

3. Define the `--values-file` flag to customize the default configuration. You must define the following fields in the `values.yaml` file for the Prisma Scanner configuration. You can add fields to activate or deactivate behaviors. You can append the values to this file as shown later in this topic. Create a `values.yaml` file by using the following configuration:

   ```
   ---
   namespace: DEV-NAMESPACE
   targetImagePullSecret: TARGET-REGISTRY-CREDENTIALS-SECRET
   prisma:
     url: PRISMA-URL
   ```

```
  basicAuth:
    name: PRISMA-ACCESS-KEY-SECRET
```

Where:

- `DEV-NAMESPACE` is your developer namespace.

> **Note**
>
> To use a namespace other than the default namespace, ensure that the namespace exists before you install. If the namespace does not exist, the scanner installation fails.

- `TARGET-REGISTRY-CREDENTIALS-SECRET` is the name of the secret that contains the credentials to pull an image from a private registry for scanning.
- `PRISMA-URL` is the FQDN of your Twistlock server.
- `PRISMA-CONFIG-SECRET` is the name of the secret you created that contains the Prisma configuration to connect to Prisma. This field is required.

The Prisma integration can work with or without the SCST - Store integration. The `values.yaml` file is slightly different for each configuration.

Access Token Authentication

1. Create a Prisma secret YAML file and insert the base64 encoded Prisma API token into the `prisma_token`:

   ```
   apiVersion: v1
   kind: Secret
   metadata:
     name: PRISMA-TOKEN-SECRET
     namespace: APP-NAME
   data:
     prisma_token: BASE64-PRISMA-API-TOKEN
   ```

   Where:

   - `PRISMA-TOKEN-SECRET` is the name of your Prisma token secret.
   - `APP-NAME` is the namespace you want to use.
   - `BASE64-PRISMA-API-TOKEN` is the name of your base64 encoded Prisma API token.

2. Apply the Prisma secret YAML file by running:

   ```
   kubectl apply -f YAML-FILE
   ```

   Where `YAML-FILE` is the name of the Prisma secret YAML file you created.

3. Define the `--values-file` flag to customize the default configuration. You must define the following fields in the `values.yaml` file for the Prisma Scanner configuration. You can add fields as needed to activate or deactivate behaviors. You can append the values to this file as shown later in this topic. Create a `values.yaml` file by using the following configuration:

   ```
   ---
   namespace: DEV-NAMESPACE
   targetImagePullSecret: TARGET-REGISTRY-CREDENTIALS-SECRET
   prisma:
     url: PRISMA-URL
   ```

```
  tokenSecret:
    name: PRISMA-CONFIG-SECRET
```

Where:

- `DEV-NAMESPACE` is your developer namespace.

> **Note**
>
> To use a namespace other than the default namespace, ensure that the namespace exists before you install. If the namespace does not exist, the scanner installation fails.

- `TARGET-REGISTRY-CREDENTIALS-SECRET` is the name of the secret that contains the credentials to pull an image from a private registry for scanning.
- `PRISMA-URL` is the FQDN of your Twistlock server.
- `PRISMA-CONFIG-SECRET` is the name of the secret you created that contains the Prisma configuration to connect to Prisma. This field is required.

SCST - Store integration

The Prisma Scanner integration can work with or without the SCST - Store integration. The `values.yaml` file is slightly different for each configuration.

When using SCST - Store integration, to persist the results found by the Prisma Scanner, you can enable the SCST - Store integration by appending the fields to the `values.yaml` file.

The Grype, Snyk, and Prisma Scanner Integrations enable the Metadata Store. To prevent conflicts, the configuration values are slightly different based on whether the Grype Scanner Integration is installed or not. If Tanzu Application Platform is installed using the Full Profile, the Grype Scanner Integration is installed unless it is explicitly excluded.

Multiple Scanners installed

In order to find your CA secret name and authentication token secret name as needed for your values.yaml when installing Prisma Scanner you must look at the configuration of a prior installed scanner in the same namespace as it already exists.

For information about how the scanner was likely initially created, see Set up multicluster Supply Chain Security Tools (SCST) - Store

An example `values.yaml` when there are other scanners already installed in the same `dev-namespace` where the Prisma Scanner is installed:

```
#! ...
metadataStore:
  #! The url where the Store deployment is accessible.
  #! Default value is: "https://metadata-store-app.metadata-store.svc.cluster.local:8443"
  url: "STORE-URL"
  caSecret:
    #! The name of the secret that contains the ca.crt to connect to the Store Deployment.
    #! Default value is: "app-tls-cert"
    name: "CA-SECRET-NAME"
    importFromNamespace: "" #! since both Prisma and Grype/Snyk both enable store, one must leave importFromNamespace blank
  #! authSecret is for multicluster configurations.
  authSecret:
```

```
    #! The name of the secret that contains the auth token to authenticate to the Stor
e Deployment.
    name: "AUTH-SECRET-NAME"
    importFromNamespace: "" #! since both Prisma and Grype/Snyk both enable store, one
must leave importFromNamespace blank
```

Where:

- `STORE-URL` is the URL where the Store deployment is accessible.
- `CA-SECRET-NAME` is the name of the secret that contains the ca.crt to connect to the Store Deployment. Default is `app-tls-cert`.
- `AUTH-SECRET-NAME` is the name of the secret that contains the authentication token to authenticate to the Store Deployment.

Prisma Only Scanner Installed

For information about creating and exporting secrets for the Metadata Store CA and authentication token referenced in the data values when installing Prisma Scanner, see Set up multicluster Supply Chain Security Tools (SCST) - Store.

An example `values.yaml` when no other scanner integrations installed in the same `dev-namespace` where the Prisma Scanner is installed:

```
#! ...
metadataStore:
  #! The url where the Store deployment is accessible.
  #! Default value is: "https://metadata-store-app.metadata-store.svc.cluster.local:84
43"
  url: "STORE-URL"
  caSecret:
    #! The name of the secret that contains the ca.crt to connect to the Store Deploym
ent.
    #! Default value is: "app-tls-cert"
    name: "CA-SECRET-NAME"
    #! The namespace where the secrets for the Store Deployment live.
    #! Default value is: "metadata-store"
    importFromNamespace: "STORE-SECRETS-NAMESPACE"
  #! authSecret is for multicluster configurations.
  authSecret:
    #! The name of the secret that contains the auth token to authenticate to the Stor
e Deployment.
    name: "AUTH-SECRET-NAME"
    #! The namespace where the secrets for the Store Deployment live.
    importFromNamespace: "STORE-SECRETS-NAMESPACE"
```

Where:

- `STORE-URL` is the URL where the Store deployment is accessible.
- `CA-SECRET-NAME` is the name of the secret that contains the `ca.crt` to connect to the Store Deployment. Default is `app-tls-cert`.
- `STORE-SECRETS-NAMESPACE` is the namespace where the secrets for the Store Deployment live. Default is `metadata-store`.
- `AUTH-SECRET-NAME` is the name of the secret that contains the authentication token to authenticate to the Store Deployment.

No Store Integration

If you do not want to enable the SCST - Store integration, explicitly deactivate the integration by appending the following field to the `values.yaml` file that is enabled by default:

```
# ...
metadataStore:
  url: "" # Deactivate Supply Chain Security Tools - Store integration
```

Prepare the ScanPolicy

To prepare the ScanPolicy, use the instructions in the following sections.

Sample ScanPolicy using Prisma Policies

The following sample ScanPolicy allows you to control whether the SupplyChain passes or fails based on the compliance and vulnerability rules configured in the Prisma Compute Console.

The policy reads the `complianceScanPassed` and `vulnerabilityScanPassed` fields returned from Prisma scanner output to control the results of the scan.

```
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ScanPolicy
metadata:
  name: prisma-scan-policy
  labels:
    'app.kubernetes.io/part-of': 'enable-in-gui'
spec:
  regoFile: |
    package main

    import future.keywords.in

    deny[msg] {
      vulnerabilityAndComplianceScanResults := {e | e := input.bom.metadata.propertie
s.property[_]}
      some result in vulnerabilityAndComplianceScanResults
      failedScans:= "false" in result
      failedScans
      vulnerabilityMessages := { message |
        components := {e | e := input.bom.components.component} | {e | e := input.bom.
components.component[_]}
        some component in components
        vulnerabilities := {e | e := component.vulnerabilities.vulnerability} | {e | e
:= component.vulnerabilities.vulnerability[_]}
        some vulnerability in vulnerabilities
        ratings := {e | e := vulnerability.ratings.rating.severity} | {e | e := vulner
ability.ratings.rating[_].severity}
        formattedRatings := concat(", ", ratings)
        message := sprintf("Vulnerability - Component: %s CVE: %s Severity: %s", [comp
onent.name, vulnerability.id, formattedRatings])
      }
      complianceMessages := { message |
        compliances := {e | e := input.bom.metadata.component.compliances.compliance}
| {e | e := input.bom.metadata.component.compliances.compliance[_]}
        some compliance in compliances
        message := sprintf("Compliance - %s \\nId: %s Severity: %s Category: %s", [com
pliance.title, compliance.id, compliance.severity, compliance.category])
      }
      combinedMessages := complianceMessages | vulnerabilityMessages
      some message in combinedMessages
      msg := message
    }
```

Sample ScanPolicy using Local Policies

The following sample ScanPolicy allows you to control whether the SupplyChain passes or fails based on the Prisma Scanner CycloneDX vulnerability results returned from the Prisma Scanner.

```
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ScanPolicy
metadata:
  name: prisma-scan-policy
  labels:
    'app.kubernetes.io/part-of': 'enable-in-gui'
spec:
  regoFile: |
    package main

    # Accepted Values: "Critical", "High", "Medium", "Low", "Negligible", "UnknownSeve
rity"
    notAllowedSeverities := ["Critical", "High", "UnknownSeverity"]
    ignoreCves := []

    contains(array, elem) = true {
      array[_] = elem
    } else = false { true }

    isSafe(match) {
      severities := { e | e := match.ratings.rating.severity } | { e | e := match.rati
ngs.rating[_].severity }
      some i
      fails := contains(notAllowedSeverities, severities[i])
      not fails
    }

    isSafe(match) {
      ignore := contains(ignoreCves, match.id)
      ignore
    }

    deny[msg] {
      comps := { e | e := input.bom.components.component } | { e | e := input.bom.comp
onents.component[_] }
      some i
      comp := comps[i]
      vulns := { e | e := comp.vulnerabilities.vulnerability } | { e | e := comp.vulne
rabilities.vulnerability[_] }
      some j
      vuln := vulns[j]
      ratings := { e | e := vuln.ratings.rating.severity } | { e | e := vuln.ratings.r
ating[_].severity }
      not isSafe(vuln)
      msg = sprintf("CVE %s %s %s", [comp.name, vuln.id, ratings])
    }
```

Apply the YAML:

```
kubectl apply -n $DEV-NAMESPACE -f SCAN-POLICY-YAML
```

Where:

- `DEV-NAMESPACE` is the name of the developer namespace you want to use.
- `SCAN-POLICY-YAML` is the name of your SCST - Scan YAML.

Install Prisma Scanner

After all prerequisites are completed, install the Prisma Scanner. See Install another scanner for Supply Chain Security Tools - Scan.

Self-Signed Registry Certificate

When attempting to pull an image from a registry with a self-signed certificate during image scans additional configuration is necessary.

Tanzu Application Platform Values Shared CA

If your `tap-values.yaml` used during install has the following shared section filled out, Prisma Scanner uses this and enable it to connect to your registry without additional configuration.

```
shared:
   ca_cert_data: | # To be passed if using custom certificates.
      -----BEGIN CERTIFICATE-----
      MIIFXzCCA0egAwIBAgIJAJYm37SFocjlMA0GCSqGSIb3DQEBDQUAMEY...
      -----END CERTIFICATE-----
```

Secret within Developer Namespace

1. Create a secret that holds the registry's CA certificate data.

   An example of the secret:

   ```
   apiVersion: v1
   kind: Secret
   metadata:
    name: prisma-registry-cert
    namespace: dev
   type: Opaque
   data:
    ca_cert_data: BASE64_CERT
   ```

2. Update your Prisma Scanner install values.yaml.

   Add `caCertSecret` to the root of your `prisma-values.yaml` when installing Prisma Scanner

   Example:

   ```
   namespace: dev
   targetImagePullSecret: tap-registry
   caCertSecret: prisma-registry-cert
   ```

Connect to Prisma through a Proxy

To connect to Prisma through a proxy, you must add `environmentVariables` configuration to your `prisma-values.yaml`.

Note All valid container `env` configurations are supported.

For example:

```
namespace: dev
targetImagePullSecret: tap-registry
environmentVariables:
- name: HTTP_PROXY
  value: "test.proxy.com"
- name: HTTPS_PROXY
  value: "test.proxy.com"
- name: NO_PROXY
  value: "127.0.0.1,.svc,.svc.cluster.local,demo.app"
```

Known Limits

- OpenShift is not supported

Install Trivy for Supply Chain Security Tools - Scan (alpha)

This topic describes how you can install SCST - Scan (Trivy) from the VMware package repository.

Important

This integration is in Alpha, which means that it is still in active development by the Tanzu Practice Global Tech Team and might be subject to change at any point. Users might encounter unexpected behavior.

Verify the latest alpha package version

Run the following command to output a list of available tags.

```
imgpkg tag list -i projects.registry.vmware.com/tanzu_practice/tap-scanners-package/tr
ivy-repo-scanning-bundle | sort -V
```

For example:

```
imgpkg tag list -i projects.registry.vmware.com/tanzu_practice/tap-scanners-package/tr
ivy-repo-scanning-bundle | sort -V

0.1.0-alpha.19
0.1.4-alpha.1
0.1.4-alpha.3
0.1.4-alpha.5
0.1.4-alpha.6
0.1.4-alpha.7
0.1.4-alpha.9
0.1.4-alpha.10
0.1.4-alpha.11
0.1.5-alpha.1
0.1.5-alpha.2
0.1.5-alpha.3
0.1.6-alpha.1
0.1.6-alpha.2
0.1.6-alpha.4
0.1.6-alpha.6
0.1.6-alpha.7
0.1.7-alpha.1
```

Use the latest alpha version available for your version of the Tanzu Application Platform.

For example, given the output above, if you are using TAP 1.4, use `0.1.4-alpha.11`. If you are using TAP 1.7, use `0.1.7-alpha.1`.

Relocate images to a registry

VMware recommends relocating the images from VMware Tanzu Network registry to your own container image registry before installing.

Trivy is in the Alpha development phase, is not packaged as part of the Tanzu Application Platform package, and is hosted on the VMware Project Repository instead of VMware Tanzu Network. If

you relocated the Tanzu Application Platform images, you might also want to relocate the Trivy package.

If you don't relocate the images, Trivy installation depends on VMware Tanzu Network for continued operation, and VMware Tanzu Network offers no uptime guarantees. The option to skip relocation is documented for evaluation and proof-of-concept only.

For information about supported registries, see the registry's documentation.

To relocate images from the VMware Project Registry to your registry:

1. Install Docker if it is not already installed.
2. Set up environment variables for installation by running:

   ```
   export INSTALL_REGISTRY_USERNAME=MY-REGISTRY-USER
   export INSTALL_REGISTRY_PASSWORD=MY-REGISTRY-PASSWORD
   export INSTALL_REGISTRY_HOSTNAME=MY-REGISTRY
   export VERSION=VERSION-NUMBER
   export INSTALL_REPO=TARGET-REPOSITORY
   ```

   Where:

   - `MY-REGISTRY-USER` is the user with write access to MY-REGISTRY.
   - `MY-REGISTRY-PASSWORD` is the password for `MY-REGISTRY-USER`.
   - `MY-REGISTRY` is your own registry.
   - `VERSION` is your Trivy version. For example, `0.1.4-alpha.6`.
   - `TARGET-REPOSITORY` is your target repository, a directory or repository on `MY-REGISTRY` that serves as the location for the installation files for Trivy.
3. Install the Carvel tool imgpkg CLI. See Deploying Cluster Essentials.
4. Relocate the images with the imgpkg CLI by running:

   ```
   imgpkg copy -b projects.registry.vmware.com/tanzu_practice/tap-scanners-packag
   e/trivy-repo-scanning-bundle:${VERSION} --to-repo ${INSTALL_REGISTRY_HOSTNAME}/
   ${INSTALL_REPO}/trivy-repo-scanning-bundle
   ```

Note

The VMware project repository does not require authentication, so you don't need to perform a Docker login.

Add Trivy package repository

Tanzu CLI packages are available on repositories. Adding the Trivy scanning package repository makes the Trivy scanning bundle and its packages available for installation.

Note

VMware recommends, but does not require, relocating images to a registry for installation. The following section requires that you relocated images to a registry. See the earlier section to fill in the variables.

VMware recommends installing Trivy objects in the existing `tap-install` namespace to keep Trivy grouped logically with the other Tanzu Application Platform components.

1. Add Trivy package repository to the cluster by running:

```
tanzu package repository add trivy-scanner-repository \
--url ${INSTALL_REGISTRY_HOSTNAME}/${INSTALL_REPO}/trivy-repo-scanning-bundl
e:$VERSION \
--namespace tap-install
```

2. Get the status of Trivy package repository, and ensure that the status updates to `Reconcile succeeded` by running:

```
tanzu package repository get trivy-scanner-repository --namespace tap-install
```

For example:

```
tanzu package repository get trivy-scanner-repository --namespace tap-install

NAME:          trivy-scanner-repository
VERSION:       7750726
REPOSITORY:    projects.registry.vmware.com/tanzu_practice/tap-scanners-packag
e/trivy-repo-scanning-bundle
TAG:           0.1.4-alpha.6
STATUS:        Reconcile succeeded
REASON:
```

3. List the available packages by running:

```
tanzu package available list --namespace tap-install
```

For example:

```
$ tanzu package available list --namespace tap-install
/ Retrieving available packages...
NAME                                                DISPLAY-NAME
SHORT-DESCRIPTION
trivy.scanning.apps.tanzu.vmware.com                  trivy
Default scan templates using Trivy
```

Prepare Trivy configuration

Before installing the Trivy, you must create the configuration necessary to install Trivy.

1. Define the `--values-file` flag to customize the default configuration. You must define the following fields in the `values.yaml` file for the Trivy Scanner configuration. You can add fields as needed to activate or deactivate behaviors. You can append the values to the `values.yaml` file. Create a `values.yaml` file by using the following configuration:

```
---
namespace: DEV-NAMESPACE
targetImagePullSecret: TARGET-REGISTRY-CREDENTIALS-SECRET
targetSourceSshSecret: TARGET-SOURCE-SSH-SECRET
```

Where:

- `DEV-NAMESPACE` is your developer namespace.

Note

> To use a namespace other than the default namespace, ensure that the namespace exists before you install. If the namespace does not exist, the scanner installation fails.

- `TARGET-REGISTRY-CREDENTIALS-SECRET` is the name of the secret that contains the credentials to pull an image from a private registry for scanning.
- `TARGET-SOURCE-SSH-SECRET` is the name of the secret containing SSH credentials for cloning private repositories

2. To see all available values, run the following command using the version that you want:

```
VERSION="0.1.4-alpha.6"
tanzu package available get trivy.scanning.apps.tanzu.vmware.com/$VERSION --val
ues-schema -n tap-install
```

Example output:

```
KEY                                          DEFAULT
TYPE    DESCRIPTION
environmentVariables                         <nil>
<nil>   Environment Variables you want added to the scan container to impact tr
ivy behavior
resources.limits.cpu                         1000m
string  Limits describes the maximum amount of cpu resources allowed.
resources.requests.cpu                       250m
string  Requests describes the minimum amount of cpu resources required.
resources.requests.memory                    128Mi
string  Requests describes the minimum amount of memory resources
scanner.docker.server
string  <nil>
scanner.docker.username
string  <nil>
scanner.docker.password
string  <nil>
scanner.pullSecret
string  <nil>
scanner.serviceAccount                       trivy-scanner
string  Name of scan pod's service ServiceAccount
scanner.serviceAccountAnnotations            <nil>
<nil>   Annotations added to ServiceAccount
trivy.cli.image.additionalArguments
string  additional arguments to be appended to the image scan command
trivy.cli.plugins.aqua.repositoryUrl
string  location of the aqua plugin tar in an OCI registry to be used in place
of the embedded version
trivy.cli.repositoryUrl
string  location of the CLI tar in an OCI registry to be used in place of the e
mbedded version
trivy.cli.source.additionalArguments
string  additional arguments to be appended to the fs scan command
trivy.db.repositoryUrl
string  location of the vulnerability database in an OCI registry to be used as
the download location prior to running a scan
caCertSecret
string  Reference to the secret containing the registry ca cert set as ca_cert_
data
metadataStore.authSecret.importFromNamespace
string  Namespace from which to import the Insight Metadata Store auth_token
metadataStore.authSecret.name
string  Name of deployed Secret with key auth_token
metadataStore.caSecret.importFromNamespace    metadata-store
string  Namespace from which to import the Insight Metadata Store CA Cert
```

```
metadataStore.caSecret.name                    app-tls-cert
string  Name of deployed Secret with key ca.crt holding the CA Cert of the Insi
ght Metadata Store
metadataStore.clusterRole                      metadata-store-read-write
string  Name of the deployed ClusterRole for read/write access to the Insight M
etadata Store deployed in the same cluster
metadataStore.url                              https://metadata-store-app.metada
ta-store.svc.cluster.local:8443  string  Url of the Insight Metadata Store
namespace                                      default
string  Deployment namespace for the Scan Templates
targetImagePullSecret
string  Reference to the secret used for pulling images from private registry
targetSourceSshSecret
string  Reference to the secret containing SSH credentials for cloning private
repositories
```

SCST - Store integration

Trivy integration can work with or without the SCST - Store integration. The `values.yaml` file is slightly different for each configuration.

To persist the results found by the Trivy, enable the SCST - Store integration by appending the SCST- scan fields to Trivy`values.yaml` file.

The Grype, Snyk, Prisma, Carbon Black, and Trivy integrations enable the Metadata Store. To prevent conflicts, the configuration values are slightly different based on whether another scanner integration is installed or not. If Tanzu Application Platform is installed using the Full Profile, the Grype Scanner Integration is installed unless it is explicitly excluded.

Multiple scanners installed

When installing Trivy, find your CA secret name and authentication token secret name for your `values.yaml` ny looking at the configuration of a prior installed scanner in the same namespace as it already exists.

For information about how the scanner was initially created, see Set up multicluster Supply Chain Security Tools (SCST) - Store.

The following example `values.yaml` has other scanners already installed in the same `dev-namespace` where Trivy is installed:

```
#! ...
metadataStore:
  #! The url where the Store deployment is accessible.
  #! Default value is: "https://metadata-store-app.metadata-store.svc.cluster.local:84
43"
  url: "STORE-URL"
  caSecret:
    #! The name of the secret that contains the ca.crt to connect to the Store Deploym
ent.
    #! Default value is: "app-tls-cert"
    name: "CA-SECRET-NAME"
    importFromNamespace: "" #! since both Trivy and Grype/Snyk both enable store, one
must leave importFromNamespace blank
  #! authSecret is for multicluster configurations.
  authSecret:
    #! The name of the secret that contains the auth token to authenticate to the Stor
e Deployment.
    name: "AUTH-SECRET-NAME"
    importFromNamespace: "" #! since both Trivy and Grype/Snyk both enable store, one
must leave importFromNamespace blank
```

Where:

- `STORE-URL` is the URL where the Store deployment is accessible.
- `CA-SECRET-NAME` is the name of the secret that contains the ca.crt to connect to the Store Deployment. Default is `app-tls-cert`.
- `AUTH-SECRET-NAME` is the name of the secret that contains the authentication token to authenticate to the Store Deployment.

Trivy is the only scanner installed

For a walk through of creating and exporting secrets for the Metadata Store CA and authentication token which referenced in the data values, see Set up multicluster Supply Chain Security Tools (SCST) - Store.

The following example `values.yaml` has no other scanner integrations installed in the same `dev-namespace` where Trivy is installed:

```
#! ...
metadataStore:
  #! The url where the Store deployment is accessible.
  #! Default value is: "https://metadata-store-app.metadata-store.svc.cluster.local:84
43"
  url: "STORE-URL"
  caSecret:
    #! The name of the secret that contains the ca.crt to connect to the Store Deploym
ent.
    #! Default value is: "app-tls-cert"
    name: "CA-SECRET-NAME"
    #! The namespace where the secrets for the Store Deployment live.
    #! Default value is: "metadata-store"
    importFromNamespace: "STORE-SECRETS-NAMESPACE"
  #! authSecret is for multicluster configurations.
  authSecret:
    #! The name of the secret that contains the auth token to authenticate to the Stor
e Deployment.
    name: "AUTH-SECRET-NAME"
    #! The namespace where the secrets for the Store Deployment live.
    importFromNamespace: "STORE-SECRETS-NAMESPACE"
```

Where:

- `STORE-URL` is the URL where the Store deployment is accessible.
- `CA-SECRET-NAME` is the name of the secret that contains the `ca.crt` to connect to the Store Deployment. Default is `app-tls-cert`.
- `STORE-SECRETS-NAMESPACE` is the namespace where the secrets for the Store Deployment live. Default is `metadata-store`.
- `AUTH-SECRET-NAME` is the name of the secret that contains the authentication token to authenticate to the Store Deployment.

No store integration

If you do not want to enable the SCST - Store integration, deactivate the integration by appending the following field to the `values.yaml` file that is enabled by default:

```
# ...
metadataStore:
  url: "" # Deactivate Supply Chain Security Tools - Store integration
```

Prepare the ScanPolicy

The following sample ScanPolicy allows you to control whether the SupplyChain passes or fails based on the CycloneDX vulnerability results returned from the Trivy.

```
---
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ScanPolicy
metadata:
   name: trivy-scan-policy
   labels:
      app.kubernetes.io/part-of: enable-in-gui
spec:
   regoFile: |
      package main

      import future.keywords.in
      import future.keywords.every

      # Accepted Values: "critical", "high", "medium", "low", unknown"
      notAllowedSeverities := ["critical", "high", "unknown"]
      notAllowedSet := {x | x := notAllowedSeverities[_]}
      ignoreCves := []

      isSafe(match) {
        severities := { e | e := match.ratings.rating.severity } | { e | e := match.ra
tings.rating[_].severity }
        every severity in severities {
            not severity in notAllowedSet
        }
      }

      isIgnored(match) {
        match.id in ignoreCves
      }

      deny[msg] {
        notAllowedVulnerabilities := { vulnerability |
          vulnerabilities := {e | e := input.bom.vulnerabilities.vulnerability} | {e |
e := input.bom.vulnerabilities.vulnerability[_]}
          some vulnerability in vulnerabilities
          not isIgnored(vulnerability)
          not isSafe(vulnerability)
        }
        formattedVulnerabilityMessages := { message |
          some vulnerability in notAllowedVulnerabilities
          ratings := {e | e := vulnerability.ratings.rating.severity} | {e | e := vuln
erability.ratings.rating[_].severity}
          formattedRatings := concat(", ", ratings)
          affectedComponents := {e | e := vulnerability.affects.target.ref} | {e | e :
= vulnerability.affects.target[_].ref}
          formattedComponents := concat("\\n", affectedComponents)
          message = sprintf("CVE: %s \\nRatings: %s\\nAffected Components: \\n%s", [vu
lnerability.id, formattedRatings, formattedComponents])
        }
        some formattedVulnerabilityMessage in formattedVulnerabilityMessages
        msg := formattedVulnerabilityMessage
      }
```

To prepare the ScanPolicy:

1. Apply the following to the YAML:

   ```
   kubectl apply -n $DEV-NAMESPACE -f SCAN-POLICY-YAML
   ```

Where:

- `DEV-NAMESPACE` is the name of the developer namespace you want to use.
- `SCAN-POLICY-YAML` is the name of your SCST - Scan YAML.

Install Trivy

After the following prerequisites are completed, install the Trivy:

- Prerequisites listed in Install another scanner for Supply Chain Security Tools - Scan.
- Install the ORAS CLI. See the ORAS documentation.

Air-gap configuration

This section explains how to configure Trivy in an air-gapped environment.

For information about additional flags and configuration, see Air-Gapped Environment in the Trivy documentation.

Relocate a Trivy database to your registry

Note

Using a relocated database means you are taking responsibility for keeping it up to date to ensure that security scans are relevant. Stale databases weaken your security posture.

If you have a host with access, you can use the ORAS CLI to perform a copy.

```
oras copy -r ghcr.io/aquasecurity/trivy-db:2 registry.company.com/project_name/trivy-d
b:2 # the tag of 2 is required

Copying 4a39b38cf2fd db.tar.gz
Copied  4a39b38cf2fd db.tar.gz
Copied ghcr.io/aquasecurity/trivy-db:2 => registry.company.com/project_name/trivy-db:2
Digest: sha256:ed57874a80499e858caac27fc92e4952346eb75a2774809ee989bcd2ce48897a
```

If not, you can use the ORAS CLI to download the database and manifest and then push to your registry.

1. Download the trivy-db.

   ```
   oras pull ghcr.io/aquasecurity/trivy-db:2
   ```

   Example output:

   ```
   oras pull ghcr.io/aquasecurity/trivy-db:2
   Downloading 1612cc15d377 db.tar.gz
   Downloaded  1612cc15d377 db.tar.gz
   Pulled ghcr.io/aquasecurity/trivy-db:2
   Digest: sha256:af903c7ddbe7516f18b06254b6297cf53c0ece918def07322925c71d2f694860
   ```

2. Download the manifest for trivy-db.

   ```
   oras manifest fetch ghcr.io/aquasecurity/trivy-db:2 > trivy-db-manifest.json
   ```

3. Add the media type to the manifest.

```
jq '.mediaType="application/vnd.oci.image.manifest.v1+json"' trivy-db-manifest.
json > updated-trivy-db-manifest.json
```

4. Push the prior downloaded trivy-db to your registry.

   ```
   oras push registry.company.com/project_name/trivy-db:2 ./db.tar.gz
   ```

   Example output:

   ```
   oras push registry.company.com/project_name/trivy-db:2 \
   ./db.tar.gz

   Uploading 1612cc15d377 db.tar.gz
   Uploaded  1612cc15d377 db.tar.gz
   Pushed registry.company.com/project_name/trivy-db:2
   Digest: sha256:41a7eeab8837e90d8a5afd56cfce73936e15d3db04c5294f992ecff9492971dc
   ```

5. Push the updated trivy-db manifest to your registry

   ```
   oras manifest push registry.company.com/project_name/trivy-db:2 updated-trivy-d
   b-manifest.json
   ```

   Example output:

   ```
   oras manifest push registry.company.com/project_name/trivy-db:2 updated-trivy-d
   b-manifest.json
   Pushed registry.company.com/project_name/trivy-db:2
   Digest: sha256:b51a2fccf38e723aac1a7217ba36ca52398b2b20e3d74c9d5089dfdcd9bb2f11
   ```

6. Cleanup files

   ```
   rm trivy-db-manifest.json updated-trivy-db-manifest.json db.tar.gz
   ```

7. Update data values with the database repository URL. Edit your `values.yaml` to add the following:

   ```
   trivy:
   db:
     repositoryUrl: "registry.company.com/project_name/trivy-db"
   ```

   The URL leaves off the tag of `2`.

Use another Trivy version

This section describes how to use a different Trivy CLI version than what is bundled with the package.

To use another Trivy version:

1. Install the ORAS CLI. See the ORAS documentation.
2. Download the version of the CLI you are interested in from their GitHub releases page. For example:
   https://github.com/aquasecurity/trivy/releases/download/v0.36.0/trivy_0.36.0_Linux-64bit.tar.gz

   ```
   wget -c https://github.com/aquasecurity/trivy/releases/download/v0.36.0/trivy_
   0.36.0_Linux-64bit.tar.gz -O trivy.tar.gz
   Length: 48363295 (46M) [application/octet-stream]
   Saving to: 'trivy.tar.gz'
   ```

```
trivy.tar.gz 100%[==>]  46.12M  50.7MB/s    in 0.9s

2023-01-25 10:47:55 (50.7 MB/s) - 'trivy.tar.gz' saved [48363295/48363295]
```

3. Relocate the CLI to your registry.

   Run the following to relocate the CLI to your registry:

```
oras push registry.company.com/project_name/trivy-cli:0.36.0 \
--artifact-type trivy/cli \
./trivy.tar.gz:application/gzip

Uploading 121f4d8282aa trivy.tar.gz
Uploaded  121f4d8282aa trivy.tar.gz
Pushed registry.company.com/project_name/trivy-cli:0.36.0
Digest: sha256:5bdb18378e8f66a72f4bef4964edeccfcc2f21883e7a6caca6dbf7a3d7233696
```

4. Edit your `values.yaml` to add the location of your CLI.

```
trivy:
cli:
  repositoryUrl: "registry.company.com/project_name/trivy-cli:0.36.0"
```

Use another Trivy Aqua plug-in version

Trivy Aqua plug-in enables Aqua SaaS integration with your Trivy scans.

To use another Trivy Aqua plug-in version:

1. Install the ORAS CLI. See the ORAS documentation.
2. Download the version of Trivy Aqua plug-in you want from the GitHub releases page. See trivy-plugin-aqua in GitHub.

   For example, v0.115.14 in GitHub:

```
TRIVY-AQUA-PLUGIN-VERSION="v0.115.6"
wget -c "https://github.com/aquasecurity/trivy-plugin-aqua/releases/download/
${TRIVY-AQUA-PLUGIN-VERSION}/linux_amd64_${TRIVY-AQUA-PLUGIN-VERSION}.tar.gz" -
O trivy-aqua-plugin.tar.gz

--2023-01-30 10:44:05--  https://github.com/aquasecurity/trivy-plugin-aqua/rele
ases/download/v0.115.6/linux_amd64_v0.115.6.tar.gz
HTTP request sent, awaiting response... 200 OK
Length: 50915539 (49M) [application/octet-stream]
Saving to: 'trivy-aqua-plugin.tar.gz'

trivy-aqua-plugin.tar.gz 100%[==>]  48.56M  35.3MB/s    in 1.4s

2023-01-30 10:44:07 (35.3 MB/s) - 'trivy-aqua-plugin.tar.gz' saved [50915539/50
915539]
```

3. The YAML file is a necessary component to tell Trivy it has the plug-in already installed. Download the plugin.yml file associated with Trivy Aqua plug-in version you downloaded.

```
TRIVY-AQUA-PLUGIN-VERSION="v0.115.6"
wget -c "https://raw.githubusercontent.com/aquasecurity/trivy-plugin-aqua/${TRI
VY-AQUA-PLUGIN-VERSION}/plugin.yaml" -O plugin.yaml

--2023-01-30 10:46:32--  https://raw.githubusercontent.com/aquasecurity/trivy-p
lugin-aqua/v0.115.6/plugin.yaml
HTTP request sent, awaiting response... 200 OK
```

```
Length: 909 [text/plain]
Saving to: ‘plugin.yaml’
plugin.yaml 100%[==>]     909  --.-KB/s    in 0s

2023-01-30 10:46:32 (54.2 MB/s) - ‘plugin.yaml’ saved [909/909]
```

4. Relocate the plug-in and YAML to your registry:

```
TRIVY-AQUA-PLUGIN-VERSION="v0.115.6"
REPOSITORY-URL="registry.company.com/project_name/trivy-aqua-plugin:$TRIVY-AQUA
-PLUGIN-VERSION"

oras push ${REPOSITORY-URL} \
--artifact-type trivy/aqua-plugin \
./trivy-aqua-plugin.tar.gz:application/gzip \
./plugin.yaml:text/yaml

Uploading 6fb65adbfde2 plugin.yaml
Uploading 7340855e31ff trivy-aqua-plugin.tar.gz
Uploaded  6fb65adbfde2 plugin.yaml
Uploaded  7340855e31ff trivy-aqua-plugin.tar.gz
Pushed registry.company.com/project_name/trivy-aqua-plugin:v0.115.6
Digest: sha256:791274e44b97fad98edf570205fddc1b0bc21c56d3d54565ad9475fd4da969ae
```

   Where:

   - `TRIVY-AQUA-PLUGIN-VERSION` is the version of Trivy Aqua plug-in you are using.
   - `REPOSITORY-URL` is the repository where you want to relocate the plug-in.

5. Edit your `values.yaml` to add the location of your CLI.

```
trivy:
plugins:
  aqua:
    repositoryUrl: "registry.company.com/project_name/trivy-aqua-plugin:v0.115.
6"
```

Integrate with the Aqua SaaS platform

To integrate with the Aqua SaaS platform:

1. In order to connect to the SaaS Platform you must have an API key. To create an API key:
   1. Log into Aqua SaaS.
   2. Enter CSPM.
   3. Click **Settings** -> **API Keys**.
   4. Click **Generate Key**.
   5. Save the information for the next steps.
2. To integrate with the Aqua SaaS Platform you must have an API key. You pass this to the scanner through environment variables, referenced in a secret. Create an auth secret:

   Example secret:

```
apiVersion: v1
kind: Secret
metadata:
name: aqua-creds
namespace: APP-NAMESPACE
stringData:
```

```
aqua-key: API-KEY
aqua-secret: API-KEY-SECRET
```

Where:

- `APP-NAMESPACE` is the developer namespace your app uses.
- `API-KEY` is the Aqua Platform API key.
- `API-KEY-SECRET` is the Aqua Platform API key's Secret.

3. Set environment variables to tell Trivy to connect and report to Aqua SaaS.

You can find plug-in options in the README.md in GitHub.

Here is an example of referencing your API key and secret from a Kubernetes Secret created earlier:

```
namespace: dev
targetImagePullSecret: registry-credentials
environmentVariables:
  - name: TRIVY-RUN-AS-PLUGIN
    value: aqua
  - name: AQUA-KEY
    valueFrom:
      secretKeyRef:
        name: aqua-creds
        key: aqua-key
  - name: AQUA-SECRET
    valueFrom:
      secretKeyRef:
        name: aqua-creds
        key: aqua-secret
```

Where:

- `TRIVY-RUN-AS-PLUGIN` is the Trivy plug-in you want to enable without using the subcommand.
- `AQUA-KEY` is the Aqua Platform API key.
- `AQUA-SECRET` is the Aqua Platform API key's Secret.

Self-signed registry certificate

You need additional configuration when attempting to pull an image from a registry with a self-signed certificate during image scans.

1. If your `tap-values.yaml` used during install has the following shared section filled out, Trivy uses this to connect to your registry without additional configuration. Use the following YAML with a Tanzu Application Platform values shared CA:

   ```
   shared:
   ca_cert_data: | # To be passed if using custom certificates.
       -----BEGIN CERTIFICATE-----
       MIIFXzCCA0egAwIBAgIJAJYm37SFocjlMA0GCSqGSIb3DQEBDQUAMEY...
       -----END CERTIFICATE-----
   ```

2. Create a secret that holds the registry's CA certificate data.

   An example secret:

   ```
   apiVersion: v1
   kind: Secret
   metadata:
   ```

```
name: trivy-registry-cert
namespace: dev
type: Opaque
data:
ca_cert_data: BASE64_CERT
```

3. Update your Trivy install `trivy-values.yaml`.

   Add `caCertSecret` to the root of your `trivy-values.yaml`.

   For example:

```
namespace: dev
targetImagePullSecret: tap-registry
caCertSecret: trivy-registry-cert
```

Spec reference

This topic describes the specifications and custom resources you can use with Supply Chain Security Tools - Scan.

With the Scan Controller and Grype Scanner installed the following Custom Resource Definitions (CRDs) are now available:

```
$ kubectl get crds | grep scanning.apps.tanzu.vmware.com
imagescans.scanning.apps.tanzu.vmware.com                2021-09-09T15:22:07Z
scanpolicies.scanning.apps.tanzu.vmware.com              2021-09-09T15:22:07Z
scantemplates.scanning.apps.tanzu.vmware.com             2021-09-09T15:22:07Z
sourcescans.scanning.apps.tanzu.vmware.com               2021-09-09T15:22:07Z
```

For more information about installing SCST - Scan, see Installing Individual Packages.

About source and image scans

Both SourceScan (`sourcescans.scanning.apps.tanzu.vmware.com`) and ImageScan (`imagescans.scanning.apps.tanzu.vmware.com`) define what will be scanned, and ScanTemplate (`scantemplates.scanning.apps.tanzu.vmware.com`) will define how to run a scan. We have provided five custom resources (CRs) pre-installed for use. You can either use them as-is or as samples to create your own.

To view the pre-installed Scan Template CRs, run:

```
kubectl get scantemplates
```

You will see the following scan templates:

CR Name	Use Case
`public-source-scan-template`	Clones and scans source code from a public repository.
`private-source-scan-template`	Connects with SSH credentials to clone and scan source code from a private repository.
`public-image-scan-template`	Pulls and scans images from a public registry.
`private-image-scan-template`	Connects with the registry credentials to pull and scan images from a private registry.
`blob-source-scan-template`	To be used in a Supply Chain. Gets a `.tar.gz` available file with `wget`, uncompresses it, and scans the source code inside it.

By default, three scan templates are deployed (`public-source-scan-template`, `public-image-scan-template`, and `blob-source-scan-template`).

If `targetImagePullSecret` is set in `tap-values.yaml`, `private-image-scan-template` is also deployed. If `targetSourceSshSecret` is set in `tap-values.yaml`, `private-source-scan-template` is also deployed.

The private scan templates reference secrets created using the Docker server and credentials you provided, which means they are ready to use immediately.

For more information about the `SourceScan` and `ImageScan` CRDs and how to customize your own, refer to Configuring Code Repositories and Image Artifacts to be Scanned.

About policy enforcement around vulnerabilities found

The Scan Controller supports policy enforcement by using an Open Policy Agent (OPA) engine. ScanPolicy (`scanpolicies.scanning.apps.tanzu.vmware.com`) allows scan results to be validated for company policy compliance and can prevent source code from being built or images from being deployed.

For more information, see Configuring Policy Enforcement using Open Policy Agent (OPA).

Scan samples for Supply Chain Security Tools - Scan

This section provides samples on multiple use cases for SCST - Scan that you can copy to your cluster for testing purposes.

- Running a sample public image scan with compliance check
- Running a sample public source scan with compliance check
- Running a sample private image scan
- Running a sample private source scan
- Running a sample public source scan of a blob/tar file

Scan samples for Supply Chain Security Tools - Scan

This section provides samples on multiple use cases for SCST - Scan that you can copy to your cluster for testing purposes.

- Running a sample public image scan with compliance check
- Running a sample public source scan with compliance check
- Running a sample private image scan
- Running a sample private source scan
- Running a sample public source scan of a blob/tar file

Sample public image scan with compliance check for Supply Chain Security Tools - Scan

This topic includes an example public image scan with compliance check for SCST - Scan.

Public image scan

The following example performs an image scan on an image in a public registry. This image revision has 223 known vulnerabilities (CVEs), spanning a number of severities. ImageScan uses the

ScanPolicy to run a compliance check against the CVEs.

The policy in this example is set to only consider `Critical` severity CVEs as a violation, which returns 21 Critical Severity Vulnerabilities.

Note

This example ScanPolicy is deliberately constructed to showcase the features available and must not be considered an acceptable base policy.

In this example, the scan does the following:

- Finds all 223 of the CVEs
- Ignores any CVEs with severities that are not critical
- Indicates in the `Status.Conditions` that 21 CVEs have violated policy compliance

Define the ScanPolicy and ImageScan

Create `sample-public-image-scan-with-compliance-check.yaml`:

```
---
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ScanPolicy
metadata:
  name: sample-scan-policy
  labels:
    'app.kubernetes.io/part-of': 'enable-in-gui'
spec:
  regoFile: |
    package main

    # Accepted Values: "Critical", "High", "Medium", "Low", "Negligible", "UnknownSeve
rity"
    notAllowedSeverities := ["Critical"]
    ignoreCves := []

    contains(array, elem) = true {
      array[_] = elem
    } else = false { true }

    isSafe(match) {
      severities := { e | e := match.ratings.rating.severity } | { e | e := match.rati
ngs.rating[_].severity }
      some i
      fails := contains(notAllowedSeverities, severities[i])
      not fails
    }

    isSafe(match) {
      ignore := contains(ignoreCves, match.id)
      ignore
    }

    deny[msg] {
      comps := { e | e := input.bom.components.component } | { e | e := input.bom.comp
onents.component[_] }
      some i
      comp := comps[i]
      vulns := { e | e := comp.vulnerabilities.vulnerability } | { e | e := comp.vulne
rabilities.vulnerability[_] }
      some j
      vuln := vulns[j]
```

```
      ratings := { e | e := vuln.ratings.rating.severity } | { e | e := vuln.ratings.r
ating[_].severity }
      not isSafe(vuln)
      msg = sprintf("CVE %s %s %s", [comp.name, vuln.id, ratings])
    }

---
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ImageScan
metadata:
  name: sample-public-image-scan-with-compliance-check
spec:
  registry:
    image: "nginx:1.16"
  scanTemplate: public-image-scan-template
  scanPolicy: sample-scan-policy
```

(Optional) Set up a watch

Before deploying the resources to a user specified namespace, set up a watch in another terminal to view the progression:

```
watch kubectl get sourcescans,imagescans,pods,taskruns,scantemplates,scanpolicies -n D
EV-NAMESPACE
```

Where `DEV-NAMESPACE` is the developer namespace where the scanner is installed.

For more information about setting up a watch, see Observing and Troubleshooting.

Deploy the resources

```
kubectl apply -f sample-public-image-scan-with-compliance-check.yaml -n DEV-NAMESPACE
```

Where `DEV-NAMESPACE` is the developer namespace where the scanner is installed.

View the scan results

```
kubectl describe imagescan sample-public-image-scan-with-compliance-check -n DEV-NAMES
PACE
```

Where `DEV-NAMESPACE` is the developer namespace where the scanner is installed.

Note

The `Status.Conditions` includes a `Reason: EvaluationFailed` and `Message: Policy violated because of 21 CVEs`.

For more information about scan status conditions, see Viewing and Understanding Scan Status Conditions.

Edit the ScanPolicy

To edit the Scan Policy, see Step 5: Sample Public Source Code Scan with Compliance Check.

Clean up

To clean up, run:

```
kubectl delete -f sample-public-image-scan-with-compliance-check.yaml -n DEV-NAMESPACE
```

Where `DEV-NAMESPACE` is the developer namespace where the scanner is installed.

Sample public source code scan with compliance check for Supply Chain Security Tools - Scan

This topic includes an example public source code scan with compliance check for SCST - Scan.

Public source scan

This example performs a source scan on a public repository. The source revision has 192 known Common Vulnerabilities and Exposures (CVEs), spanning several severities. SourceScan uses the ScanPolicy to run a compliance check against the CVEs.

The example policy is set to only consider `Critical` severity CVEs as violations, which returns 7 Critical Severity Vulnerabilities.

Note

This example ScanPolicy is deliberately constructed to showcase the features available and must not be considered an acceptable base policy.

For this example, the scan (at the time of writing):

- Finds all 192 of the CVEs.
- Ignores any CVEs that have severities that are not critical.
- Indicates in the `Status.Conditions` that 7 CVEs have violated policy compliance.

Run an example public source scan

To perform an example source scan on a public repository:

1. Create `sample-public-source-scan-with-compliance-check.yaml` to define the ScanPolicy and SourceScan:

```
---
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ScanPolicy
metadata:
  name: sample-scan-policy
  labels:
    'app.kubernetes.io/part-of': 'enable-in-gui'
spec:
  regoFile: |
    package main

    # Accepted Values: "Critical", "High", "Medium", "Low", "Negligible", "Unkn
ownSeverity"
    notAllowedSeverities := ["Critical"]
    ignoreCves := []

    contains(array, elem) = true {
      array[_] = elem
    } else = false { true }

    isSafe(match) {
      severities := { e | e := match.ratings.rating.severity } | { e | e := mat
```

```
ch.ratings.rating[_].severity }
      some i
      fails := contains(notAllowedSeverities, severities[i])
      not fails
    }

    isSafe(match) {
      ignore := contains(ignoreCves, match.id)
      ignore
    }

    deny[msg] {
      comps := { e | e := input.bom.components.component } | { e | e := input.b
om.components.component[_] }
      some i
      comp := comps[i]
      vulns := { e | e := comp.vulnerabilities.vulnerability } | { e | e := com
p.vulnerabilities.vulnerability[_] }
      some j
      vuln := vulns[j]
      ratings := { e | e := vuln.ratings.rating.severity } | { e | e := vuln.ra
tings.rating[_].severity }
      not isSafe(vuln)
      msg = sprintf("CVE %s %s %s", [comp.name, vuln.id, ratings])
    }

---
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: SourceScan
metadata:
  name: sample-public-source-scan-with-compliance-check
spec:
  git:
    url: "https://github.com/houndci/hound.git"
    revision: "5805c650"
  scanTemplate: public-source-scan-template
  scanPolicy: sample-scan-policy
```

2. (Optional) Before deploying the resources to a user specified namespace, set up a watch in another terminal to view the progression:

   ```
   watch kubectl get sourcescans,imagescans,pods,taskruns,scantemplates,scanpolici
   es -n DEV-NAMESPACE
   ```

   Where `DEV-NAMESPACE` is the developer namespace where the scanner is installed.

   For more information, see Observing and Troubleshooting.

3. Deploy the resources by running:

   ```
   kubectl apply -f sample-public-source-scan-with-compliance-check.yaml -n DEV-NA
   MESPACE
   ```

   Where `DEV-NAMESPACE` is the developer namespace where the scanner is installed.

4. When the scan completes, view the results by running:

   ```
   kubectl describe sourcescan sample-public-source-scan-with-compliance-check -n
   DEV-NAMESPACE
   ```

   The `Status.Conditions` includes a `Reason: EvaluationFailed` and `Message: Policy violated because of 7 CVEs`. For more information, see Viewing and Understanding Scan Status Conditions.

5. If the failing CVEs are acceptable or the build must be deployed regardless of these CVEs, the app is patched to remove the vulnerabilities. Update the `ignoreCVEs` array in the ScanPolicy to include the CVEs to ignore:

```
...
spec:
  regoFile: |
    package policies

    default isCompliant = false

    # Accepted Values: "UnknownSeverity", "Critical", "High", "Medium", "Low",
"Negligible"
    violatingSeverities := ["Critical"]
    # Adding the failing CVEs to the ignore array
    ignoreCVEs := ["CVE-2018-14643", "GHSA-f2jv-r9rf-7988", "GHSA-w457-6q6x-cgp
9", "CVE-2021-23369", "CVE-2021-23383", "CVE-2020-15256", "CVE-2021-29940"]
...
```

6. The changes applied to the new ScanPolicy trigger the scan to run again. Reapply the resources by running:

```
kubectl apply -f sample-public-source-scan-with-compliance-check.yaml -n DEV-NA
MESPACE
```

7. Re-describe the SourceScan CR by running:

```
kubectl describe sourcescan sample-public-source-scan-with-compliance-check -n
DEV-NAMESPACE
```

8. Ensure that `Status.Conditions` now includes a `Reason: EvaluationPassed` and `No CVEs were found that violated the policy`. You can update the `violatingSeverities` array in the ScanPolicy if you want. For reference, the Grype scan returns the following Severity spread of vulnerabilities:
    - Critical: 7
    - High: 88
    - Medium: 92
    - Low: 5
    - Negligible: 0
    - UnknownSeverity: 0
9. Clean up by running:

```
kubectl delete -f sample-public-source-scan-with-compliance-check.yaml -n DEV-N
AMESPACE
```

Sample private image scan for Supply Chain Security Tools - Scan

This example describes how you can perform a scan against an image located in a private registry for SCST - Scan.

Define the resources

Set up target image pull secret

1. Confirm that target image secret is configured. This is completed during Tanzu Application Platform installation. If the target image secret exists, see Create the private image scan.
2. If the target image secret was not configured, create a secret containing the credentials used to pull the target image you want to scan. For information about secret creation, see the Kubernetes documentation.

   ```
   kubectl create secret docker-registry TARGET-REGISTRY-CREDENTIALS-SECRET \
   --docker-server=YOUR-REGISTRY-SERVER \
   --docker-username=YOUR-NAME \
   --docker-password=YOUR-PASSWORD \
   --docker-email=YOUR-EMAIL \
   -n DEV-NAMESPACE
   ```

   Where:

   - `TARGET-REGISTRY-CREDENTIALS-SECRET` is the name of the secret that is created.
   - `DEV-NAMESPACE` is the developer namespace where the scanner is installed.
   - `YOUR-REGISTRY-SERVER` is the registry server you want to use.
   - `YOUR-NAME` is the name associated with the secret.
   - `YOUR-PASSWORD` is the password associated with the secret.
   - `YOUR-EMAIL` is the email associated with the secret.
3. Update the `tap-values.yaml` file to include the name of secret created earlier.

   ```
   grype:
   targetImagePullSecret: "TARGET-REGISTRY-CREDENTIALS-SECRET"
   ```
4. Upgrade Tanzu Application Platform with the modified `tap-values.yaml` file.

   ```
   tanzu package installed update tap -p tap.tanzu.vmware.com -v ${TAP-VERSION}  -
   -values-file tap-values.yaml -n tap-install
   ```

   Where `TAP-VERSION` is the Tanzu Application Platform version.

Create the private image scan

Create `sample-private-image-scan.yaml`:

```
---
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ImageScan
metadata:
  name: sample-private-image-scan
spec:
  registry:
    image: IMAGE-URL
  scanTemplate: private-image-scan-template
```

Where `IMAGE-URL` is the URL of an image in a private registry.

(Optional) Set up a watch

Before deploying the resources to a user specified namespace, set up a watch in another terminal to view the progression:

```
watch kubectl get sourcescans,imagescans,pods,taskruns,scantemplates,scanpolicies -n D
EV-NAMESPACE
```

Where `DEV-NAMESPACE` is the developer namespace where the scanner is installed.

For more information, see Observing and Troubleshooting.

Deploy the resources

```
kubectl apply -f sample-private-image-scan.yaml -n DEV-NAMESPACE
```

Where `DEV-NAMESPACE` is the developer namespace where the scanner is installed.

View the scan results

When the scan completes, run:

```
kubectl describe imagescan sample-private-image-scan -n DEV-NAMESPACE
```

Where `DEV-NAMESPACE` is the developer namespace where the scanner is installed.

Note

The `Status.Conditions` includes a `Reason: JobFinished` and `Message: The scan job finished`. See Viewing and Understanding Scan Status Conditions.

Clean up

```
kubectl delete -f sample-private-image-scan.yaml -n DEV-NAMESPACE
```

Where `DEV-NAMESPACE` is the developer namespace where the scanner is installed.

View vulnerability reports

After completing the scans, query the Supply Chain Security Tools - Store to view your vulnerability results.

Sample private source scan for Supply Chain Security Tools - Scan

This example shows how you can perform a private source scan for SCST - Scan.

Define the resources

1. Create a Kubernetes secret with an SSH key for cloning a Git repository. See the Kubernetes documentation.

   ```
   cat <<EOF | kubectl create -f -
   apiVersion: v1
   kind: Secret
   metadata:
   name: SECRET-SSH-AUTH
   namespace: DEV-NAMESPACE
   annotations:
   ```

```
  tekton.dev/git-0: https://github.com
  tekton.dev/git-1: https://gitlab.com
type: kubernetes.io/ssh-auth
stringData:
ssh-privatekey: |
  -----BEGIN OPENSSH PRIVATE KEY-----
  ....
  ....
  -----END OPENSSH PRIVATE KEY-----
EOF
```

Where:

- `SECRET-SSH-AUTH` is the name of the secret that is being created.
- `DEV-NAMESPACE` is the developer namespace where the scanner is installed.
- `.stringData.ssh-privatekey` contains the private key with pull-permissions.

2. Update the `tap-values.yaml` file to include the name of secret created above.

```
grype:
targetSourceSshSecret: "SECRET-SSH-AUTH"
```

3. Upgrade Tanzu Application Platform with the modified `tap-values.yaml` file.

```
tanzu package installed update tap -p tap.tanzu.vmware.com -v ${TAP-VERSION}  -
-values-file tap-values.yaml -n tap-install
```

Where `TAP-VERSION` is the Tanzu Application Platform version.

4. Create `sample-private-source-scan.yaml`:

```
---
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: SourceScan
metadata:
name: sample-private-source-scan
spec:
git:
  url: URL
  revision: REVISION
  knownHosts: |
    KNOWN-HOSTS
scanTemplate: private-source-scan-template
```

Where:

- `URL` is the Git clone repository using SSH.
- `REVISION` is the commit hash.
- `KNOWN-HOSTS` are the SSH client stored host keys generated by ssh-keyscan.
  - For example, `ssh-keyscan github.com` produces:

```
github.com ssh-rsa AAAAB3NzaC1yc2EAAAABIwAAAQEAq2A7hRGmdnm9tUDbO9I
DSwBK6TbQa+PXYPCPy6rbTrTtw7PHkccKrpp0yVhp5HdEIcKr6pLlVDBfOLX9QUsyC
OV0wzfjIJNlGEYsdlLJizHhbn2mUjvSAHQqZETYP81eFzLQNnPHt4EVVUh7VfDESU8
4KezmD5QlWpXLmvU31/yMf+Se8xhHTvKSCZIFImWwoG6mbUoWf9nzpIoaSjB+weqqU
UmpaaasXVal72J+UX2B+2RPW3RcT0eOzQgqlJL3RKrTJvdsjE3JEAvGq3lGHSZXy28
G3skua2SmVi/w4yCE6gbODqnTWlg7+wC604ydGXA8VJiS5ap43JXiUFFAaQ==
github.com ecdsa-sha2-nistp256 AAAAE2VjZHNhLXNoYTItbmlzdHAyNTYAAAA
IbmlzdHAyNTYAAABBBEmKSENjQEezOmxkZMy7opKgwFB9nkt5YRrYMjNuG5N87uRgg
6CLrbo5wAdT/y6v0mKV0U2w0WZ2YB/++Tpockg=
```

```
github.com ssh-ed25519 AAAAC3NzaC1lZDI1NTE5AAAAIOMqqnkVzrm0SdG6UOo
qKLsabgH5C9okWi0dh2l9GKJl
```

For example:

```
---
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: SourceScan
metadata:
name: sample-private-source-scan
spec:
git:
  url: git@github.com:acme/website.git
  revision: 25as5e7df56c6401111be514a2f3666179ba04d0
  knownHosts: |
    10.254.171.53 ecdsa-sha2-nistp256 AAAAE2VjZHNhLXNoYTItb
POVVQF/CzuAeQNv4fZVf2pLxpGHle15zkpxOosckequUDxoq
scanTemplate: private-source-scan-template
```

(Optional) Set up a watch

Before deploying the resources to a user specified namespace, set up a watch in another terminal to view the progression:

```
watch kubectl get sourcescans,imagescans,pods,taskruns,scantemplates,scanpolicies -n D
EV-NAMESPACE
```

Where `DEV-NAMESPACE` is the developer namespace where the scanner is installed.

See Observing and Troubleshooting.

Deploy the resources

```
kubectl apply -f sample-private-source-scan.yaml -n DEV-NAMESPACE
```

Where `DEV-NAMESPACE` is the developer namespace where the scanner is installed.

View the scan status

After the scan has completed, run:

```
kubectl describe sourcescan sample-private-source-scan -n DEV-NAMESPACE
```

Where `DEV-NAMESPACE` is the developer namespace where the scanner is installed.

Notice the `Status.Conditions` includes a `Reason: JobFinished` and `Message: The scan job finished`. See Viewing and Understanding Scan Status Conditions.

Clean up

```
kubectl delete -f sample-private-source-scan.yaml -n DEV-NAMESPACE
```

Where `DEV-NAMESPACE` is the developer namespace where the scanner is installed.

View vulnerability reports

After completing the scans, query the Supply Chain Security Tools - Store to view your vulnerability results.

Sample public source scan of a blob for Supply Chain Security Tools - Scan

You can do a public source scan of a blob for SCST - Scan. This example performs a scan against source code in a `.tar.gz` file. This is helpful in a Supply Chain, where there is a `GitRepository` step that handles cloning a repository and outputting the source code as a compressed archive.

Define the resources

Create `public-blob-source-example.yaml`:

```
---
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: SourceScan
metadata:
  name: public-blob-source-example
spec:
  blob:
    url: "https://gitlab.com/nina-data/ckan/-/archive/master/ckan-master.tar.gz"
  scanTemplate: blob-source-scan-template
```

(Optional) Set up a watch

Before deploying the resources to a user specified namespace, set up a watch in another terminal to view the progression:

```
watch kubectl get sourcescans,imagescans,pods,taskruns,scantemplates,scanpolicies -n D
EV-NAMESPACE
```

Where `DEV-NAMESPACE` is the developer namespace where the scanner is installed.

For more information, see Observing and Troubleshooting.

Deploy the resources

```
kubectl apply -f public-blob-source-example.yaml -n DEV-NAMESPACE
```

Where `DEV-NAMESPACE` is the developer namespace where the scanner is installed.

View the scan results

When the scan completes, perform:

```
kubectl describe sourcescan public-blob-source-example -n DEV-NAMESPACE
```

Where `DEV-NAMESPACE` is the developer namespace where the scanner is installed.

Notice the `Status.Conditions` includes a `Reason: JobFinished` and `Message: The scan job finished`.

For more information, see Viewing and Understanding Scan Status Conditions.

Clean up

```
kubectl delete -f public-blob-source-example.yaml -n DEV-NAMESPACE
```

Where `DEV-NAMESPACE` is the developer namespace where the scanner is installed.

View vulnerability reports

After completing the scans, query the Supply Chain Security Tools - Store to view your vulnerability results.

Use vulnerability scanning in offline and air-gapped environments for Supply Chain Security Tools - Scan

This topic tells you how to use Grype in air-gapped (offline) environments for Supply Chain Security Tools (SCST) - Scan.

Note

For air-gapped (offline) environments, VMware recommends using Aqua Security's Trivy scanner with Scan 2.0. This greatly simplifies the installation and maintenance experiences over Anchore Grype and Scan 1.0. See here for more information on Scan 1.0 versus Scan 2.0.

Using Trivy with SCST - Scan 2.0

The Aqua Trivy vulnerability scanner uses two databases to perform vulnerability scans:

1. Vulnerability Database: This database contains the vulnerability information used to scan artifacts. This database is built every six hours on GitHub and is distributed using GitHub Container registry (GHCR).
2. Java Index Database: This database enables Trivy to identify the `groupId`, `artifactId`, and `version` of JAR files. It is built once a day on GitHub and distributed using GitHub Container registry (GHCR).

In an online installation of Tanzu Application Platform, these databases are automatically downloaded from GHCR (Github Container Registry) with each scan execution. To enable scanning in an offline environment, these two databases must be relocated to your private container image registry, and Trivy must be configured to use your private location instead of downloading from GHCR.

For more information about the Trivy vulnerability databases, see the Trivy documentation.

Relocate Trivy Images

The databases are stored in an OCI-compliant registry as OCI artifacts. To copy these to your private registry, Trivy recommends using the ORAS CLI.

To make the Trivy databases available in your private registry:

1. Create a repository within your private registry. This example uses aquasecurity to remain consistent with the GHCR repository.
2. Copy the vulnerability database from GHCR to your private registry:

   ```
   oras cp ghcr.io/aquasecurity/trivy-db:2 CONTAINER-REGISTRY/aquasecurity/trivy-db:2
   ```

> **Note**
>
> The Trivy scanner is hardcoded to use the `2` tag for the vulnerability database.

Where `CONTAINER-REGISTRY` is the URL for your registry. For example, `harbor.example.com`

3. Copy the Java index database from GHCR to your private registry:

```
oras cp ghcr.io/aquasecurity/trivy-java-db:1 harbor.CONTAINER-REGISTRY/aquasecu
rity/trivy-java-db:1
```

Where `CONTAINER-REGISTRY` is the URL for your registry. For example, `harbor.example.com`

> **Note**
>
> The Trivy scanner is hardcoded to use the `1` tag for the Java index database.

The databases are now available locally in your air-gapped environment. The next step is to configure the supply chain to use the air-gapped location for Trivy. For more information about using Trivy in an air-gapped environment, see the Trivy documentation.

Configure Trivy in the Supply Chain

Now that you have relocated the images, you must configure the scanning step of the supply chain to use Trivy with the SCST - Scan 2.0, and provide the location of the database artifacts in the private registry.

1. To enable SCST - Scan 2.0 with Trivy with private registries, update your `tap-values.yaml` file to specify the Trivy `ClusterImageTemplate`. For example:

```
ootb_supply_chain_testing_scanning:
  image_scanner_template_name: image-vulnerability-scan-trivy
  scanning:
    steps:
      env_vars:
      - name: TRIVY_DB_REPOSITORY
        value: CONTAINER-REGISTRY/aquasecurity/trivy-db
      - name: TRIVY_JAVA_DB_REPOSITORY
        value: CONTAINER-REGISTRY/aquasecurity/trivy-java-db
      - name: TRIVY_OFFLINE_SCAN
        value: "true"
```

Where `CONTAINER-REGISTRY` is the URL for your registry. For example, `harbor.example.com`

2. Update your Tanzu Application Platform installation by running:

```
tanzu package installed update tap -p tap.tanzu.vmware.com -v TAP-VERSION  --va
lues-file tap-values.yaml -n tap-install
```

Where `TAP-VERSION` is the version of Tanzu Application Platform installed.

Trivy is now configured to use resources in your air-gapped environment when executed with the supply chain. For more information about using Trivy in an air-gapped environment, see the Trivy documentation.

Using Grype with Scan 1.0

VMware recommends using Aqua Trivy with SCST - Scan 2.0 for offline or air-gapped environments due to the simplified setup and maintenance. However, if you require policy enablement based on vulnerability scanning, use the following steps to enable Grype scanning with SCST - Scan 1.0.

The Grype CLI attempts to perform two over-the-Internet calls:

- One to verify for later versions of the CLI.
- One to update the vulnerability database before scanning.

For the Grype CLI to function in an offline or air-gapped environment, the vulnerability database must be hosted in the environment. You must configure the Grype CLI with the internal URL.

The Grype CLI accepts environment variables to satisfy these needs.

Host the Grype vulnerability database

To host the Grype vulnerability database in an air-gapped environment:

1. Retrieve the Grype listing file from its public endpoint: https://toolbox-data.anchore.io/grype/databases/listing.json.
2. Create your own `listing.json` file.

   Note Different Grype versions require specific database schema versions. To avoid compatibility issues between different versions, include a database schema for each version. For example:

```
    {
      "available": {
        "1": [
          {
            "built": "2023-06-16T01:33:30Z",
            "version": 1,
            "url": "https://toolbox-data.anchore.io/grype/databases/vulnerabili
ty-db_v1_2023-06-16T01:33:30Z_1621f4169ffd15bea9e5.tar.gz",
            "checksum": "sha256:3f2c1b432945cca9a69b2e604f6fb231fec450fdd27f494
6fc5608692b63a9d1"
          }
        ],
        "2": [
          {
            "built": "2023-06-16T01:33:30Z",
            "version": 2,
            "url": "https://toolbox-data.anchore.io/grype/databases/vulnerabili
ty-db_v2_2023-06-16T01:33:30Z_d6eee5e78d9b78285e1a.tar.gz",
            "checksum": "sha256:7b7e3a2a7712c72b8c5cc777733c4d8d140d8cfee65e4f0
4540abbdfe3ef1f65"
          }
        ],
        "3": [
          {
            "built": "2023-06-16T01:33:30Z",
            "version": 3,
            "url": "https://toolbox-data.anchore.io/grype/databases/vulnerabili
ty-db_v3_2023-06-16T01:33:30Z_f96ae38a7b05987c3ece.tar.gz",
            "checksum": "sha256:8ea9fae3fda3bf3bf35bd5e5eb656fc127b59cd3c42db4c
36795556aab8a9cf0"
          }
        ],
        "4": [
          {
            "built": "2023-06-16T01:33:30Z",
            "version": 4,
```

```
            "url": "https://toolbox-data.anchore.io/grype/databases/vulnerabili
ty-db_v4_2023-06-16T01:33:30Z_13bba2fa8ff62b7f8b26.tar.gz",
            "checksum": "sha256:3b53d20241b88e5aa45feb817b325c53d6efbe9fa1fc5a6
7eeddaecafa7687e0"
          }
        ],
        "5": [
          {
            "built": "2023-06-16T01:33:30Z",
            "version": 5,
            "url": "https://toolbox-data.anchore.io/grype/databases/vulnerabili
ty-db_v5_2023-06-16T01:33:30Z_e07da3853f6db6eb1104.tar.gz",
            "checksum": "sha256:93d4d9d2f9e39f86570f832cf85b7149a949ca6f1613581
b10c12393509d884f"
          }
        ]
      }
    }
```

Where `url` points to a tarball containing Grype's `vulnerability.db` and `metadata.json` files.

3. Download and host the tarballs in your internal file server.

> **Note**
>
> Some storage solutions for internal file servers change the name of TAR files automatically because of their limits. Notice these modified names and reflect the changes in the `url`. Ensure that the timestamp in the name is correctly formatted because Grype parses the name of TAR artifact to get the timestamp.

4. Update the download `url` to point at your internal endpoint.

   For information about setting up an offline vulnerability database, see the Anchore Grype README in GitHub.

To enable Grype in offline air-gapped environments

1. Add the following to your `tap-values.yaml` file:

```
grype:
  db:
    dbUpdateUrl: INTERNAL-VULN-DB-URL
```

   Where `INTERNAL-VULN-DB-URL` is the URL that points to the internal file server.

2. Update Tanzu Application Platform:

```
tanzu package installed update tap -f tap-values.yaml -n tap-install
```

Configure Grype environmental variables

1. Create a secret that contains the ytt overlay to add the Grype environment variable to the ScanTemplates.

```
apiVersion: v1
kind: Secret
metadata:
  name: grype-airgap-environmental-variables
  namespace: tap-install
```

```
stringData:
  patch.yaml: |
    #@ load("@ytt:overlay", "overlay")

    #@overlay/match by=overlay.subset({"kind":"ScanTemplate"}),expects="1+"
    ---
    spec:
      template:
        initContainers:
          #@overlay/match by=overlay.subset({"name": "scan-plugin"}), expects
="1+"
          - name: scan-plugin
            #@overlay/match missing_ok=True
            env:
              #@overlay/append
              - name: GRYPE_CHECK_FOR_APP_UPDATE
                value: "false"
```

Where `spec.template.initContainers[]` specifies setting one or more environment variables in the `scan-plugin initContainer`.

Note

If you are using the Namespace Provisioner to provision a new developer namespace and want to apply a package overlay for Grype, you must import the overlay `Secret`. See Import overlay secrets.

Troubleshooting

ERROR failed to fetch latest cli version

Symptom

Error message:

```
ERROR failed to fetch latest version: Get "https://toolbox-data.anchore.io/grype/releases/latest/VERSION": dial tcp: lookup toolbox-data.anchore.io on [::1]:53: read udp [::1]:65010->[::1]:53: read: connection refused
```

Cause

The Grype CLI checks for later versions of the CLI by contacting the anchore endpoint over-the-Internet.

Solution

This message is a warning and the Grype scan still runs.

To deactivate this check, set the environment variable `GRYPE_CHECK_FOR_APP_UPDATE` to `false` by using a package overlay:

1. Create a secret that contains the ytt overlay to add the Grype environment variable to the ScanTemplates.

   ```
   apiVersion: v1
   kind: Secret
   metadata:
     name: grype-airgap-deactivate-cli-check-overlay
   ```

```
  namespace: tap-install #! namespace where tap is installed
stringData:
  patch.yaml: |
    #@ load("@ytt:overlay", "overlay")

    #@overlay/match by=overlay.subset({"kind":"ScanTemplate"}),expects="1+"
    ---
    spec:
      template:
        initContainers:
          #@overlay/match by=overlay.subset({"name": "scan-plugin"}), expects
="1+"
          - name: scan-plugin
            #@overlay/match missing_ok=True
            env:
              #@overlay/append
              - name: GRYPE_CHECK_FOR_APP_UPDATE
                value: "false"
```

2. Configure `tap-values.yaml` to use `package_overlays`. Add the following to your `tap-values.yaml` file:

```
package_overlays:
  - name: "grype"
    secrets:
        - name: "grype-airgap-deactivate-cli-check-overlay"
```

3. Update Tanzu Application Platform:

```
tanzu package installed update tap -f tap-values.yaml -n tap-install
```

Database is too old

Symptom

Error message:

```
1 error occurred:
  * db could not be loaded: the vulnerability database was built N days/weeks ago (max
allowed age is 5 days)
```

Cause

Grype needs up-to-date vulnerability information to provide accurate matches. By default, it fails to run if the local database was not built in the last 5 days.

Solution

There are two options to resolve this:

1. Stale databases weaken your security posture. VMware recommends updating the database daily.
2. If you cannot update the database daily, configure the data staleness check using the environment variable `GRYPE_DB_MAX_ALLOWED_BUILT_AGE` and apply a package overlay:
    1. Create a secret that contains the ytt overlay to add the Grype environment variable to the ScanTemplates.

```
apiVersion: v1
kind: Secret
metadata:
  name: grype-airgap-override-stale-db-overlay
  namespace: tap-install #! namespace where tap is installed
stringData:
  patch.yaml: |
    #@ load("@ytt:overlay", "overlay")

    #@overlay/match by=overlay.subset({"kind":"ScanTemplate"}),expects="1
+"
    ---
    spec:
      template:
        initContainers:
          #@overlay/match by=overlay.subset({"name": "scan-plugin"}), exp
ects="1+"
          - name: scan-plugin
            #@overlay/match missing_ok=True
            env:
              #@overlay/append
              - name: GRYPE_DB_MAX_ALLOWED_BUILT_AGE #! see note on best
practices
                value: "120h"
```

Note

The default maximum allowed built age of Grype's vulnerability database is 5 days. This means that scanning with a 6 day old database causes the scan to fail. You can use the `GRYPE_DB_MAX_ALLOWED_BUILT_AGE` parameter to override the default in accordance with your security posture.

2. Configure `tap-values.yaml` to use `package_overlays`. Add the following to your `tap-values.yaml` file:

```
package_overlays:
  - name: "grype"
    secrets:
        - name: "grype-airgap-override-stale-db-overlay"
```

3. Update Tanzu Application Platform:

```
tanzu package installed update tap -f tap-values.yaml -n tap-install
```

Vulnerability database is invalid

Symptom

Error message:

```
scan-pod[scan-plugin]  1 error occurred:
scan-pod[scan-plugin]  * failed to load vulnerability db: vulnerability database is in
valid (run db update to correct): database metadata not found: /.cache/grype/db/5
```

Solution

Examine the `listing.json` file you created. This matches the format of the listing file. The listing file is located at Anchore Grype's public endpoint. See the Grype README.md in GitHub.

An example `listing.json`:

```
{
  "available": {
    "5": [
      {
        "built": "2023-03-28T01:29:38Z",
        "version": 5,
        "url": "https://toolbox-data.anchore.io/grype/databases/vulnerability-db_v5_20
23-03-28T01:29:38Z_e49d318c32a6113eed07.tar.gz",
        "checksum": "sha256:408ce2932f04dee929a5df524e92494f2d635c6b19e30ff9f0a50425b1
fc29a1"
      },
      .....
    ]
  }
}
```

Where:

- `5` refers to the Grype vulnerability database schema.
- `built` is the build timestamp in the format `yyyy-MM-ddTHH:mm:ssZ`.
- `url` is the download URL for the tarball containing the database. This points at your internal endpoint. The tarball contains the following files:
    - `vulnerability.db` is an SQLite file that is Grype's vulnerability database. Each time the data shape of the vulnerability database changes, a new schema is created. Different Grype versions require specific database schema versions. For example, Grype `v0.54.0` requires database schema version v5.
    - `metadata.json` file
- `checksum` is the SHA used to verify the database's integrity.

Verify these possible reasons why the vulnerability database is not valid:

1. The database schema is invalid. Confirm that the required database schema for the installed Grype version is used. Confirm that the top level version key matches the nested `version`. For example, the top level version `1` in the following snippet does not match the nested `version: 5`.

    ```
    {
      "available": {
        "1": [{
              "built": "2023-02-08T08_17_20Z",
              "version": 5,
              "url": "https://INTERNAL-ENDPOINT/PATH-TO-TARBALL/vulnerability-db_v
    5_2023-02-08T08_17_20Z_6ef73016d160043c630f.tar.gz",
              "checksum": "sha256:aab8d369933c845878ef1b53bb5c26ee49b91ddc5cd87c9e
    b57ffb203a88a72f"
        }]
      }
    }
    ```

    Where `PATH-TO-TARBALL` is the path to the tarball containing the vulnerability database.

    As stale databases weaken your security posture, VMware recommends using the newest entry of the relevant schema version in the `listing.json` file. See Anchore's grype-db in GitHub.

2. The `built` parameters in the `listing.json` file are incorrectly formatted. The proper format is `yyyy-MM-ddTHH:mm:ssZ`.
3. The `url` that you modified to point at an internal endpoint is not reachable from the cluster. For information about verifying connectivity, see Debug Grype database in a cluster.
4. Verify if there are syntax errors in the listing.json:

   ```
   grype db check
   ```

5. Validate the configured listing.json:

   ```
   grype db list -o raw
   ```

Debug Grype database in a cluster

1. Describe the failed source scan or image scan to verify the name of the ScanTemplate being used.
   - For `sourcescan`, run:

     ```
     kubectl describe sourcescan SCAN-NAME -n DEV-NAMESPACE
     ```

   - For `imagescan`, run:

     ```
     kubectl describe imagescan SCAN-NAME -n DEV-NAMESPACE
     ```

   Where `SCAN-NAME` is the name of the source or image scan that failed.
2. Pause reconciliation of the `grype.scanning.apps.tanzu.vmware.com` package:

   ```
   kctrl package installed pause -i <PACKAGE-INSTALL-NAME> -n tap-install
   ```

   Where `PACKAGE-INSTALL-NAME` is the name of the `grype.scanning.apps.tanzu.vmware.com` package, for example, grype
3. Edit the ScanTemplate's `scan-plugin` container to include a "sleep" entrypoint which allows you to troubleshoot inside the container:

   ```
   - name: scan-plugin
     volumeMounts:
       ...
     image: #@ data.values.scanner.image
     imagePullPolicy: IfNotPresent
     env:
       ...
     command: ["/bin/bash"]
     args:
     - "sleep 1800" # insert 30 min sleep here
   ```

4. Re-run the scan.
5. Get the name of the `scan-plugin` pod.

   ```
   kubectl get pods -n DEV-NAMESPACE
   ```

6. Get a shell to the container.

   ```
   kubectl exec --stdin --tty SCAN-PLUGIN-POD -c step-scan-plugin -- /bin/bash
   ```

Where `SCAN-PLUGIN-POD` is the name of the `scan-plugin` pod. For more information, see the Kubernetes documentation.

7. Inside the container, run Grype CLI commands to report database status and verify connectivity from the cluster to the mirror. See the Grype documentation in GitHub.
    - Report current status of Grype's database, such as location, build date, and checksum:

      ```
      grype db status
      ```

8. Ensure that the built parameters in the `listing.json` have timestamps in this proper format `yyyy-MM-ddTHH:mm:ssZ`.
9. After you complete troubleshooting, to trigger reconciliation, run:

   ```
   kctrl package installed kick -i <PACKAGE-INSTALL-NAME> -n tap-install
   ```

   Where `PACKAGE-INSTALL-NAME` is the name of the `grype.scanning.apps.tanzu.vmware.com` package, such as Grype.

Grype package overlays are not applied to scantemplates created by Namespace Provisioner

If you used the Namespace Provisioner to provision a new developer namespace and want to apply a package overlay for Grype, see Import overlay secrets.

Triage and Remediate CVEs for Supply Chain Security Tools - Scan

This topic explains how you can triage and remediate CVEs related to SCST - Scan.

Confirm that Supply Chain stopped due to failed policy enforcement

To confirm that Supply Chain failure is related to policy enforcement:

1. Verify that the status of the workload is `MissingValueAtPath` due to waiting on a `.status.compliantArtifact` from either the SourceScan or ImageScan:

   ```
   kubectl describe workload WORKLOAD-NAME -n DEVELOPER-NAMESPACE
   ```

2. Describe the SourceScan or ImageScan to determine what CVE(s) violated the ScanPolicy:

   ```
   kubectl describe sourcescan NAME -n DEVELOPER-NAMESPACE
   kubectl describe imagescan NAME -n DEVELOPER-NAMESPACE
   ```

Triage

The goal of triage is to analyze and prioritize the reported vulnerability data to discover the appropriate course of action to take at the remediation step. To remediate efficiently and appropriately, you need context on the vulnerabilities that are blocking your supply chain, the packages that are affected, and the impact they can have.

During triage, review which packages are impacted by the CVEs that violated your scan policy. Use the Supply Chain Choreographer in the Tanzu Developer Portal to visualize your supply chain,

including scans, scan policy, and CVEs. You can also use the Tanzu CLI Insight plug-in to query packages, vulnerabilities, and create vulnerability analysis. See Tanzu CLI Insight plug-in.

During this stage, VMware recommends reviewing information pertaining to the CVEs from sources such as the National Vulnerability Database or the release page of a package.

Remediation

After triage is complete, the next step is to remediate the blocking vulnerabilities quickly. Some common methods for CVE remediation are as follows:

- Updating the affected component to remove the CVE
- Amending the scan policy with an exception if you decide to accept the CVE and unblock your supply chain

Updating the affected component

Vulnerabilities that occur in older versions of a package might be resolved in later versions. Apply a patch by upgrading to a later version. You can further adopt security best practices by using your project's package manager tools, such as `go mod graph` for projects in Go, to identify transitive or indirect dependencies that can affect CVEs.

Amending the scan policy

If you decide to proceed without remediating the CVE, for example, when a CVE is evaluated to be a false positive or when a fix is not available, you can amend the ScanPolicy to ignore one or more CVEs. For information about common scanner limitations, see Note on Vulnerability Scanners. For information about templates, see Writing Policy Templates.

Under RBAC, users with the `app-operator-scanning` role that is part of the `app-operator` aggregate role, have permission to edit the ScanPolicy. See Detailed role permissions breakdown.

Observe Supply Chain Security Tools - Scan

This topic outlines observability and troubleshooting methods and issues you can use with SCST - Scan components.

Observability

The scans run inside a Tekton TaskRun where the TaskRun creates a pod. Both the TaskRun and pod are cleaned up after completion.

Before applying a new scan, you can set a watch on the TaskRuns, Pods, SourceScans, and Imagescans to observe their progression:

```
watch kubectl get sourcescans,imagescans,pods,taskruns,scantemplates,scanpolicies -n D
EV-NAMESPACE
```

Where `DEV-NAMESPACE` is the developer namespace where the scanner is installed.

Troubleshoot Supply Chain Security Tools - Scan

This topic describes troubleshooting methods you can use with Supply Chain Security Tools (SCST) - Scan.

Debugging commands

Run these commands to get more logs and details about the errors around scanning. The TaskRuns and pods persist for a predefined amount of seconds before getting deleted. (`deleteScanJobsSecondsAfterFinished` is the tap pkg variable that defines this)

Debugging Tekton TaskRun

To retrieve TaskRun events:

```
kubectl describe taskrun TASKRUN-NAME -n DEV-NAMESPACE
```

Where:

- `TASKRUN-NAME` is the name of the TaskRun.
- `DEV-NAMESPACE` is the name of the developer namespace you want to use.

Debugging Scan pods

Run the following to get error logs from a pod when scan pods are in a failing state:

```
kubectl logs scan-pod-name -n DEV-NAMESPACE
```

Where `DEV-NAMESPACE` is the name of the developer namespace you want to use.

See here for more details about debugging Kubernetes pods.

The following is an example of a successful scan run output:

```
scan:
  cveCount:
    critical: 20
    high: 120
    medium: 114
    low: 9
    unknown: 0
  scanner:
    name: Grype
    vendor: Anchore
    version: v0.37.0
  reports:
  - /workspace/scan.xml
eval:
  violations:
  - CVE node-fetch GHSA-w7rc-rwvf-8q5r Low
store:
  locations:
  - https://metadata-store-app.metadata-store.svc.cluster.local:8443/api/sources?repo=
hound&sha=5805c6502976c10f5529e7f7aeb0af0c370c0354&org=houndci
```

A scan run that has an error means that one of the init containers: `scan-plugin`, `metadata-store-plugin`, `compliance-plugin`, `summary`, or any other additional containers had a failure.

To inspect for a specific init container in a pod:

```
kubectl logs scan-pod-name -n DEV-NAMESPACE -c init-container-name
```

Where `DEV-NAMESPACE` is the name of the developer namespace you want to use.

See Debug Init Containers in the Kubernetes documentation for debug init container tips.

Debugging SourceScan and ImageScan

To retrieve status conditions of an SourceScan and ImageScan, run:

```
kubectl describe sourcescan SOURCE-SCAN -n DEV-NAMESPACE
```

Where:

- `DEV-NAMESPACE` is the name of the developer namespace you want to use.
- `SOURCE-SCAN` is the name of the SourceScan you want to use.

```
kubectl describe imagescan IMAGE-SCAN -n DEV-NAMESPACE
```

Where:

- `DEV-NAMESPACE` is the name of the developer namespace you want to use.
- `IMAGE-SCAN` is the name of the ImageScan you want to use.

Under `Status.Conditions`, for a condition look at the “Reason”, “Type”, “Message” values that use the keyword “Error” to investigate issues.

Debugging Scanning within a SupplyChain

See here for Tanzu workload commands for tailing build and runtime logs and getting workload status and details.

Viewing the Scan-Controller manager logs

To retrieve scan-controller manager logs:

```
kubectl -n scan-link-system logs -f deployment/scan-link-controller-manager -c manager
```

Restarting Deployment

If you encounter an issue with the scan-link controller not starting, run the following to restart the deployment to see if it’s reproducible or flaking upon starting:

```
kubectl rollout restart deployment scan-link-controller-manager -n scan-link-system
```

Troubleshooting scanner to MetadataStore configuration

Insight CLI failed to post scan results to metadata store due to failed certificate verification

If you encounter this issue:

```
✖  Error: Post "https://metadata-store.tap.tanzu.example.com/api/sourceReport?": tls:
failed to verify certificate: x509: certificate signed by unknown authority
```

To ensure that the `caSecret` from the scanner `DEV-NAMESPACE` matches the `caSecret` from the `METADATASTORE-NAMESPACE` namespace:

1. In a single cluster, the connection between the scanning pod and the metadata store happens inside the cluster and does not pass through ingress. This is automatically configured. You do not need to provide an ingress connection to the store. If you provided an ingress connection to the store, delete it.
2. Get the `caSecret.name` depending if your setup is single or multicluster.
    1. If you are using a single cluster setup, the default value for `grype.metadataStore.caSecret.name` is `app-tls-cert`. See Install Supply Chain

Security Tools - Scan.

2. If you are using a multicluster setup, retrieve `grype.metadataStore.caSecret.name` from the Grype config:

```
grype:
metadataStore:
  caSecret:
    name: store-ca-cert
    importFromNamespace: metadata-store-secrets
```

Note `caSecret.name` is set to `store-ca-cert`. See Set up multicluster Supply Chain Security Tools (SCST) - Store.

3. Verify that the `CA-SECRET` secret exists in the `DEV-NAMESPACE`.

```
kubectl get secret CA-SECRET -n DEV-NAMESPACE
```

4. If the secret `CA-SECRET` doesn't exist in your `DEV-NAMESPACE`, verify that the `CA-SECRET` exists in the `METADATASTORE-NAMESPACE` namespace:

```
kubectl get secret CA-SECRET -n METADATASTORE-NAMESPACE
```

Where `METADATASTORE-NAMESPACE` is the namespace that contains the secret `CA-SECRET`. If you are using a single cluster, it is configured using the `metadata-store` namespace. If multicluster, it is configured using the `metadata-store-secrets`.

- If `CA-SECRET` doesn't exist in the metadata store namespace, configure the certificate. See Custom certificate configuration.

5. Check if the secretexport and secretimport exist and are reconciling successfully:

```
kubectl get secretexports.secretgen.carvel.dev -n `METADATASTORE-NAMESPACE`
kubectl get secretimports.secretgen.carvel.dev -n `DEV-NAMESPACE`
```

- SCST - Store creates the single cluster secretexport by default. See Deployment details and configuration.
- For information about creating the multicluster secretexport, see Set up multicluster Supply Chain Security Tools (SCST) - Store.

6. Verify that the `ca.crt` field in both secrets from `METADATASTORE-NAMESPACE` and `DEV-NAMESPACE` match, or that the `ca.crt` field of the secret in the `METADATASTORE-NAMESPACE` includes the `ca.crt` field of the `DEV-NAMESPACE` secret.

Confirm this by base64 decoding both secrets and verifying that there is a match:

```
kubectl get secret CA-SECRET -n DEV-NAMESPACE -o json | jq -r '.data."ca.crt"'
| base64 -d
kubectl get secret CA-SECRET -n METADATASTORE-NAMESPACE -o json | jq -r '.dat
a."ca.crt"' | base64 -d
```

The certificates in the `METADATASTORE-NAMESPACE` and `DEV-NAMESPACE` must have a match for the scanner to connect to the metadata-store.

Troubleshooting issues

Source scan missing in supply chain

The source scan step is opt-in in Tanzu Application Platform 1.6 to better support languages that resolve dependencies at build time. For information and how to opt-in to source scanning in the

out-of-the-box test and scan supply chain, see Scan Types for Supply Chain Security Tools - Scan.

Troubleshooting Grype in air gap Environments

For information about issues with Grype in air gap environments, see Use vulnerability scanning in offline and air-gapped environments.

Missing target SSH secret

Scanning source code from a private source repository requires an SSH secret present in the namespace and referenced as `grype.targetSourceSshSecret` in `tap-values.yaml`. See Installing the Tanzu Application Platform Package and Profiles.

If a private source scan is triggered and the secret cannot be found, the scan pod includes a `FailedMount` warning in Events with the message `MountVolume.SetUp failed for volume "ssh-secret" : secret "secret-ssh-auth" not found`, where `secret-ssh-auth` is the value specified in `grype.targetSourceSshSecret`.

Missing target image pull secret

Scanning an image from a private registry requires an image pull secret to exist in the Scan CRs namespace and be referenced as `grype.targetImagePullSecret` in `tap-values.yaml`. See Installing the Tanzu Application Platform Package and Profiles.

If a private image scan is triggered and the secret is not configured, the scan TaskRun's pod's `step-scan-plugin` container fails with the following error:

```
Error: GET https://dev.registry.tanzu.vmware.com/v2/vse-dev/spring-petclinic/manifest
s/sha256:128e38c1d3f10401a595c253743bee343967c81e8f22b94e30b2ab8292b3973f: UNAUTHORIZE
D: unauthorized to access repository: vse-dev/spring-petclinic, action: pull: unauthor
ized to access repository: vse-dev/spring-petclinic, action: pull
```

Deactivate Supply Chain Security Tools (SCST) - Store

SCST - Store is required to install SCST - Scan. If you install without the SCST - Store, you must edit the configurations to deactivate the Store:

```
---
metadataStore:
  url: ""
```

Install the package with the edited configurations by running:

```
tanzu package install scan-controller \
  --package scanning.apps.tanzu.vmware.com \
  --version VERSION \
  --namespace tap-install \
  --values-file tap-values.yaml
```

Resolving Incompatible Syft Schema Version

You might encounter the following error:

```
The provided SBOM has a Syft Schema Version which doesn't match the version that is su
pported by Grype...
```

This means that the Syft Schema Version from the provided SBOM doesn't match the version supported by the installed `grype-scanner`. There are two different methods to resolve this incompatibility issue:

- Install a version of Tanzu Build Service that provides an SBOM with a compatible Syft Schema Version. This is the method VMware recommends.
- Deactivate the `failOnSchemaErrors` in `grype-values.yaml`. See Install Supply Chain Security Tools - Scan. Although this change bypasses the check on Syft Schema Version, it does not resolve the incompatibility issue and produces a partial scanning result.

  ```
  syft:
    failOnSchemaErrors: false
  ```

Resolving incompatible scan policy

If your scan policy appears to not be enforced, it might be because the Rego file defined in the scan policy is incompatible with the scanner that is being used. For example, the Grype Scanner outputs in the CycloneDX XML format while the Snyk Scanner outputs SPDX JSON.

See Sample ScanPolicy for Snyk in SPDX JSON format for an example of a ScanPolicy formatted for SPDX JSON.

Could not find CA in secret

If you encounter the following issue, it might be due to not exporting `app-tls-cert` to the correct namespace:

```
{"level":"error","ts":"2022-06-08T15:20:48.43237873Z","logger":"setup","msg":"Could no
t find CA in Secret","err":"unable to set up connection to Supply Chain Security Tools
- Store"}
```

Configure `ns_for_export_app_cert` in your `tap-values.yaml` file.

```
metadata_store:
  ns_for_export_app_cert: "DEV-NAMESPACE"
```

Where `DEV-NAMESPACE` is the name of the developer namespace you want to use.

If there are multiple developer namespaces, use `ns_for_export_app_cert: "*"`.

Blob Source Scan is reporting wrong source URL

A Source Scan for a blob artifact can cause reporting in the `status.artifact` and `status.compliantArtifact` the wrong URL for the resource, passing the remote SSH URL instead of the cluster local fluxcd one. One symptom of this issue is the `image-builder` failing with a `ssh:// is an unsupported protocol` error message.

You can confirm you're having this problem by running `kubectl describe` in the affected resource and comparing the `spec.blob.url` value against the `status.artifact.blob.url`. The problem occurs if they are different URLs. For example:

```
kubectl describe sourcescan SOURCE-SCAN-NAME -n DEV-NAMESPACE
```

Where:

- `SOURCE-SCAN-NAME` is the name of the source scan you want to configure.
- `DEV-NAMESPACE` is the name of the developer namespace you want to use. And compare the output:

```
...
spec:
  blob:
```

```
    ...
    url: http://source-controller.flux-system.svc.cluster.local./gitrepository/sample/
repo/8d4cea98b0fa9e0112d58414099d0229f190f7f1.tar.gz
    ...
status:
  artifact:
    blob:
      ...
      url: ssh://git@github.com:sample/repo.git
  compliantArtifact:
    blob:
      ...
      url: ssh://git@github.com:sample/repo.git
```

Workaround: This problem happens in SCST - Scan `v1.2.0` when you use a Grype Scanner ScanTemplates earlier than `v1.2.0`, because this is a deprecated path. To fix this problem, upgrade your Grype Scanner deployment to `v1.2.0` or later. See Upgrading Supply Chain Security Tools - Scan for step-by-step instructions.

Resolving failing scans that block a Supply Chain

If the Supply Chain is not progressing due to CVEs found in either the SourceScan or ImageScan, see the CVE triage workflow in Triaging and Remediating CVEs.

Policy not defined in the Tanzu Developer Portal

If you encounter `No policy has been defined`, it might be because the Tanzu Application Platform GUI is unable to view the Scan Policy resource.

Confirm that the Scan Policy associated with a SourceScan or ImageScan exists. For example, the `scanPolicy` in the scan matches the name of the Scan Policy.

```
kubectl describe sourcescan NAME -n DEV-NAMESPACE
kubectl describe imagescan NAME -n DEV-NAMESPACE
kubectl get scanpolicy NAME -n DEV-NAMESPACE
```

Where `DEV-NAMESPACE` is the name of the developer namespace you want to use.

Add the `app.kubernetes.io/part-of` label to the Scan Policy. See Enable Tanzu Application Platform GUI to view ScanPolicy Resource.

Lookup error when connecting to SCST - Store

If your scan pod is failing, you might see the following connection error in the logs:

```
dial tcp: lookup metadata-store-app.metadata-store.svc.cluster.local on 10.100.0.10:5
3: no such host
```

A connection error while attempting to connect to the local cluster URL causes this error. If this is a multicluster deployment, set the `grype.metadataStore.url` property in your Build profile `values.yaml`. You must set the ingress domain of SCST - Store which is deployed in the View cluster. For information about this configuration, see How to configure Grype in the Build profile values file.

Sourcescan error with SCST - Store endpoint without a prefix

If your Source Scan resource is failing, the status might show this error:

```
Error: endpoint require 'http://' or 'https://' prefix
```

This is because the `grype.metadataStore.url` value in the Tanzu Application Platform profile `values.yaml` was not configured with the correct prefix. Verify that the URL starts with either `http://` or `https://`.

Deprecated pre-v1.2 templates

If the scan phase is in `Error` and the status condition message is:

```
Summary logs could not be retrieved: . error opening stream pod logs reader: container
summary is not valid for pod scan-grypeimagescan-sample-public-zmj2g-hqv5g
```

This error might be a consequence of using Grype Scanner ScanTemplates shipped with SCST - Scan v1.1 or earlier. These ScanTemplates are deprecated and are not supported in Tanzu Application Platform v1.4.0 and later.

There are two options to resolve this issue:

- Option 1: Upgrade to the latest Grype Scanner version. This automatically replaces the old ScanTemplates with the upgraded ScanTemplates.
- Option 2: Create a ScanTemplate. Follow the steps in Create a scan template.

Incorrectly configured self-signed certificate

The following error in the pod logs indicate that the self-signed certificate might be incorrectly configured:

```
x509: certificate signed by unknown authority
```

To resolve this issue, ensure that `shared.ca_cert_data` contains the required certificate. For an example of setting up the shared self-signed certificate, see Build profile.

For information about `shared.ca_cert_data`, see View possible configuration settings for your package.

Unable to pull scan controller and scanner images from a specified registry

The `docker` field and related sub-fields by SCST - Scan Controller, Grype Scanner, or Snyk Scanner are deprecated in Tanzu Application Platform v1.4.0 and removed in Tanzu Application Platform v1.9.1. Previously these fields might be used to populate the `registry-credentials` secret. You might encounter the following error during installation:

```
UNAUTHORIZED: unauthorized to access repository
```

The recommended migration path for users setting up their namespaces manually is to add registry credentials to both the developer namespace and the `scan-link-system` namespace, using these instructions.

Important

This step does not apply to users who used `--export-to-all-namespaces` when setting up the Tanzu Application Platform package repository.

Grype database not available

Before running a scan, the Grype scanner downloads a copy of its database. If the database fails to download, the following log entry might appear.

```
Vulnerability DB [no update available] New version of grype is available: 0.50.2 [000
0] WARN unable to check for vulnerability database update 1 error occurred: * failed t
o load vulnerability db: vulnerability database is corrupt (run db update to correct):
database metadata not found: ~/Library/Caches/grype/db/3
```

To resolve this issue, ensure that Grype has access to its vulnerability database:

- If you set up a mirror of the vulnerability database in Use vulnerability scanning in offline and air-gapped environments, verify that it is populated and reachable.
- If you did not set up a mirror, Grype manages its database behind the scenes. Verify that the cluster has access to https://anchore.com/.

This issue is unrelated to Supply Chain Security Tools for Tanzu – Store.

Scanner Pod restarts once in SCST - Scan `v1.5.0` or later

For SCST - Scan `v1.5.0` or later, you see scanner pods restart:

```
Pods
   NAME                                READY   STATUS      RESTARTS   AGE
   my-scan-45smk-pod                   0/9     Completed   1          14m
```

One restart in scanner pods is expected with successful scans. To support Tanzu Service Mesh (TSM) integration, jobs were replaced with TaskRuns. This restart is an artifact of how Tekton cleans up sidecar containers by patching the container specifications.

Reconciliation of SCST - Scan fails when upgrading to v1.9

When upgrading the SCST - Scan from a previous version to v1.9, you might see a reconciliation failure similar to:

```
NAME                                PACKAGE-NAME
PACKAGE-VERSION                 STATUS
scanning                            scanning.apps.tanzu.vmware.com
1.9.1-build.36081392+c072d305  Reconcile failed
```

If getting the package by running the command `tanzu package installed get scanning -n tap-install` you might see an error similar to:

```
STATUS:                  Reconcile failed
CONDITIONS:              - type: ReconcileFailed
  status: "True"
  reason: ""
  message: Error (see .status.usefulErrorMessage for details)
USEFUL-ERROR-MESSAGE:    ytt: Error: Overlaying data values (in following order: addit
ional data values):
One or more data values were invalid
====================================Given data value is not declared in schema
values.yaml:
    |
  2 |   url: ""
    |    = found: url
    = expected: a map item with the key named "exports" (from .ytt/data.yaml:52)
```

This is because the field `scanning.metadataStore.url` is removed. If this field is present in `tap-values.yaml` provided for the upgrade, the reconciliation fails. To resolve this problem, remove the field from the values file and run the upgrade command again.

Scanning in a cluster with restricted Kubernetes Pod Security Standards

As part of compliance with the restricted profile Kubernetes Pod Security Standards, you must set the `securityContext` of containers and initContainers. This applies to the `prepare` initContainers created by Tekton. When a pod does not meet pod Security Standards, it is not created and vulnerability scanning cannot proceed. For more information, see the Kubernetes documentation.

You might see an error message similar to the following when describing the TaskRun:

```
"scan-source-scan-with-passing-policy-zx46t-pod" is forbidden: violates PodSecurity "r
estricted:latest": allowPrivilegeEscalation != false (container "prepare" must set sec
urityContext.allowPrivilegeEscalation=false), unrestricted capabilities (container "pr
epare" must set securityContext.capabilities.drop=["ALL"]), seccompProfile (pod or con
tainer "prepare" must set securityContext.seccompProfile.type to "RuntimeDefault" or
"Localhost"). Maybe invalid TaskSpec. ScanPodError PodNotFound: no pod found
```

1. Update your Tekton Pipelines package configuration in your `tap-values.yaml` file with the following changes.

   ```
   tekton_pipelines:
       feature_flags:
           set_security_context: "true"
   ```

   Setting the `securityContext` resolves the `prepare` initContainer violation.

2. Update your Tanzu Application Platform installation by running:

   ```
   tanzu package installed update tap -p tap.tanzu.vmware.com -v TAP-VERSION  --va
   lues-file tap-values.yaml -n tap-install
   ```

   Where `TAP-VERSION` is the version of Tanzu Application Platform installed.

3. Re-run the scan.

Troubleshoot Rego files with a scan policy for Supply Chain Security Tools - Scan

This topic describes how you can use an example output to troubleshoot your Rego file for SCST - Scan. You use a Rego file in a scan policy custom resource. See Enforce compliance policy using Open Policy Agent.

For information about how to write Rego, see Open Policy Agent documentation.

Using the Rego playground

Use the Rego Playground, to evaluate your Rego file against an input. In this example, use the example output of an image or source scan custom resource.

Sample input in CycloneDX's XML re-encoded as JSON format

The following is an example scan custom resource output in CycloneDX's XML structure re-encoded as JSON. This example output contains CVEs at low, medium, high, and critical severities.

To troubleshoot using this example output:

1. Paste your Rego file and the example output into the Rego Playground.
2. Evaluate your Rego file against the example output and verify that your Rego file detects the intended CVEs. See this Rego example.

```

Example input in SPDX JSON format

The example in this section is a modified scan custom resource input, in `.spdx.json`, that contains CVEs at low, medium, high, and critical severities. You can use this example input to evaluate your Rego file.

To troubleshoot using this example output:

1. Paste your Rego file and the example input into the Rego Playground.
2. Evaluate your Rego file against the output and verify that your Rego file detects the intended CVEs. See this Rego example.

Configure code repositories and image artifacts for Supply Chain Security Tools - Scan

This topic describes how you can configure code repositories and image artifacts for SCST - Scan.

Prerequisite

Both the source and image scans require you to define a `ScanTemplate`. Run `kubectl get scantemplates` for the ScanTemplates provided with the scanner installation. For information about how to reference these ScanTemplates, see How to create a ScanTemplate.

Deploy scan custom resources

The scan controller defines two custom resources to create scans:

- SourceScan
- ImageScan

SourceScan

The `SourceScan` custom resource helps you define and trigger a scan for a given repository. You can deploy `SourceScan` with source code existing in a public repository or a private one:

1. Create the `SourceScan` custom resource.

   Example:

   ```
   apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
   kind: SourceScan
   metadata:
     # set the name of the source scan CR
     name: sample-source-scan
   spec:
     # At least one of these fields (blob or git) must be defined.
     blob:
       # location to a file with the source code compressed (supported files: .ta
   r.gz)
       url:
     git:
       # A multiline string defining the known hosts that are going to be used for
   the SSH client on the container
       knownHosts:
       # Branch, tag, or commit digest
       revision:
       # The name of the kubernetes secret containing the private SSH key informat
   ion.
       sshKeySecret:
       # A string containing the repository URL.
       url:
       # The username needed to SSH connection. Default value is “git”
       username:

     # A string defining the name of an existing ScanTemplate custom resource.
     scanTemplate: my-scan-template

      # A string defining the name of an existing ScanPolicy custom resource. See
   "Enforcement Policies (OPA)" section.
     scanPolicy: my-scan-policy
   ```

2. Deploy the `SourceScan` custom resource to the desired namespace on cluster by running:

   ```
   kubectl apply -f <path_to_the_cr>/<custom_resource_filename>.yaml -n <desired_n
   amespace>
   ```

After the scanning completes, the following fields appear in the custom resource and are filled by the scanner:

```
# These fields are populated from the source scan results
status:
  # The source code information as provided in the CycloneDX `bom>metadata>comp
onent>*` fields
  artifact:
    blob:
      url:
    git:
      url:
      revision:

  # An array populated with information about the scanning status
  # and the policy validation. These conditions might change in the lifecycle
  # of the scan, refer to the "View Scan Status and Understanding Conditions" s
ection to learn more.
  conditions: []

  # The URL of the vulnerability scan results in the Metadata Store integratio
n.
  # Only available when the integration is configured.
  metadataUrl:

  # When the CRD is updated to point at new revisions, this lets you know
  # if the status reflects the latest one or not
  observedGeneration: 1
  observedPolicyGeneration: 1
  observedTemplateGeneration: 1

  # The latest datetime when the scanning was successfully finished.
  scannedAt:
  # Information about the scanner that was used for the latest image scan.
  # This information reflects what's in the CycloneDX `bom>metadata>tools>tool>
*` fields.
  scannedBy:
    scanner:
      # The name of the scanner that was used.
      name: my-image-scanner

      # The name of the scanner's development company or team
      vendor: my-image-scanner-provider

      # The version of the scanner used.
      version: 1.0.0
```

ImageScan

The `ImageScan` custom resource helps you define and trigger a scan for a given image. You can deploy `ImageScan` with an image existing in a public or private registry:

1. Create the `ImageScan` custom resource.

   Example:

```
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ImageScan
metadata:
  # set the name of the image scan CR
  name: sample-image-scan
spec:
  registry:
    # Required. A string containing the image name can additionally add its tag
```

```
or its digest
    image: nginx:1.16

    # A string containing the secret needed to pull the image from a private re
gistry.
    # The secret needs to be deployed in the same namespace as the ImageScan
    imagePullSecret: my-image-pull-secret

  # A string defining the name of an existing ScanTemplate custom resource. See
"How To Create a ScanTemplate" section.
  scanTemplate: my-scan-template

  # A string defining the name of an existing ScanPolicy custom resource. See
"Enforcement Policies (OPA)" section.
  scanPolicy: my-scan-policy
```

2. Deploy the `ImageScan` custom resource to the desired namespace on cluster by running:

```
kubectl apply -f <path_to_the_cr>/<custom_resource_filename>.yaml -n <desired_n
amespace>
```

After the scanning completes, the following fields appear in the custom resource and are filled by the scanner:

```
 # These fields are populated from the image scan results
status:
  artifact:
    registry:
      # The image name with its digest as provided in the CycloneDX `bom>metada
ta>component>*` fields
      image:
      imagePullSecret:

  # An array that is populated with information about the scanning status
  # and the policy validation. These conditions might change in the lifecycle
  # of the scan, refer to the "View Scan Status and Understanding Conditions" s
ection to learn more.
  conditions: []

  # The URL of the vulnerability scan results in the Metadata Store integratio
n.
  # Only available when the integration is configured.
  metadataUrl:

  # When the CRD is updated to point at new revisions, this lets you know
  # whether the status reflects the latest one
  observedGeneration: 1
  observedPolicyGeneration: 1
  observedTemplateGeneration: 1

  # The latest datetime when the scanning was successfully finished.
  scannedAt:
  # Information about the scanner used for the latest image scan.
  # This information reflects what's in the CycloneDX `bom>metadata>tools>tool>
*` fields.
  scannedBy:
    scanner:
      # The name of the scanner that was used.
      name: my-image-scanner

      # The name of the scanner's development company or team
      vendor: my-image-scanner-provider
```

```
      # The version of the scanner used.
      version: 1.0.0
```

onent>*` fields
  artifact:
    blob:
      url:
    git:
      url:
      revision:

  # An array populated with information about the scanning status
  # and the policy validation. These conditions might change in the lifecycle
  # of the scan, refer to the "View Scan Status and Understanding Conditions" s
ection to learn more.
  conditions: []

  # The URL of the vulnerability scan results in the Metadata Store integratio
n.
  # Only available when the integration is configured.
  metadataUrl:

  # When the CRD is updated to point at new revisions, this lets you know
  # if the status reflects the latest one or not
  observedGeneration: 1
  observedPolicyGeneration: 1
  observedTemplateGeneration: 1

  # The latest datetime when the scanning was successfully finished.
  scannedAt:
  # Information about the scanner that was used for the latest image scan.
  # This information reflects what's in the CycloneDX `bom>metadata>tools>tool>
*` fields.
  scannedBy:
    scanner:
      # The name of the scanner that was used.
      name: my-image-scanner

      # The name of the scanner's development company or team
      vendor: my-image-scanner-provider

      # The version of the scanner used.
      version: 1.0.0
```

ImageScan

The `ImageScan` custom resource helps you define and trigger a scan for a given image. You can deploy `ImageScan` with an image existing in a public or private registry:

1. Create the `ImageScan` custom resource.

   Example:

```
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ImageScan
metadata:
  # set the name of the image scan CR
  name: sample-image-scan
spec:
  registry:
    # Required. A string containing the image name can additionally add its tag
or its digest
    image: nginx:1.16

    # A string containing the secret needed to pull the image from a private re
gistry.
    # The secret needs to be deployed in the same namespace as the ImageScan
    imagePullSecret: my-image-pull-secret

  # A string defining the name of an existing ScanTemplate custom resource. See
"How To Create a ScanTemplate" section.
  scanTemplate: my-scan-template

  # A string defining the name of an existing ScanPolicy custom resource. See
"Enforcement Policies (OPA)" section.
  scanPolicy: my-scan-policy
```

2. Deploy the `ImageScan` custom resource to the desired namespace on cluster by running:

```
kubectl apply -f <path_to_the_cr>/<custom_resource_filename>.yaml -n <desired_n
amespace>
```

After the scanning completes, the following fields appear in the custom resource and are filled by the scanner:

```
 # These fields are populated from the image scan results
status:
  artifact:
    registry:
      # The image name with its digest as provided in the CycloneDX `bom>metada
ta>component>*` fields
      image:
      imagePullSecret:

  # An array that is populated with information about the scanning status
  # and the policy validation. These conditions might change in the lifecycle
  # of the scan, refer to the "View Scan Status and Understanding Conditions" s
ection to learn more.
  conditions: []

  # The URL of the vulnerability scan results in the Metadata Store integratio
n.
  # Only available when the integration is configured.
  metadataUrl:

  # When the CRD is updated to point at new revisions, this lets you know
  # whether the status reflects the latest one
  observedGeneration: 1
  observedPolicyGeneration: 1
  observedTemplateGeneration: 1

  # The latest datetime when the scanning was successfully finished.
  scannedAt:
  # Information about the scanner used for the latest image scan.
  # This information reflects what's in the CycloneDX `bom>metadata>tools>tool>
*` fields.
  scannedBy:
```

```
    scanner:
      # The name of the scanner that was used.
      name: my-image-scanner

      # The name of the scanner's development company or team
      vendor: my-image-scanner-provider

      # The version of the scanner used.
      version: 1.0.0
```

Enforce compliance policy using Open Policy Agent

This topic describes how you can use Open Policy Agent to enforce compliance policy for Supply Chain Security Tools - Scan.

Writing a policy template

The Scan Policy custom resource (CR) allows you to define a Rego file for policy enforcement that you can reuse across image scan and source scan CRs.

The Scan Controller supports policy enforcement by using an Open Policy Agent (OPA) engine with Rego files. This allows you to validate scan results for company policy compliance and can prevent source code from being built or images from being deployed.

Rego file contract

To define a Rego file for an image scan or source scan, you must comply with the requirements defined for every Rego file for the policy verification to work. For information about how to write Rego, see Open Policy Agent documentation.

- **Package main:** The Rego file must define a package in its body called `main`. The system looks for this package to verify the scan results compliance.
- **Input match:** The Rego file evaluates one vulnerability match at a time, iterating as many times as the Rego file finds vulnerabilities in the scan. The match structure is accessed in the `input.currentVulnerability` object inside the Rego file and has the CycloneDX format.
- **deny rule:** The Rego file must define a `deny` rule inside its body. `deny` is a set of error messages that are returned to the user. Each rule you write adds to that set of error messages. If the conditions in the body of the `deny` statement are true then the user is handed an error message. If false, the vulnerability is allowed in the Source or Image scan.

Define a Rego file for policy enforcement

Follow these steps to define a Rego file for policy enforcement that you can reuse across image scan and source scan CRs that output in the CycloneDX XML format.

Note

The Snyk Scanner outputs SPDX JSON. For an example of a ScanPolicy formatted for SPDX JSON output, see Sample ScanPolicy for Snyk in SPDX JSON format.

1. Create a scan policy with a Rego file. The following is an example scan policy resource:

```
---
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ScanPolicy
```

```
metadata:
  name: scan-policy
  labels:
    app.kubernetes.io/part-of: enable-in-gui
spec:
  regoFile: |
    package main

    # Accepted Values: "Critical", "High", "Medium", "Low", "Negligible", "Unkn
ownSeverity"
    notAllowedSeverities := ["Critical", "High", "UnknownSeverity"]
    ignoreCves := []

    contains(array, elem) = true {
      array[_] = elem
    } else = false { true }

    isSafe(match) {
      severities := { e | e := match.ratings.rating.severity } | { e | e := mat
ch.ratings.rating[_].severity }
      some i
      fails := contains(notAllowedSeverities, severities[i])
      not fails
    }

    isSafe(match) {
      ignore := contains(ignoreCves, match.id)
      ignore
    }

    deny[msg] {
      comps := { e | e := input.bom.components.component } | { e | e := input.b
om.components.component[_] }
      some i
      comp := comps[i]
      vulns := { e | e := comp.vulnerabilities.vulnerability } | { e | e := com
p.vulnerabilities.vulnerability[_] }
      some j
      vuln := vulns[j]
      ratings := { e | e := vuln.ratings.rating.severity } | { e | e := vuln.ra
tings.rating[_].severity }
      not isSafe(vuln)
      msg = sprintf("CVE %s %s %s", [comp.name, vuln.id, ratings])
    }
```

You can edit the following text boxes of the Rego file as part of the CVE triage workflow:

- `notAllowedSeverities` contains the categories of CVEs that cause the SourceScan or ImageScan failing policy enforcement. The following example shows an `app-operator` blocking only `Critical`, `High` and `UnknownSeverity` CVEs.

  ```
  ...
  spec:
  regoFile: |
    package main

    # Accepted Values: "Critical", "High", "Medium", "Low", "Negligible",
  "UnknownSeverity"
    notAllowedSeverities := ["Critical", "High", "UnknownSeverity"]
    ignoreCves := []
  ...
  ```

- `ignoreCves` contains individual ignored CVEs when determining policy enforcement. In the following example, an `app-operator` ignores `CVE-2018-14643` and `GHSA-f2jv-r9rf-7988` if they are false positives. See A Note on Vulnerability Scanners.

```
...
spec:
regoFile: |
  package main

  notAllowedSeverities := []
  ignoreCves := ["CVE-2018-14643", "GHSA-f2jv-r9rf-7988"]
...
```

2. Deploy the scan policy to the cluster:

```
kubectl apply -f <path_to_scan_policy>/<scan_policy_filename>.yaml -n <desired_
namespace>
```

For information about how scan policies are used in the CVE triage workflow, see Triaging and Remediating CVEs.

Further refine the Scan Policy for use

The scan policy earlier demonstrates how vulnerabilities are ignored during a compliance check. It is not possible to audit why a vulnerability is ignored. You might want to allow an exception, where a build with a failing vulnerability is allowed to progress through a supply chain. You can allow this exception for a certain period of time, requiring an expiration date. Vulnerability Exploitability Exchange (VEX) documents are gaining popularity to capture security advisory information pertaining to vulnerabilities. You can use Rego for these use cases.

For example, the following scan policy includes an additional text box to capture comments regarding why the scan ignores a vulnerability. The `notAllowedSeverities` array remains an array of strings, but the `ignoreCves` array updates from an array of strings to an array of objects. This causes a change to the `contains` function, splitting it into separate functions for each array.

```
---
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ScanPolicy
metadata:
  name: scan-policy
  labels:
    app.kubernetes.io/part-of: enable-in-gui
spec:
  regoFile: |
    package main

    # Accepted Values: "Critical", "High", "Medium", "Low", "Negligible", "UnknownSeve
rity"
    notAllowedSeverities := ["Critical", "High", "UnknownSeverity"]

    # List of known vulnerabilities to ignore when deciding whether to fail complianc
e. Example:
    # ignoreCves := [
    #   {
    #     "id": "CVE-2018-14643",
    #     "detail": "Determined affected code is not in the execution path."
    #   }
    # ]
    ignoreCves := []

    containsSeverity(array, elem) = true {
      array[_] = elem
    } else = false { true }

    isSafe(match) {
```

```
      severities := { e | e := match.ratings.rating.severity } | { e | e := match.rati
ngs.rating[_].severity }
      some i
      fails := containsSeverity(notAllowedSeverities, severities[i])
      not fails
    }

    containsCve(array, elem) = true {
      array[_].id = elem
    } else = false { true }

    isSafe(match) {
      ignore := containsCve(ignoreCves, match.id)
      ignore
    }

    deny[msg] {
      comps := { e | e := input.bom.components.component } | { e | e := input.bom.comp
onents.component[_] }
      some i
      comp := comps[i]
      vulns := { e | e := comp.vulnerabilities.vulnerability } | { e | e := comp.vulne
rabilities.vulnerability[_] }
      some j
      vuln := vulns[j]
      ratings := { e | e := vuln.ratings.rating.severity } | { e | e := vuln.ratings.r
ating[_].severity }
      not isSafe(vuln)
      msg = sprintf("CVE %s %s %s", [comp.name, vuln.id, ratings])
    }
```

The following example includes an expiration text box and only allows the vulnerability to be ignored for a period of time:

```
---
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ScanPolicy
metadata:
  name: scan-policy
  labels:
    app.kubernetes.io/part-of: enable-in-gui
spec:
  regoFile: |
    package main

    # Accepted Values: "Critical", "High", "Medium", "Low", "Negligible", "UnknownSeve
rity"
    notAllowedSeverities := ["Critical", "High", "UnknownSeverity"]

    # List of known vulnerabilities to ignore when deciding whether to fail complianc
e. Example:
    # ignoreCves := [
    #   {
    #     "id": "CVE-2018-14643",
    #     "detail": "Determined affected code is not in the execution path.",
    #     "expiration": "2022-Dec-31"
    #   }
    # ]
    ignoreCves := []

    containsSeverity(array, elem) = true {
      array[_] = elem
    } else = false { true }

    isSafe(match) {
```

```
      severities := { e | e := match.ratings.rating.severity } | { e | e := match.rati
ngs.rating[_].severity }
      some i
      fails := containsSeverity(notAllowedSeverities, severities[i])
      not fails
    }

    containsCve(array, elem) = true {
      array[_].id = elem
      curr_time := time.now_ns()
      date_format := "2006-Jan-02"
      expire_time := time.parse_ns(date_format, array[_].expiration)
      curr_time < expire_time
    } else = false { true }

    isSafe(match) {
      ignore := containsCve(ignoreCves, match.id)
      ignore
    }

    deny[msg] {
      comps := { e | e := input.bom.components.component } | { e | e := input.bom.comp
onents.component[_] }
      some i
      comp := comps[i]
      vulns := { e | e := comp.vulnerabilities.vulnerability } | { e | e := comp.vulne
rabilities.vulnerability[_] }
      some j
      vuln := vulns[j]
      ratings := { e | e := vuln.ratings.rating.severity } | { e | e := vuln.ratings.r
ating[_].severity }
      not isSafe(vuln)
      msg = sprintf("CVE %s %s %s", [comp.name, vuln.id, ratings])
    }
```

Troubleshooting Rego files (Scan Policy)

To troubleshoot or confirm that any modifications made to the rego file in the provided sample scan policy are functioning as intended, see Troubleshooting Rego Files.

Enable Tanzu Developer Portal to view ScanPolicy Resource

For the Tanzu Developer Portal to view the ScanPolicy resource, it must have a matching `kubernetes-label-selector` with a `part-of` prefix.

The following example is portion of a ScanPolicy that is viewable by the Tanzu Developer Portal:

```
---
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ScanPolicy
metadata:
  name: scan-policy
  labels:
    app.kubernetes.io/part-of: enable-in-gui
spec:
  regoFile: |
    ...
```

Note

Anything van be a value for the label. The Tanzu Application Platform GUI is looking for the existence of the `part-of` prefix string and doesn't match for anything else specific.

Deprecated Rego file Definition

Before Scan Controller v1.2.0, you must use the following format where the rego file differences are:

- The package name must be `package policies` instead of `package main`.
- The deny rule is a Boolean `isCompliant` instead of `deny[msg]`.
    - **isCompliant rule:** The Rego file must define inside its body an `isCompliant` rule. This must be a Boolean type containing the result whether the vulnerability violates the security policy or not. If `isCompliant` is `true`, the vulnerability is allowed in the Source or Image scan. Otherwise, `false` is considered. Any scan that finds at least one vulnerability that evaluates to `isCompliant=false` makes the `PolicySucceeded` condition set to false.

The following is an example scan policy resource:

```
apiVersion: scanning.apps.tanzu.vmware.com/v1alpha1
kind: ScanPolicy
metadata:
  name: v1alpha1-scan-policy
  labels:
    app.kubernetes.io/part-of: enable-in-gui
spec:
  regoFile: |
    package policies

    default isCompliant = false

    ignoreSeverities := ["Critical", "High"]

    contains(array, elem) = true {
      array[_] = elem
    } else = false { true }

    isCompliant {
      ignore := contains(ignoreSeverities, input.currentVulnerability.Ratings.Rating
[_].Severity)
      ignore
    }
```

Create a ScanTemplate with Supply Chain Security Tools - Scan

This topic describes how to create a ScanTemplate with Supply Chain Security Tools - Scan.

Overview

The `ScanTemplate` custom resource (CR) defines how the scan Pod fulfills the task of vulnerability scanning. There are default `ScanTemplates` provided out of the box using the Tanzu Application Platform default scanner, `Anchore Grype`. One or more `initContainers` run to complete the scan and must save results to a shared `volume`. After the `initContainers` completes, a single container

on the scan Pod called `summary` combines the result of the initContainers so that the `Scan CR` status is updated.

A customized ScanTemplate is created by editing or replacing `initContainer` definitions and reusing the `summary` container from the `grype` package. A container can read the `out.yaml` from an earlier step to locate relevant inputs.

Output Model

Each initContainer can create a subdirectory in `/workspace` to use as a scratch space. Before terminating the container must create an `out.yaml` file in the subdirectory containing the relevant subset of fields from the output model:

```
fetch:
  git:
    url:
    revision:
    path:
  blob:
    url:
    revision:
    path:
  image:
    url:
    revision:
    path:
sbom:
    packageCount:
    reports: []
scan:
  cveCount:
    critical:
    high:
    medium:
    low:
    unknown:
  scanner:
    name:
    vendor:
    version:
    db:
      version:
  reports: []
eval:
  violations: []
store:
  locations: []
```

The `scan` portion of the earlier output is required and if missing the scan controller fails to properly update the final status of the `Scan CR`. Other portions of the output, including those of `store` and `policy evaluation`, are optional and can be omitted if not applicable in a custom supply chain setup.

ScanTemplate Structure

```
apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
kind: ScanTemplate
spec:
    template: # a core/v1 PodSpec
      # Here are list volumes mounted for writing to or
      # reading from during different stages of the scan
```

```
      volumes:
        # required the results of different scan stages
        # should be saved in files digestible by the scan
        # controller in this volume
        - name: workspace
        emptyDir: { }
      # different steps required for a scanning can be staged
      # in sequential stages through initContainers.
      initContainers:
      # Summary container will take results of initContainers
      # and will let Controller to update Scan CR status.
      containers:
        - name: summary
```

Note: You cannot name a container `sleep` because there is already a container named `sleep` which comes from the scan-link controller.

Sample Outputs

```
# example for a typical git clone (source scan fetch stage)
# saved at: /workspace/git-clone/out.yaml
fetch:
  git:
    url: github.com/my/repo
    revision: aee9f8
    path: /workspace/git-clone/cloned-repository
```

```
# an example of typical scan stage
# saved at: /workspace/grype-scan/out.yaml
scan:
  cveCount:
    critical: 0
    high: 1
    medium: 3
    low: 25
    unknown: 0
  scanner:
    name: grype
    vendor: Anchore
    version: 0.33.0
    db:
      version: 2022-04-13
  reports:
  - /workspace/grype-scan/repo.cyclonedx.xml
  - /workspace/grype-scan/app.cyclonedx.xml
  - /workspace/grype-scan/base.cyclonedx.xml
```

```
# example of a typical evaluation stage
# saved at: /workspace/policy-eval/out.yaml
eval:
  violations:
    - banned package log4j
    - critical CVE 2022-01-01-3333
    - number of critical CVEs over threshold
```

```
# example of a typical upload to store stage
# saved at: /workspace/upload-to-store/out.yaml
store:
  locations:
    - http://metadata-store.cluster.local:8080/reports/3
```

View scan status conditions for Supply Chain Security Tools - Scan

This topic explains how you can view scan status conditions for Supply Chain Security Tools - Scan.

Viewing scan status

You can view the scan status by using `kubectl describe` on a `SourceScan` or `ImageScan`. You can see information about the scan status under the Status field for each scan CR.

Overview of conditions

The `Status.Conditions` array is populated with the scan status information during and after scanning execution, and the policy validation (if defined for the scan) after the results are available.

Condition types for the scans

Scanning

The Condition with type `Scanning` indicates running the scanning TaskRun. The Status field indicates whether the scan is running or has already finished. For example, if `Status: True`, the scan TaskRun is still running and if `Status: False`, the scan is done.

The Reason field is `JobStarted` while the scan is running and `JobFinished` when it is done.

The Message fieldcan either be `The scan job is running` or `The scan job terminated` depending on the current Status and Reason.

Succeeded

The Condition with type `Succeeded` indicates the scanning TaskRun result. The Status field indicates whether the scan finished successfully or if it encountered an error. For example, the status is `Status: True` if it completed successfully or `Status: False` otherwise.

The Reason field is `JobFinished` if the scanning was successful or `Error` if otherwise.

The Message and Error fields have more information about the last seen status of the scan TaskRun.

SendingResults

The condition with type `SendingResults` indicates sending the scan results to the metadata store. In addition to a successful process of sending the results, the condition can also indicate that the metadata store integration has not been configured or that there was an error sending. An error is usually a misconfigured metadata store URL or that the metadata store is inaccessible. Verify the installation steps to ensure that the configuration is correct regarding secrets being set within the `scan-link-system` namespace.

PolicySucceeded

The Condition with type `PolicySucceeded` indicates the compliance of the scanning results against the defined policies. See Code Compliance Policy Enforcement using Open Policy Agent (OPA). The Status field indicates whether the results are compliant or not (`Status: True` or `Status: False` respectively) or `Status: Unknown` in case an error occurred during the policy verification.

The Reason field is `EvaluationPassed` if the scan complies with the defined policies. The Reason field is `EvaluationFailed` if the scan is not compliant, or `Error` if something went wrong.

The Message and Error fields are populated with `An error has occurred` and an error message if something went wrong during policy verification. Otherwise, the Message field displays `No CVEs were found that violated the policy` if there are no non-compliant vulnerabilities found or `Policy violated because of X CVEs` indicating the count of unique vulnerabilities found.

Overview of CVECount

The `status.CVECount` is populated with the number of CVEs in each category (CRITICAL, HIGH, MEDIUM, LOW, UNKNOWN) and the total (CVETOTAL).

Note

You can also view scan CVE summary in print columns with `kubectl get` on a `SourceScan` or `ImageScan`.

Overview of MetadataURL

The `status.metadataURL` is populated with the URL of the vulnerability scan results in> the metadata store integration. This is only available when the integration is configured.

Overview of Phase

The `status.phase` field is populated with the current phase of the scan. The phases are: Pending, Scanning, Completed, Failed, and Error.

- `Pending`: initial phase of the scan.
- `Scanning`: execution of the scan TaskRun is running.
- `Completed`: scan completed and no CVEs were found that violated the scan policy.
- `Failed`: scan completed but CVEs were found that violated the scan policy.
- `Error`: indication of an error (e.g., an invalid scantemplate or scan policy).

Note

The PHASE print column also shows this with `kubectl get` on a `SourceScan` or `ImageScan`.

Overview of ScannedBy

The `status.scannedBy` field is populated with the name, vendor, and scanner version that generates the security assessment report.

Overview of ScannedAt

The `status.scannedAt` field is populated with the latest date when the scanning finishes.

Troubleshoot Rego files with a scan policy for Supply Chain Security Tools - Scan

This topic describes how you can use an example output to troubleshoot your Rego file for SCST - Scan. You use a Rego file in a scan policy custom resource. See Enforce compliance policy using

Open Policy Agent.

For information about how to write Rego, see Open Policy Agent documentation.

Using the Rego playground

Use the Rego Playground, to evaluate your Rego file against an input. In this example, use the example output of an image or source scan custom resource.

Sample input in CycloneDX's XML re-encoded as JSON format

The following is an example scan custom resource output in CycloneDX's XML structure re-encoded as JSON. This example output contains CVEs at low, medium, high, and critical severities.

To troubleshoot using this example output:

1. Paste your Rego file and the example output into the Rego Playground.
2. Evaluate your Rego file against the example output and verify that your Rego file detects the intended CVEs. See this Rego example.

```

Example input in SPDX JSON format

The example in this section is a modified scan custom resource input, in `.spdx.json`, that contains CVEs at low, medium, high, and critical severities. You can use this example input to evaluate your Rego file.

To troubleshoot using this example output:

1. Paste your Rego file and the example input into the Rego Playground.
2. Evaluate your Rego file against the output and verify that your Rego file detects the intended CVEs. See this Rego example.

Supply Chain Security Tools - Scan 2.0

This topic gives you an overview of Supply Chain Security Tools (SCST) - Scan 2.0. Include this component in your software supply chain to help identify vulnerabilities earlier in the development life cycle. This helps to increase the security posture of your application.

Overview

SCST - Scan 2.0 is the next-generation scanning framework for Tanzu Application Platform. It will supersede the SCST - Scan component in a future release. It provides a framework to scan workload components.

With SCST - Scan 2.0 you can:

- Scan container images for a workload that is built by the supply chain or provided as part of a workload definition for known Common Vulnerabilities and Exposures (CVEs).
- Use your preferred container image scan solution such as Anchore's Grype, Aqua's Trivy, Palo Alto's Prisma, and VMware Carbon Black Cloud.
- Post the scan results in an industry-standard format, such as CycloneDX or SPDX, as an OCI artifact to an OCI-compliant container image registry. By using industry standards, you do not need to be familiar with proprietary Tanzu Application Platform configurations.

AMR Observer

Downstream services such as Tanzu CLI Insight plug-in, Supply Chain Choreographer, and Security Analysis dashboards in the Tanzu Developer Portal depend on data being in the SCST - Store component. Because pushing scan results to the proprietary store endpoint is decoupled from the scan framework in SCST - Scan 2.0, AMR Observer observes results pushed to a registry, parses the results, and pushes them to the SCST - Store component.

For information about AMR observer, see Overview of Supply Chain Security Tools for Tanzu – Store.

Integrating into a supply chain

The SCST - Scan 2.0 component defines how to scan a container image with a scan solution using the generic Kubernetes custom resource `ImageVulnerabilityScan`. This provides a generic interface that allows you to declare how the Tanzu Application Platform executes a scan on a container image for a container image scan solution. For Cartographer to stamp out an `ImageVulnerabilityScan` custom resource as part of a supply chain execution, the

`ImageVulnerabilityScan` must be wrapped in a `ClusterImageTemplate` custom resource. This custom resource tells Cartographer not only how to stamp out the `ImageVulnerabilityScan` template, but also what configurations are passed to it.

Getting started with SCST - Scan 2.0

To use the SCST - Scan 2.0 component, see Getting Started with Supply Chain Security Tools - Scan 2.0.

Getting Started with Supply Chain Security Tools - Scan 2.0

Get started with Supply Chain Security Tools (SCST) - Scan 2.0 by using the following topics:

Install Supply Chain Security Tools - Scan 2.0 in a cluster

Enable App Scanning for default Test and Scan supply chains

Bring your own scanner with Supply Chain Security Tools - Scan 2.0

Verifying Scanning with Supply Chain Integration

Install Supply Chain Security Tools - Scan 2.0 in a cluster

This topic describes how to install Supply Chain Security Tools (SCST) - Scan 2.0 if are not using a profile. By default, SCST - Scan 2.0 is installed in the build and full profiles.

Note

Follow the steps in this topic if you do not want to use a profile to install SCST - Scan 2.0. For more information about profiles, see Installation profiles in Tanzu Application Platform v1.9.

Prerequisites

SCST - Scan 2.0 requires the following prerequisites:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- Install the Tekton component.
- To store results, install AMR, and AMR Observer. Downstream Tanzu Application Platform services, such as Tanzu Developer Portal and Tanzu CLI, depend on scan results stored in SCST - Store to display correctly. For more information, see Artifact Metadata Repository Observer for Supply Chain Security Tools - Store.

Note

If you are installing SCST - Scan 2.0 in a cluster with restricted Kubernetes Pod Security Standards, you must update configurations for the Tekton Pipelines package. See Scanning in a cluster with restricted Kubernetes Pod Security Standards.

Configure properties

When you install SCST - Scan 2.0, you can configure the following optional properties:

Key	Default	Type	Description
caCertData	""	string	The custom certificates trusted by the scan's connections
docker.import	true	Boolean	Import `docker.pullSecret` from another namespace (requires secretgen-controller). Set to false if the secret is already present.
docker.pullSecret	registries-credentials	string	Name of a Docker pull secret in the deployment namespace to pull the scanner images
scans.maxConcurrentScans	10	integer	Maximum number of scans running at one time. Set to 0 to have no limit.
scans.priorityClassName	""	string	Name of a predefined PriorityClass to apply to scan pods
workspace.storageSize	2Gi	string	Size of the PersistentVolume that the Tekton pipelineruns uses
workspace.storageClass	""	string	Name of the storage class to use while creating the PersistentVolume claims used by Tekton pipelineruns

Note

If the StorageClass you select does not have a node limit but uses the node storage, such as hostpath, the nodes must have large enough disks. For example, if a scan creates a 2Gi volume on a hostpath type storage class, `2Gi * number of AMR images` indicates how much storage this cluster needs overall. `2Gi * number of AMR images / number of nodes` indicates how much storage each node needs.

Install

To install SCST - Scan 2.0:

1. List version information for the package:

   ```
   tanzu package available list app-scanning.apps.tanzu.vmware.com --namespace tap-install
   ```

   For example:

   ```
   $ tanzu package available list app-scanning.apps.tanzu.vmware.com --namespace tap-install
   - Retrieving package versions for app-scanning.apps.tanzu.vmware.com...
     NAME                                VERSION              RELEASED-AT
     app-scanning.apps.tanzu.vmware.com  0.1.0              2023-03-01 20:00:00 -0400 EDT
   ```

2. (Optional) Make changes to the default installation settings:

   Retrieve the configurable settings:

   ```
   tanzu package available get app-scanning.apps.tanzu.vmware.com/VERSION --values-schema --namespace tap-install
   ```

   Where `VERSION` is your package version number. For example, `0.1.0`.

   For example:

```
tanzu package available get app-scanning.apps.tanzu.vmware.com/0.1.0 --values-s
chema --namespace tap-install
| Retrieving package details for app-scanning.apps.tanzu.vmware.com/0.1.0...

  KEY                     DEFAULT                 TYPE     DESCRIPTION
  docker.import           true                    boolean  Import `docker.pullS
ecret` from another namespace (requires
                                                           secretgen-controlle
r). Set to false if the secret will already be present.
  docker.pullSecret       registries-credentials  string   Name of a Docker pul
l secret in the deployment namespace to pull the scanner
                                                           images.
  workspace.storageSize   2Gi                     string   Size of the Persiste
nt Volume to be used by the tekton pipelineruns
  workspace.storageClass                          string   Name of the storage
class to use while creating the Persistent Volume Claims
                                                           used by tekton pipel
ineruns
  caCertData                                      string   The custom certifica
tes to be trusted by the scan's connections
```

To edit any of the default installation settings, create an `app-scanning-values-file.yaml` and append the key-value pairs to be modified to the file. For example:

```
scans:
  workspace:
    storageSize: 200Mi
```

3. Install the package. If you did not edit the default installation settings, you do not need to specify the `--values-file` flag.

```
tanzu package install app-scanning --package-name app-scanning.apps.tanzu.vmwar
e.com \
    --version VERSION \
    --namespace tap-install \
    --values-file app-scanning-values-file.yaml
```

Where `VERSION` is your package version number. For example, `0.1.0`.

For example:

```
tanzu package install app-scanning --package app-scanning.apps.tanzu.vmware.com
\
    --version 0.1.0 \
    --namespace tap-install \
    --values-file app-scanning-values-file.yaml

    Installing package 'app-scanning.apps.tanzu.vmware.com'
    Getting package metadata for 'app-scanning.apps.tanzu.vmware.com'
    Creating service account 'app-scanning-default-sa'
    Creating cluster admin role 'app-scanning-default-cluster-role'
    Creating cluster role binding 'app-scanning-default-cluster-rolebinding'
    Creating package resource
    Waiting for 'PackageInstall' reconciliation for 'app-scanning'
    'PackageInstall' resource install status: Reconciling
    'PackageInstall' resource install status: ReconcileSucceeded
```

Configure service accounts and registry credentials

This section contains instructions for running a standalone `ImageVulnerabilityScan` or using multiple registries.

If the image that you are scanning using a default scanner or your own scanner, and your vulnerability scanner image are located in private registries different from the `Tanzu Application Platform bundles registry`, you must edit your scanner service account to include registry credentials for these registries.

Important

If your use case is listed below, skip this topic and proceed to Enable App Scanning for default Test and Scan supply chains.

- You are running an `ImageVulnerabilityScan` in the context of a supply chain.
- You used the Namespace Provisioner to provision your developer namespace. For more information, see the Namespace Provisioner documentation.

To configure service accounts and registry credentials, SCST - Scan 2.0 requires the following access:

Registry	Permission	Service Account	Example
Tanzu Application Platform bundles registry	Read	scanner	`registry.tanzu.vmware.com`
Target image registry	Read	scanner	`your-registry.io`
Vulnerability scanner image registry	Read	scanner	`your-registry.io`
Scan results location registry	Write	publisher	`your-registry.io`

Where:

- `Tanzu Application Platform bundles registry` is the registry containing the Tanzu Application Platform bundles. This is the registry from the Relocate images to a registry step or `registry.tanzu.vmware.com`.
- `Target image registry` is the registry containing the image to scan. This registry credential is required if you are scanning a private image. The `image to scan is` called the `target image` or `TARGET-IMAGE`.
- `Vulnerability scanner image registry` is the registry containing your vulnerability scanner image. This is only needed if you are bringing your own scanner and your vulnerability scanner image is located in a private registry different from the `Tanzu Application Platform bundles registry`.
- `Scan results location registry` is the registry where scan results are published.

To configure service accounts and registry credentials:

1. Create a secret `scanning-tap-component-read-creds` with read access to the registry containing the Tanzu Application Platform bundles. This pulls the SCST - Scan 2.0 images. If you previously relocated the Tanzu Application Platform bundles to your own registry, you can also place your vulnerability scanner image in this registry.

```
read -s TAP_REGISTRY_PASSWORD
kubectl create secret docker-registry scanning-tap-component-read-creds \
  --docker-username=TAP-REGISTRY-USERNAME \
  --docker-password=$TAP_REGISTRY_PASSWORD \
  --docker-server=TAP-REGISTRY-URL \
  -n DEV-NAMESPACE
```

Where `DEV-NAMESPACE` is the developer namespace where scanning occurs.

2. If you are scanning a private target image, create a secret `target-image-read-creds` with read access to the registry containing that target image.

Important

If you followed the directions for Install Tanzu Application Platform, you can skip this step and use the `targetImagePullSecret` secret with your service account as referenced in your `tap-values.yaml`. See Full profile.

```
read -s REGISTRY_PASSWORD
kubectl create secret docker-registry target-image-read-creds \
  --docker-username=REGISTRY-USERNAME \
  --docker-password=$REGISTRY_PASSWORD \
  --docker-server=REGISTRY-URL \
  -n DEV-NAMESPACE
```

3. Create a secret `write-creds` with write access to the registry for the scanner to upload the scan results to.

```
read -s WRITE_PASSWORD
kubectl create secret docker-registry write-creds \
  --docker-username=WRITE-USERNAME \
  --docker-password=$WRITE_PASSWORD \
  --docker-server=DESTINATION-REGISTRY-URL \
  -n DEV-NAMESPACE
```

4. (Optional) If you are bringing your own vulnerability scanner and your vulnerability scanner image is located in a private registry different from the registry containing your Tanzu Application Platform bundles, you must create a secret `vulnerability-scanner-image-read-creds` with read access to the registry.

```
read -s WRITE_PASSWORD
kubectl create secret docker-registry vulnerability-scanner-image-read-creds \
  --docker-username=WRITE-USERNAME \
  --docker-password=$WRITE_PASSWORD \
  --docker-server=REGISTRY-URL \
  -n DEV-NAMESPACE
```

5. Create a `scanner-sa.yaml` file containing the service account `scanner` which enables SCST - Scan 2.0 to pull both the vulnerability scanner image and target image. Attach the one or more read secrets created earlier pulling the Tanzu Application Platform bundles, and optionally, your vulnerability scanner image under `imagePullSecrets`. Attach the read secret created earlier for your target image under `secrets`.

```
apiVersion: v1
kind: ServiceAccount
metadata:
  name: scanner
  namespace: DEV-NAMESPACE
imagePullSecrets:
- name: scanning-tap-component-read-creds
- name: vulnerability-scanner-image-read-creds # optional
secrets:
- name: target-image-read-creds
```

Where:

- `imagePullSecrets.name` includes the name of the secret used to pull the scan component from the registry. If you are bringing your own vulnerability scanner and the vulnerability scanner image is located in a separate private registry, you must also include the name of the secret with those registry credentials.
- `secrets.name` is the name of the secret used to pull the target image to scan. This is required if the image you are scanning is private.

6. Apply the service account to your developer namespace by running:

```
kubectl apply -f scanner-sa.yaml
```

7. Create a `publisher-sa.yaml` file containing the service account `publisher` which enables SCST - Scan 2.0 to push the scan results to a user specified registry.

```
apiVersion: v1
kind: ServiceAccount
metadata:
  name: publisher
  namespace: DEV-NAMESPACE
imagePullSecrets:
- name: scanning-tap-component-read-creds
secrets:
- name: write-creds
```

Where:

- `imagePullSecrets.name` is the name of the secret used to pull the scan component image from the registry.
- `secrets.name` is the name of the secret used to publish the scan results.

8. Apply the service account to your developer namespace by running:

```
kubectl apply -f publisher-sa.yaml
```

(Optional) Set up your registry retention policy

Although Tanzu Application Platform ingests scan artifacts into the Metadata Store, and stores information such as packages and parsed vulnerabilities, only a pointer to the original SBOM location is stored. The original SBOM generated by the scan is not preserved within the Metadata Store. VMware recommends that you keep these original artifacts according to your organization's archival requirements.

If the registry specified to push scan results to support retention policies, you can configure the registry to delete old scan results automatically, depending on your archival requirements. Scan result artifacts accumulate over time and can quickly consume hard disk space.

For information about configuring Harbor tag retention rules, see the Harbor documentation. For example, you can configure Harbor to retain the most recently pushed # artifacts or retain the artifacts pushed within the last # days.

Retention policy setup differs between registry providers. Confirm with your specific registry's documentation about the configuration options.

Enable SCST - Scan 2.0 for default Test and Scan supply chains

This topic tells you how to enable Supply Chain Security Tools (SCST) - Scan 2.0 and an included container image scanner for Out of the Box Supply Chain with Testing and Scanning. The default configuration for Out of the Box Supply Chain with Testing and Scanning is SCST - Scan 1.0.

Overview

SCST - Scan 2.0 includes two integrations for container image scanners:

Container Image Scanner	Documentation	Cluster Image Template Name	Status
Aqua Trivy	Link	`image-vulnerability-scan-trivy`	Recommended scanner for SCST - Scan 2.0
Anchore Grype	Link	`image-vulnerability-scan-grype`	Alternative to Trivy that is used in SCST - Scan 1.0

VMware recommends using Aqua Trivy scanner with Tanzu Application Platform for container image scanning. If you want to remain consistent with the default scanner in SCST - Scan 1.0, Anchore Grype is included as an open-source alternative. Additionally, you can build an integration for additional scanners. For more information, see Bring your own scanner with Supply Chain Security Tools - Scan 2.0.

Enable with OOTB supply chain

To enable SCST - Scan 2.0 with an OOTB supply chain using the Trivy scanner:

1. Update your `tap-values.yaml` file to specify the Trivy `ClusterImageTemplate`. For example:

   ```
   ootb_supply_chain_testing_scanning:
     image_scanner_template_name: image-vulnerability-scan-trivy
   ```

2. (Optional) In Tanzu Application Platform v1.8 if you are using a vulnerability scanner other than Trivy, you must specify the registry location of the container image to use for scanning. For example, if you are using the Grype template, set `ootb_supply_chain_testing_scanning.image_scanning_cli` to the Grype image, for example,

   ```
   ootb_supply_chain_testing_scanning:
     image_scanner_template_name: image-vulnerability-scan-grype
     image_scanning_cli:
       image: registry.tanzu.vmware.com/tanzu-application-platform/tap-packages@sh
   a256:feb1cdbd5c918aae7a89bdb2aa39d486bf6ffc81000764b522842e5934578497
   ```

   This example uses the packaged Grype image, but you can also use images from public repositories such as `anchore/grype:latest`.

3. Update your Tanzu Application Platform installation by running:

   ```
   tanzu package installed update tap -p tap.tanzu.vmware.com -v TAP-VERSION  --va
   lues-file tap-values.yaml -n tap-install
   ```

   Where `TAP-VERSION` is the version of Tanzu Application Platform installed.

4. Verify the scan capability is working as expected by creating a workload. See Verify scanning with Supply Chain integration.

Bring your own scanner with Supply Chain Security Tools - Scan 2.0

This topic tells you how to bring your own scanner to use with Supply Chain Security Tools (SCST) - Scan 2.0.

Overview

Supply Chain Security Tools (SCST) - Scan 2.0 includes integrations with Trivy and Grype and examples for the following container image scanning tools:

- Trivy
- Prisma
- Snyk
- Carbon Black Cloud

You might have an existing investment in a scan solution that VMware does not have a published integration with. You can build an integration to your existing scan solution with SCST - Scan 2.0. To use your own scanner:

1. Create an ImageVulnerabilityScan template that tells Tanzu Application Platform how to run your scanner. See Customize an ImageVulnerabilityScan.
2. Verify that your ImageVulnerabilityScan is working correctly so that downstream Tanzu Application Platform services work correctly. See Verify an ImageVulnerabilityScan.
3. Wrap your ImageVulnerabilityScan in a ClusterImageTemplate. The ClusterImageTemplate wraps the ImageVulnerabilityScan and allows the Tanzu Application Platform supply chain to run the scan job. See Author a ClusterImageTemplate for Supply Chain integration.

Prerequisites

You must have the following prerequisites:

- Provide a Vulnerability Scanner Image with one of the following methods:
    - Use a publicly available image that contains the scanner CLI. For example, the official Aqua image for Trivy from Dockerhub.
    - Build your own image with the scanner CLI, which allows for a more customizable scanning experience. For example, you can create an image with the scanner CLI with any dependencies required to run the scanner CLI and manage your image to meet the Tanzu Application Platform compliance standards.
- Know how your preferred scanner works. For example, what commands to use to call scan results.

Bring your own scanner using an ImageVulnerabilityScan

This topic tells you how to bring your own scanner using an `ImageVulnerabilityScan`. An `ImageVulnerabilityScan` allows you to scan with any scanner by defining your scan as a Tekton step. For more information, see the Tekton documentation.

Customize an ImageVulnerabilityScan

To customize an ImageVulnerabilityScan to use your scanner:

1. Create a file named `image-vulnerability-scan.yaml`.

    ```
    apiVersion: app-scanning.apps.tanzu.vmware.com/v1alpha1
    kind: ImageVulnerabilityScan
    ```

```
metadata:
  name: generic-image-scan
  namespace: DEV-NAMESPACE
  annotations:
    app-scanning.apps.tanzu.vmware.com/scanner-name: SCANNER-NAME
spec:
  image: TARGET-IMAGE
  scanResults:
    location: registry/project/scan-results
  serviceAccountNames:
    scanner: scanner
    publisher: publisher
  steps:
  - name: scan
    image: SCANNER-IMAGE
    command: ["SCANNER-CLI-COMMAND"]
    args:
    ...
```

Where:

- `DEV-NAMESPACE` is the developer namespace where scanning occurs.
- `spec.image` is the image that you are scanning. You must specify the digest. See Retrieving an image digest.
- `scanResults.location` is the registry URL where results are uploaded. For example, `my.registry/scan-results`.
- `serviceAccountNames` includes:
  - `scanner` is the service account that runs the scan. It must have read access to `image`.
  - `publisher` is the service account that uploads results. It must have write access to `scanResults.location`.
- `SCANNER-IMAGE` is your vulnerability scanner image, such as the image containing the scanner of your choice.
- `SCANNER-CLI-COMMAND` is the scanner's CLI command.
- `SCANNER-NAME` is the scanner image name that is reported in the Tanzu Developer Portal, formerly Tanzu Application Platform GUI.

Important

Do not define `write-certs` or `cred-helper` as step names. These names are already used during scanning.

2. Configure the `scan` step. You must input your scanner specific `image`, `command`, and `args`. For example:

```
- name: scan
  image: anchore/grype:latest
  command: ["grype"]
  args:
  - registry:$(params.image)
  - -o
  - cyclonedx
  - --file
  - $(params.scan-results-path)/scan.cdx
```

To pass `spec.image` and `scanResults.location` to `args`, you can use `$(params.image)` and `$(params.scan-results-path)`.

Because volumes on a Tekton pipeline are shared amongst steps, files created by one step are consumable by the other steps. The scan controller applies the following security context to `pipelinerun.spec.podTemplate`:

```
runAsUser: 65534
fsGroup: 65534
runAsGroup: 65534
```

Note

If you populate any of the following fields in the `securityContext`, you must populate all the other fields or you might see a runtime error in the `ImageVulnerabilityScan` controller:

```
allowPrivilegeEscalation
runAsNonRoot
seccompProfile
capabilities
```

The `SCANNER-IMAGE` runs and manipulates files with user and group ids of `65534`.

Configuration options

This section lists optional and required ImageVulnerabilityScan specifications fields.

Required fields:

- `image` is the registry URL and digest of the target image. For example, `nginx@sha256:aa0afebbb3cfa473099a62c4b32e9b3fb73ed23f2a75a65ce1d4b4f55a5c2ef2`.
- `scanResults.location` is the registry URL where results are uploaded. For example, `my.registry/scan-results`.

Optional fields:

- `activeKeychains` is an array of enabled credential helpers to authenticate against registries using workload identity mechanisms.

  ```
  activeKeychains:
  - name: acr  # Azure Container Registry
  - name: ecr  # Elastic Container Registry
  - name: gcr  # Google Container Registry
  - name: ghcr # Github Container Registry
  ```

- `serviceAccountNames` includes:
  - `scanner` is the service account that runs the scan. It must have read access to `image`.
  - `publisher` is the service account that uploads results. It must have write access to `scanResults.location`.
- `workspace` includes:
  - `size` is size of the PersistentVolumeClaim the scan uses to download the image and vulnerability database.
  - `bindings` are additional array of secrets, ConfigMaps, or EmptyDir volumes to mount to the running scan. The `name` is used as the mount path.

```
bindings:
- name: additionalconfig
  configMap:
    name: my-configmap
- name: additionalsecret
  secret:
    secretName: my-secret
- name: scratch
  emptyDir: {}
```

For information about workspace bindings, see Using other types of volume sources. Only Secrets, ConfigMaps, and EmptyDirs are supported.

Default environment

The following describes the default environment for Tekton workspaces:

- `/home/app-scanning` is a memory-backed EmptyDir mount that contains service account credentials loaded by Tekton.
- `/cred-helper` is a memory-backed EmptyDir mount containing:
    - config.json combines static credentials with workload identity credentials when `activeKeychains` is enabled.
    - `trusted-cas.crt` when SCST - Scan 2.0 is deployed with `caCertData`
- `/workspace` is a PersistentVolumeClaim to hold scan artifacts and results.
    - The working directory for all Steps is by default located at `/workspace/scan-results`.

Environment variables

If undefined by your `step` definition the environment uses the following default variables:

- HOME=/home/app-scanning
- DOCKER_CONFIG=/cred-helper
- XDG_CACHE_HOME=/workspace/.cache
- TMPDIR=/workspace/tmp
- SSL_CERT_DIR=/etc/ssl/certs:/cred-helper

Tekton pipeline parameters:

These parameters are populated after creating the GrypeImageVulnerabilityScan. For information about parameters, see the Tekton documentation.

Parameters	Default	Type	Description
image	""	string	The scanned image
scan-results-path	/workspace/scan-results	string	Location to save scanner output
trusted-ca-certs	""	string	PEM data from the installation's `caCertData`

Note

The `publisher` service account uploads any files, such as scanner output, in the `scan-results-path` directory to the registry of your choice. For information about configuring the registry URL where the `publisher` service account uploads scan results, see Configure your custom ImageVulnerabilityScan samples.

Retrieving an image digest

SCST - Scan 2.0 custom resources require the digest form of the URL. For example, `nginx@sha256:aa0afebbb3cfa473099a62c4b32e9b3fb73ed23f2a75a65ce1d4b4f55a5c2ef2`.

Use the Docker documentation to pull and inspect an image digest:

```
docker pull nginx:latest
docker inspect --format='{{index .RepoDigests 0}}' nginx:latest
```

Alternatively, you can install krane to retrieve the digest without pulling the image:

```
krane digest nginx:latest
```

Verifying an ImageVulnerabilityScan

This topic tells you how to verify an ImageVulnerabilityScan without Supply Chain integration.

Overview

After you build an ImageVulnerabilityScan to bring your own scanner, you can validate the capabilities to verify the integration.

Ensure that the scan integration is working correctly so that downstream servers such as AMR Observer, Tanzu Developer Portal, and the insight CLI can use scan results.

To verify scanning:

1. Verify that a triggered scan is completed.
2. Retrieve the scan results from the registry.
3. Verify that the scan results are in a supported format.

Trigger and observe scanning

To verify that you can scan an image using your ImageVulnerabilityScan:

1. Deploy your ImageVulnerabilityScan to the cluster by running:

   ```
   kubectl apply -f image-vulnerability-scan.yaml -n DEV-NAMESPACE
   ```

   Where `DEV-NAMESPACE` is the name of the developer namespace you want to use.

2. Child resources are created. View the child PipelineRun, TaskRuns, and pods:

   ```
   kubectl get -l imagevulnerabilityscan pipelinerun,taskrun,pod -n DEV-NAMESPACE
   ```

3. When the scanning completes, the status is shown. Specify `-o wide` to see the digest of the image scanned and the location of the published results.

   ```
   kubectl get imagevulnerabilityscans -n DEV-NAMESPACE -o wide
   ```

   The following is an example of expected output:

   ```
   NAME                 SCANRESULT                            SCANNEDIMAGE
   SUCCEEDED   REASON
   generic-image-scan   registry/project/scan-results@digest nginx:latest@digest
   True        Succeeded
   ```

Retrieve scan results

Scan results are uploaded to the container image registry as an imgpkg bundle. To retrieve a vulnerability report:

1. Retrieve the result location from the ImageVulnerabilityScan CR Status:

```
SCAN_RESULT_URL=$(kubectl get imagevulnerabilityscan my-scan -n DEV-NAMESPACE -
o jsonpath='{.status.scanResult}')
```

2. Download the bundle to a local directory and list the content:

```
imgpkg pull -b $SCAN_RESULT_URL -o scan-results/
ls scan-results/
```

Validating scan format

After retrieving the scan results, you must verify that the scan results are in a format that downstream Tanzu Application Platform services such as AMR Observer support. AMR Observer supports the following SBOM formats and versions.

Verifying an ImageVulnerabilityScan

SBOM Formats	Versions
CycloneDX	1.2, 1.3, 1.4, 1.5
SPDX	2.2

VMware recommends validating the scan results by using this CycloneDX tool, sbom-utility. This tool validates CycloneDX and SPDX BOMs against versioned schemas.

Note The output of the scan must be valid in accordance with SPDX or CycloneDX specifications. If not, although it might be parsed correctly, VMware cannot ensure that the information is parsed correctly, and results might not be displayed accurately in Tanzu Developer Portal and Tanzu Application s CLI.

To validate a scan format with sbom:

1. Setup and install sbom. See the sbom documentation.
2. Run the `sbom-utility` CLI with the subcommand validate to validate the scan report against its declared format, such as SPDX, CycloneDX, and version.

```
./sbom-utility validate -i SCAN-REPORT-FILE-NAME
```

Where `SCAN-REPORT-FILE-NAME` is the name of the scan report.

For example:

```
sbom-utility-v0.11.0-darwin-amd64 % ./sbom-utility validate -i scan-results/sca
n.json
Welcome to the sbom-utility! Version `v0.11.0` (sbom-utility) (darwin/amd64)
================================================================================
[INFO] Loading license policy config file: `license.json`...
[WARN] Invalid flag for command: `output-file` (`o`). Ignoring...

[INFO] Validating `/Users/lrobin/go/src/gitlab/app-scanning/scan-results-grype-
cyclonedx-json/scan.json`...
[INFO] SBOM valid against JSON schema: `true`
```

Important

The `sbom-utility` only accepts JSON as input. Your scan report must be a JSON file to use this tool.

Author a ClusterImageTemplate for Supply Chain integration

This topic tells you how to create your own ClusterImageTemplate and customize the embedded ImageVulnerabilityScan to use the scanner of your choice.

Prerequisites

The following prerequisite is required to author a ClusterImageTemplate for Supply Chain integration:

- You create your own ImageVulnerabilityScan or configured one of the samples provided in Configure your custom ImageVulnerabilityScan.
- For more information, see ClusterImageTemplate in the Cartographer documentation.
- Understand `ytt` templates. See Carvel `ytt` docs for documentation and playground samples.

Create a ClusterImageTemplate

This section describes how to create a ClusterImageTemplate using an ImageVulnerabilityScan with Trivy. To use a different scanner, replace the embedded ImageVulnerabilityScan with your own.

ClusterImageTemplate parameters and values:

- The `spec.params` in this sample YAML define default values for fields within the ImageVulnerabilityScan. For more information, see `params` in the Cartographer documentation.
    - `#@ data.values.params` in the `ytt` template block and in the ImageVulnerabilityScan both reference `spec.params` fields.
- The values in the `data.values.workload` such as `metadata`, `labels`, `annotations`, and `spec` come from the supply chain workload.
- The `data.values.image` is the container image built from Buildpacks in the supply chain step that scans for vulnerabilities.
- The example YAML in this topic uses `ytt` to define a resource template written in `ytt` for the ImageVulnerabilityScan Custom Resource. For more information, see `ytt` in the Cartographer documentation. For example, inside the `ytt` template are defined functions that you can use within the ImageVulnerabilityScan.

To create a ClusterImageTemplate:

1. Create a YAML file with the following content and name it `custom-ivs-template.yaml`.

```
apiVersion: carto.run/v1alpha1
kind: ClusterImageTemplate
metadata:
  name: image-vulnerability-scan-custom # input name of your ClusterImageTempla
te
spec:
  imagePath: .status.scannedImage
  retentionPolicy:
    maxFailedRuns: 10
    maxSuccessfulRuns: 10
  lifecycle: immutable

  healthRule:
    multiMatch:
      healthy:
        matchConditions:
          - status: "True"
            type: ScanCompleted
          - status: "True"
            type: Succeeded
      unhealthy:
        matchConditions:
          - status: "False"
            type: ScanCompleted
          - status: "False"
            type: Succeeded

  params:
    - name: image_scanning_workspace_size
      default: 4Gi
    - name: image_scanning_service_account_scanner
      default: scanner
    - name: image_scanning_service_account_publisher
      default: publisher
    - name: image_scanning_active_keychains
      default: []
    - name: image_scanning_workspace_bindings
      default: []
    - name: image_scanning_steps_env_vars
      default: []
    - name: trivy_db_repository
      default: ghcr.io/aquasecurity/trivy-db
    - name: trivy_java_db_repository
      default: ghcr.io/aquasecurity/trivy-java-db
    - name: registry
      default:
        server: REGISTRY-SERVER    # input your registry server
        repository: REGISTRY-REPOSITORY    # input your registry repository

  ytt: |
    #@ load("@ytt:data", "data")
    #@ load("@ytt:template", "template")

    #@ def merge_labels(fixed_values):

          value: #@ data.values.params.trivy_java_db_repository
        - name: TRIVY_CACHE_DIR
          value: /workspace/trivy-cache
        - name: XDG_CACHE_HOME
          value: /workspace/.cache
        - name: TMPDIR
          value: /workspace
        - #@ template.replace(data.values.params.image_scanning_steps_env_vars)
        args:
        - image
        - $(params.image)
        - --exit-code=0
        - --no-progress
        - --scanners=vuln
        - --format=cyclonedx
        - --output=$(params.scan-results-path)/scan.cdx.json
```

Note

`apps.tanzu.vmware.com/correlationid` contains the metadata of the mapping to the source of the scanned resource.

2. Edit the following in your `custom-ivs-template.yaml` file:
    - `.metadata.name` is the name of your ClusterImageTemplate. Ensure that it does not conflict with the names of packaged templates. See Author your supply chains.
    - `REGISTRY-SERVER` is the registry server used for the scan results location.
    - `REGISTRY-REPOSITORY` is the registry repository used for the scan results location.
    - `TRIVY-SCANNER-IMAGE` is the location of your Trivy scanner CLI image
    - `.metadata.annotations.'app-scanning.apps.tanzu.vmware.com/scanner-name'` is the scanner image name reported in the Tanzu Developer Portal, formerly Tanzu Application Platform GUI.

3. Create the ClusterImageTemplate:

```
kubectl apply -f custom-ivs-template.yaml
```

4. After you create your custom ClusterImageTemplate, you can integrate it with SCST - Scan 2.0. See Add App Scanning to default Test and Scan supply chains.

Configure your custom ImageVulnerabilityScan samples for Supply Chain Security Tools - Scan

This topic gives you sample ImageVulnerabilityScans for various scanners, and any associated secrets.

ImageVulnerabilityScan samples

This section includes ImageVulnerabilityScans (IVS) for various scanners. To use them, copy the YAML content for the scanner you want to use in the following topics:

- Carbon Black
- Snyk
- Prisma
- Trivy
- Grype

Use custom ImageVulnerabilityScan samples

To use a custom ImageVulnerabilityScan sample:

1. Copy the sample YAML into a file named `custom-ivs.yaml`. Some scanners, such as Carbon Black, Snyk, and Prisma Scanner, require specific credentials that you must specify in the secret.
2. Obtain the one or more necessary images. For example, an image containing the scanner.
3. Edit these fields of your ImageVulnerabilityScan:
    - `spec.image` is the image that you are scanning. See Retrieving an image digest.
    - `scanResults.location` is the registry URL where the `publisher` service account uploads the scan results. For example, `my.registry/scan-results`.
    - `serviceAccountNames` includes:
        - `scanner` is the service account that runs the scan. It must have read access to `image`.
        - `publisher` is the service account that uploads results. It must have write access to `scanResults.location`.
4. Complete any scanner specific changes specified on the sample ImageVulnerabilityScan page.
5. You can either incorporate your custom ImageVulnerabilityScan into a ClusterImageTemplate or run a standalone scan using:

    ```
    kubectl apply -f custom-ivs.yaml -n DEV-NAMESPACE
    ```

    Where `DEV-NAMESPACE` is the name of the developer namespace where scanning occurs.

Retrieving an image digest

SCST - Scan 2.0 custom resources require the digest form of the URL. For example, `nginx@sha256:aa0afebbb3cfa473099a62c4b32e9b3fb73ed23f2a75a65ce1d4b4f55a5c2ef2`.

Use the Docker documentation to pull and inspect an image digest:

```
docker pull nginx:latest
docker inspect --format='{{index .RepoDigests 0}}' nginx:latest
```

Alternatively, you can install krane to retrieve the digest without pulling the image:

```
krane digest nginx:latest
```

Configure a ImageVulnerabilityScan for Carbon Black

This topic gives you an example of how to configure a secret and ImageVulnerabilityScan (IVS) for Carbon Black.

Example secret

This section contains a sample secret containing the Carbon Black credentials inside the `~/.cbctl/cbctl.yaml` config file. These credentials are used to authenticate your Carbon Black account. You can find these credentials in the Carbon Black console. See the Carbon Black documentation. You must apply this once to your developer namespace.

```
apiVersion: v1
kind: Secret
metadata:
  name: cbctl-creds
stringData:
  cbctl: |
    cb_api_id: CB-API-ID
    cb_api_key: CB-API-KEY
    org_key: ORG-KEY
    saas_url: SAAS-URL
```

Where:

- `CB-API-ID` is the API ID obtained from Carbon Black Cloud.
- `CB-API-KEY` is the API Key obtained from Carbon Black.
- `ORG-KEY` is the Org Key for your Carbon Black organization.
- `SAAS-URL` is the Carbon Black Backend URL.

Example ImageVulnerabilityScan

This section contains a sample IVS that uses Carbon Black to scan a targeted image and push the results to the specified registry location. For information about the IVS specification, see Configuration Options.

Set the tekton-pipelines feature-flags configmap `enable-api-fields` to `alpha`. This lets you use the `stdoutConfig` which is needed to output the scan report as a file.

```
apiVersion: app-scanning.apps.tanzu.vmware.com/v1alpha1
kind: ImageVulnerabilityScan
metadata:
  name: carbon-black-ivs
```

```
  annotations:
    app-scanning.apps.tanzu.vmware.com/scanner-name: Carbon-Black
spec:
  image: nginx@sha256:... # The image to be scanned. Digest must be specified.
  scanResults:
    location: registry/project/scan-results
  serviceAccountNames:
    publisher: publisher
    scanner: scanner
  workspace:
    bindings:
    - name: cbctl
      secret:
        secretName: cbctl-creds
        items:
          - key: cbctl
            path: .cbctl.yaml
  steps:
  - name: carbon-black
    image: CARBON-BLACK-SCANNER-IMAGE
    imagePullPolicy: IfNotPresent
    command:
    - cbctl
    - image
    - scan
    - --force=true
    - $(params.image)
    - --config
    - /cbctl/.cbctl.yaml
    - -ocyclonedx
    stdoutConfig:
      path: /workspace/scan-results/scan-results.cdx.xml
```

Where:

- `CARBON-BLACK-SCANNER-IMAGE` is the Carbon Black scanner image. For example, `cbartifactory/cbctl:latest`. For information about publicly available Carbon Black images, see DockerHub. For more information about using the Carbon Black Scanner CLI, see the Carbon Black documentation.

The Carbon Black `cbctl-creds` secret is mounted as a workspace binding and the credentials are inserted into a `cbctl.yaml` config file that the Carbon Black CLI uses.

`stdoutConfig.path` is specified to take the output stream of the step to a file where you can publish it to the registry. For more information, see the Tekton documentation.

Disclaimer

For the publicly available Carbon Black scanner CLI image, CLI commands and parameters used are accurate at the time of documentation.

Configure an ImageVulnerabilityScan for Snyk

This topic gives you an example of how to configure a secret and ImageVulnerabilityScan (IVS) for Snyk.

Example Secret

Important

> For the publicly available Snyk scanner CLI image, CLI commands and parameters used are accurate at the time of documentation.

This section contains a sample secret containing the Snyk API token, which authenticates your Snyk account. You must apply this once to your developer namespace.

```
apiVersion: v1
kind: Secret
metadata:
  name: snyk-token
stringData:
  snyk: |
    {"api": "SNYK-API-TOKEN"}
```

Where:

- `SNYK-API-TOKEN` is your Snyk API token obtained by following the instructions in the Snyk documentation. Do not base64 encode this value.

Example ImageVulnerabilityScan

This section contains a sample IVS that uses Snyk to scan a targeted image and push the results to the specified registry location. For information about the IVS specification, see Configuration Options.

```
apiVersion: app-scanning.apps.tanzu.vmware.com/v1alpha1
kind: ImageVulnerabilityScan
metadata:
  name: snyk-ivs
  annotations:
    app-scanning.apps.tanzu.vmware.com/scanner-name: Snyk
spec:
  image: TARGET-IMAGE
  scanResults:
    location: registry/project/scan-results
  serviceAccountNames:
    publisher: publisher
    scanner: scanner
  workspace:
    bindings:
    - name: snyk
      secret:
        secretName: snyk-token
        items:
          - key: snyk
            path: configstore/snyk.json
  steps:
  - name: snyk
    image: SNYK-SCANNER-IMAGE
    env:
    - name: XDG-CONFIG-HOME
      value: /snyk
    command: ["snyk","container","test",$(params.image),"--json-file-output=$(params.s
can-results-path)/scan.json"]
    onError: continue
  - name: snyk2spdx # You will need to create your own image. See explanation below.
    image: SNYK2SPDX-IMAGE
    command: ["/bin/bash"]
    args:
      - "-c"
      - |
        set -e
```

```
        cat $(params.scan-results-path)/scan.json | /app/bin/snyk2spdx --output=$(para
ms.scan-results-path)/scan.spdx.json
```

Where:

- `TARGET-IMAGE` is the image to be scanned. You must specify the digest.
- `SNYK-SCANNER-IMAGE` is the image containing the Snyk CLI. For example, `snyk/snyk:golang`. For information about publicly available Snyk images, see DockerHub. For more information about using the Snyk CLI, see the Snyk documentation.
- `XDG-CONFIG-HOME` is the directory that contains your Snyk CLI config file, `configstore/snyk.json`, which is populated using the snyk-token `Secret` you created. For more information, see the Snyk Config documentation.
- `SNYK2SPDX-IMAGE` is the image used to convert the Snyk CLI output `scan.json` in the `snyk` step to SPDX format and have its missing `DOCUMENT DESCRIBES` relation inserted. See the Snyk snyk2spdx repository in GitHub. To do this:
    1. Clone the snyk2spdx repository.
    2. Add the following Dockerfile to the root of the repository:

        ```
        FROM node AS build

        RUN npm install -g typescript
        RUN npm install -g ts-node

        WORKDIR /build-dir
        ADD . .

        RUN npm install --legacy-peer-deps
        RUN npm run build && npm prune --json --omit=dev --legacy-peer-deps
        RUN npx nexe@3.3.7 dist/index.js  -r './dist/**/*.js' -t linux-x64-12.16.
        2 -o snyk2spdx-linux

        FROM paketobuildpacks/builder-jammy-base AS run

        COPY --from=build /build-dir/dist/ /app/dist/
        COPY --from=build /build-dir/node_modules /app/node_modules
        COPY --from=build /build-dir/snyk2spdx-linux /app/bin/snyk2spdx

        ENTRYPOINT ["/app/bin/snyk2spdx"]
        CMD ["/app/bin/snyk2spdx"]
        ```

    3. Build and push the image to a registry. Replace `SNYK2SPDX-IMAGE` with the new image you built.

Note

The `snyk2spdx` output does not conform to the verification process. Although the results might be ingested to the Tanzu Application Platform metadata store, VMware does not ensure the accuracy of the results.

Note

After detecting vulnerabilities, the Snyk image exits with Exit Code 1 and causes a failed scan task. You can ignore the step error by setting `onError` and handling the error in a subsequent step. For instructions, see the Tekton documentation.

For information about setting up scanner credentials, see the Snyk CLI documentation.

Configure an ImageVulnerabilityScan for Prisma

This topic gives you an example of how to configure a secret and ImageVulnerabilityScan (IVS) for Prisma.

Example secret

This section contains a sample secret containing the Prisma Cloud account access key, secret key, and console URL which are used to authenticate your Prisma account. You must apply this once to your developer namespace.

```
apiVersion: v1
kind: Secret
metadata:
  name: prisma-auth
stringData:
  username: USERNAME
  password: PASSWORD
  address: ADDRESS
```

Where:

- `USERNAME` is the access Key from the Prisma Cloud account.
- `PASSWORD` is the secret Key from the Prisma Cloud account.
- `ADDRESS` is the URL for Console from the Prisma Cloud account.

Example ImageVulnerabilityScan

This section contains a sample IVS that uses Prisma to scan a targeted image and push the results to the specified registry location. For information about the IVS specification, see Configuration Options.

```
apiVersion: app-scanning.apps.tanzu.vmware.com/v1alpha1
kind: ImageVulnerabilityScan
metadata:
  name: prisma-ivs
  annotations:
    app-scanning.apps.tanzu.vmware.com/scanner-name: Prisma
spec:
  image: TARGET-IMAGE
  scanResults:
    location: registry/project/scan-results
  serviceAccountNames:
    publisher: publisher
    scanner: scanner
  steps:
  - name: prisma
    image: PRISMA-SCANNER-IMAGE
    imagePullPolicy: IfNotPresent
    workingDir: /workspace
    securityContext:
      privileged: true
      allowPrivilegeEscalation: true
      seccompProfile:
        type: RuntimeDefault
      capabilities:
        drop:
          - ALL
```

```
    script: |
      #!/bin/bash
      # Alternative method of making twistcli available in the container
      curl --output ./twistcli --write-out "%{http_code}" -s -L -k -u $USER_NAME:$PASS
WORD $ADDRESS/api/v1/util/twistcli
      chmod +x /workspace/twistcli

      if [[ ! -e /cred-helper/config.json ]]; then
      echo "{}" > /cred-helper/config.json
      fi

      podman pull $IMAGE
      twistcli images scan --podman-path /usr/bin/podman --address $ADDRESS --user $US
ER_NAME --password $PASSWORD $IMAGE --output-file ./twist-scan.json --containerized

      # Input commands used for your Prisma summary report conversion. See below for m
ore detail.
      twistoutput=./twist-scan.json
      twistversion=$(./twistcli -v | sed "s/twistcli version //")
      IMAGE_NAME=$(echo $IMAGE | cut -d'@' -f1)
      IMAGE_DIGEST=$(echo $IMAGE | cut -d'@' -f2)
      /prismaconverter image $twistversion $twistoutput "./" "./scan-results/twist-sca
n-cdx.json" $IMAGE_NAME $IMAGE_DIGEST
    env:
    - name: USER_NAME
      valueFrom:
        secretKeyRef:
          key: username
          name: prisma-auth
          optional: false
    - name: PASSWORD
      valueFrom:
        secretKeyRef:
          key: password
          name: prisma-auth
          optional: false
    - name: ADDRESS
      valueFrom:
        secretKeyRef:
          key: address
          name: prisma-auth
          optional: false
    - name: IMAGE
      value: $(params.image)
  workspace: {}
```

Where:

- `TARGET-IMAGE` is the image to scan. You must specify the digest.
- `PRISMA-SCANNER-IMAGE` is the image containing the Prisma Cloud twistcli, podman, and a utility to convert the Prisma summary report in JSON format to a CycloneDX SBOM in XML format. The Prisma scanner produces a proprietary output instead of community standard CycloneDX or SPDX. Because of this, you cannot use the scan report summary produced by Prisma as is and you must convert it. Contact your account team if you want to use Prisma and need this utility.
- The `securityContext` grants root access as Prisma requires root access to run. If permission is not given, you might encounter a `cannot clone: Operation not permitted` error message. For information about the `securityContext`, see Customize an ImageVulnerabilityScan. Due to needing root access, you cannot run Prisma scans in clusters with restricted pod Security Standards.

For information about using the CLI, see the Prisma twistcli docs.

Configure an ImageVulnerabilityScan for Trivy

This topic gives you an example of how to configure an ImageVulnerabilityScan (IVS) for Trivy.

Example ImageVulnerabilityScan

This section gives you an example IVS that uses Trivy to scan a targeted image and push the results to the specified registry location. For information about the IVS specification, see Configuration Options.

```
apiVersion: app-scanning.apps.tanzu.vmware.com/v1alpha1
kind: ImageVulnerabilityScan
metadata:
  name: trivy-ivs
  annotations:
    app-scanning.apps.tanzu.vmware.com/scanner-name: Trivy
spec:
  image: TARGET-IMAGE
  scanResults:
    location: registry/project/scan-results
  serviceAccountNames:
    publisher: publisher
    scanner: scanner
  steps:
  - name: trivy
    image: TRIVY-SCANNER-IMAGE
    command: ["trivy"]
    args:
    - image
    - $(params.image)
    - --exit-code=0
    - --no-progress
    - --scanners=vuln
    - --format=cyclonedx
    - --output=$(params.scan-results-path)/scan.cdx.json
```

Where:

- `TARGET-IMAGE` is the image to be scanned. Digest must be specified.
- `TRIVY-SCANNER-IMAGE` is the image containing the Trivy CLI. For example, `aquasec/trivy:0.42.1`. For information about publicly available Trivy images, see DockerHub. For more information about using the Trivy CLI, see the Trivy documentation.

Note

Trivy versions greater than 0.42.1 are not supported as they output CycloneDX 1.5 which is not supported for ingestion.

Trivy database size requirement

The recommended `storageSize` for Trivy scans is 4Gi due to the size of the Trivy database. If the `storageSize` is not sufficient, you might encounter a `no space left on device` error when initializing the database in the scan pod.

Update the `app-scanning-values-file.yaml` for the `app-scanning.apps.tanzu.vmware.com` package to change the default `storageSize`. See installation documentation.

```
scans:
  workspace:
    storageSize: 4Gi
```

If you do not want to set a default `storageSize` by updating the `app-scanning-values-file.yaml`, you must specify the `spec.workspace.size` when creating each standalone ImageVulnerabilityScan or embedded ImageVulnerabilityScan in a ClusterImageTemplate.

Warning As a publicly maintained image that is built outside of VMware build systems, the image might not meet the security standards VMware has established. Ensure that you review the image before use to ensure that it meets your organizations security and compliance policies. For the publicly available Trivy scanner CLI image, CLI commands and parameters used are accurate at the time of documentation.

Configure a ImageVulnerabilityScan for Grype

This topic gives you an example of how to configure an ImageVulnerabilityScan (IVS) for Grype.

Example ImageVulnerabilityScan

This section contains a sample IVS that uses Grype to scan a targeted image and push the results to the specified registry location. For information about the IVS specification, see Configuration Options.

```
apiVersion: app-scanning.apps.tanzu.vmware.com/v1alpha1
kind: ImageVulnerabilityScan
metadata:
  name: grype-ivs
  annotations:
    app-scanning.apps.tanzu.vmware.com/scanner-name: Grype
spec:
  image: TARGET-IMAGE
  scanResults:
    location: registry/project/scan-results
  serviceAccountNames:
    publisher: publisher
    scanner: scanner
  steps:
  - name: grype
    image: GRYPE-SCANNER-IMAGE
    args:
    - -o
    - cyclonedx-json
    - registry:$(params.image)
    - --file
    - /workspace/scan-results/scan.cdx.json
    env:
    - name: GRYPE_ADD_CPES_IF_NONE
      value: "false"
    - name: GRYPE_EXCLUDE
    - name: GRYPE_SCOPE
```

Where:

- `TARGET-IMAGE` is the image to scan. You must specify digest.
- `GRYPE-SCANNER-IMAGE` is the image containing the Grype CLI. For example, `anchore/grype:latest`. For information about publicly available Grype images, see DockerHub. For more information about using the Grype CLI, see the Grype documentation.

Grype database size requirement

The recommended `storageSize` for Grype scans is 4Gi due to the size of the Grype database. If the `storageSize` is not sufficient, you might encounter an error indicating insufficient space when initializing the database in the scan pod.

Update the `app-scanning-values-file.yaml` for the `app-scanning.apps.tanzu.vmware.com` package to change the default `storageSize`. See installation documentation.

```
scans:
  workspace:
    storageSize: 4Gi
```

If you do not want to set a default `storageSize` by updating the `app-scanning-values-file.yaml`, you must specify the `spec.workspace.size` when creating each standalone ImageVulnerabilityScan or embedded the ImageVulnerabilityScan in a ClusterImageTemplate.

Warning As a publicly maintained image that is built outside of VMware build systems, the image might not meet the security standards VMware established. Ensure that you review the image before use to ensure that it meets your organizations security and compliance policies. For the publicly available Grype scanner CLI image, CLI commands and parameters used are accurate at the time of documentation.

Verify scanning with Supply Chain integration

This topic tells you how to verify scanning with Supply Chains.

Create a workload

Create a sample workload with a pre-built image by using the `tanzu apps workload create` command:

```
tanzu apps workload create WORKLOAD-NAME \
  --app APP-NAME \
  --git-repo GIT-REPO \
  --git-branch GIT-BRANCH \
  --type TYPE \
  --namespace DEV-NAMESPACE
```

Where:

- `WORKLOAD-NAME` is the name you choose for your workload.
- `APP-NAME` is the name of your app.
- `GIT-REPO` is the Git repository from which the workload is created.
- `GIT-BRANCH` is the branch in a Git repository from where the workload is created.
- `TYPE` is the type of your app.
- `DEV-NAMESPACE` is the name of the developer namespace where scanning occurs.

Note For information about how to use the Tanzu CLI workload creation, see Create a Workload.

Retrieve scan results

Scan results are uploaded to the container image registry as an imgpkg bundle. To retrieve a vulnerability report:

1. Retrieve the result location from the ImageVulnerabilityScan CR Status:

```
SCAN_RESULT_URL=$(kubectl get imagevulnerabilityscan my-scan -n DEV-NAMESPACE -
o jsonpath='{.status.scanResult}')
```

2. Download the bundle to a local directory and list the content:

```
imgpkg pull -b $SCAN_RESULT_URL -o scan-results/
ls scan-results/
```

Set up recurring scanning

This topic describes how to set up recurring scans using Supply Chain Security Tools (SCST) - Scan 2.0.

Overview

Scan workloads with updated vulnerability databases frequently. Use the scanner of your choice to scan images produced by your software supply chain, and any container images running in your Tanzu Application Platform clusters.

Use SCST - Scan 2.0 to schedule container image scans with the following capabilities:

- Detect vulnerabilities without a supply chain run for the following container image sources:
    - Images produced by the supply chain using Tanzu Build Service or kaniko.
    - Images defined in a workload when using a prebuilt container image in your supply chain.
    - Images running in a Tanzu Application Platform cluster that were not produced by a software supply chain.
- Customize how far back you want to scan container images based on:
    - When the container image was created in the supply chain.
    - When the container image entered a running state on your Tanzu Application Platform cluster.
- Use one of the `ImageVulnerabilityScan` samples or create your own.
    - For more information, see ImageVulnerabilityScan samples or Bring your own scanner using an ImageVulnerabilityScan.
- View discovered vulnerabilities from your most recent image built for a workload in the Tanzu Developer Portal Supply Chain Choreographer plug-in.
- Use when either SCST - Scan 1.0 or SCST - Scan 2.0 is used to scan a recently built container in your supply chain.

Set up recurring scanning

Unlike scans that occur as part of the software supply chain, scans invoked by recurring scanning run as a centralized scan job in a single namespace. The scan job gathers images from all namespaces. To set up recurring scanning, you must create a `RecurringImageVulnerabilityScan`. A `RecurringImageVulnerabilityScan` defines:

- The interval in which to scan container images in crontab format.
- How many images, created using the supply chain, to scan as determined by the selected number of days in the past.

- How many images, started in your Tanzu Application Platform clusters, to scan as determined by the selected number of days in the past.
- The steps from the IVS template to use to scan your images, which define which scanner to use.
- The OCI-compliant registry to push the recurring scan results to.

Prerequisites

Before you define your `RecurringImageVulnerabilityScan` template, you must have:

- A repository created on an OCI compliant registry that scan results are pushed to.
- A namespace in which to create the recurring scan template. This is where all the recurring scan jobs will run.
- A service account within the namespace that can push an OCI artifact to the results repository.
- Credentials for any registry the scanner must pull images from to scan.

Recurring scanning uses the SCST - Scan 2.0 component, which is in the `Full` and `Build Profiles`.

Note

Pay special attention to the service accounts and credentials that are needed. For a simplified setup of the namespace, VMware recommends that you use Namespace Provisioner to create a namespace. Namespace Provisioner automatically creates the service accounts and secrets needed for images created by supply chains. The examples in this topic use a namespace created by Namespace Provisioner. For more information, see Namespace Provisioner.

Example RecurringImageVulnerabilityScan template

The following sample template provides an explanation of the input variables for the `RecurringImageVulnerabilityScan` CR. Use the Grype and Trivy samples in a namespace created by Namespace Provisioner. The Grype and Trivy examples are a subset of this template. Add additional configurations from this template to the Grype and Trivy samples for more advanced configurations.

```
apiVersion: app-scanning.apps.tanzu.vmware.com/v1alpha1
kind: RecurringImageVulnerabilityScan
metadata:
  name: recurring-scan-template
spec:
  images:
    ranWithinDays: RAN-INTERVAL
    createdWithinDays: CREATED-INTERVAL
  retentionPolicy:
    maxFailedScans: FAILED-RETENTION
    maxSuccessfulScans: SUCESSFUL-RETENTION
  schedule:
    cron: CRON-SCHEDULE
    startingDeadline: START-DEADLINE
  scan:
    activeKeychains:
    # Only enable keychains for registries you are using
    - name: acr  # Azure Container Registry
    - name: ecr  # Elastic Container Registry
    - name: gcr  # Google Container Registry
```

```
    - name: ghcr # Github Container Registry
    workspace:
      size: WORKSPACE-SIZE
    scanResults:
      location: RESULTS-REPOSITORY
    steps:
      STEPS-FROM-IVS-TEMPLATE
```

Where:

- `RAN-INTERVAL`: How many prior days of images from pods that have started on the Tanzu Application Platform clusters to scan.
- `CREATED-INTERVAL` How many prior days of images from supply chains to scan.
- `FAILED-RETENTION`: The number of failed recurring scan executions to keep in Kubernetes.
- `CRON-SCHEDULE`: The schedule in which to invoke recurring scans in crontab format. For example, to execute a scan daily at 3:00 AM, the value is `0 3 * * *`
- `START-DEADLINE`: The period of time beyond the scheduled start time when scans can be started if they did not start on time. If this period elapses, the scheduled scan is skipped.
- `SUCESSFUL-RETENTION`: The number of successful recurring scan executions to keep in Kubernetes.
- `WORKSPACE-SIZE`: The size of the workspace used when scanning images. This is created as a Kubernetes PVC. This depends mostly on the size of the vulnerability database, the number of images to be scanned, and the output of the vulnerability scanner. `10Gi` is the recommended starting point.
- `RESULTS-REPOSITORY`: The registry URL where results are uploaded. For example, `my.registry/scan-results`.
- `STEPS-FROM-IVS-TEMPLATE`: The steps to execute to scan the list of the container images. See ImageVulnerabilityScan samples for commonly used samples. To pass `spec.image` and `scanResults.location` to `args`, you can use `{image}` and `{output}` respectively. These interpolation variables differ from the ones currently used in the `ImageVulnerabilityScan` (`$(params.image)` and `$(params.scan-results-path)`).

Note

The scan step should be the last step in the `steps` property.

Pay special attention to the scanning runtime, the scan frequency, and the configured deadline. Setting `RAN-INTERVAL` and `CREATED-INTERVAL` to a large number of days can increase the number of images scanned, and in turn, the scanning runtime. If the scan runtime is greater than the `CRON-SCHEDULE` frequency, the scans start to queue up. VMware recommends running the scan once every 24 hours at a time when your cluster load is low.

Grype RecurringImageVulnerabilityScan template

The SCST - Scan 1.0 default scanner is Grype, and this template works with the SCST - Scan 1.0 default configuration.

Note

You must match the scanner and version to the scanner and version used in the software supply chain. Using different types of scanners between build time and

recurring scans is not supported and results in vulnerabilities being double counted in the Security Analysis plug-in in Tanzu Developer Portal.

To apply this configuration, save it to a file and apply it to the namespace created for recurring scans:

```
kubectl apply -f grype-recurring-scan.yaml  --namespace NAMESPACE
```

```
apiVersion: app-scanning.apps.tanzu.vmware.com/v1alpha1
kind: RecurringImageVulnerabilityScan
metadata:
  name: grype-recurring-scan
spec:
  images:
    createdWithinDays: 180
    ranWithinDays: 0
  retentionPolicy:
    maxFailedScans: 1
    maxSuccessfulScans: 1
  schedule:
    cron: 0 3 * * *
    startingDeadline: 60m
  scan:
    workspace:
      size: 10Gi
    scanResults:
      location: RESULTS-REPOSITORY
    steps:
    - name: update-db
      image: anchore/grype:latest
      command: [/grype]
      args:
      - db
      - update
      env:
      - name: GRYPE_DB_CACHE_DIR
        value: /workspace/grype-cache
    - name: grype-scan
      image: anchore/grype:latest
      command: [/grype]
      args:
      - "{image}"
      - "-o"
      - "cyclonedx-json"
      - "--file"
      - "{output}"
      env:
      - name: GRYPE_DB_AUTO_UPDATE
        value: "false"
      - name: GRYPE_CHECK_FOR_APP_UPDATE
        value: "false"
      - name: GRYPE_DB_CACHE_DIR
        value: /workspace/grype-cache
```

This sample configuration, downloads the latest Grype vulnerability database and then scans with the stored database. This prevents multiple database updates while running concurrent scans.

The placeholder `{image}` is replaced by each one of the container images that are being scanned. This is equivalent to the `$(params.image)` placeholder used in the `ImageVulnerabilityScan`.

The placeholder `{output}` is replaced by an auto-generated path to store the results for the scanned image. This is equivalent to the `$(params.scan-results-path)` placeholder used in the

`ImageVulnerabilityScan`.

Trivy RecurringImageVulnerabilityScan template

The SCST - Scan 2.0 default scanner is Trivy, and this template works with the Scan 2.0 default configuration.

Note

You must match the scanner and version to the scanner and version used in the software supply chain. Using different types of scanners between build time and recurring scans is not supported and results in vulnerabilities being double counted in the Security Analysis plug-in in Tanzu Developer Portal.

To apply this configuration, save it to a file and apply it to the namespace created for recurring scans:

```
kubectl apply -f trivy-recurring-scan.yaml --namespace NAMESPACE
```

```
apiVersion: app-scanning.apps.tanzu.vmware.com/v1alpha1
kind: RecurringImageVulnerabilityScan
metadata:
  name: trivy-recurring-scan
spec:
  images:
    createdWithinDays: 180
    ranWithinDays: 0
  retentionPolicy:
    maxFailedScans: 1
    maxSuccessfulScans: 1
  schedule:
    cron: 0 3 * * *
    startingDeadline: 60m
  scan:
    workspace:
      size: 10Gi
    scanResults:
      location: RESULTS-REPOSITORY
    steps:
    - name: update-db
      image: aquasec/trivy:0.48.3
      command: [/usr/local/bin/trivy]
      args:
      - image
      - --download-db-only
      - --no-progress
      - --cache-dir=/workspace/trivy-cache
    - name: update-java-db
      image: aquasec/trivy:0.48.3
      command: [/usr/local/bin/trivy]
      args:
      - image
      - --download-java-db-only
      - --no-progress
      - --cache-dir=/workspace/trivy-cache
    - name: trivy-generate-report
      image: aquasec/trivy:0.48.3
      command: [/usr/local/bin/trivy]
      args:
      - image
      - '{image}'
```

```
    - --exit-code=0
    - --no-progress
    - --scanners=vuln
    - --format=cyclonedx
    - --output={output}
    - --cache-dir=/workspace/trivy-cache
    - --skip-db-update
    - --skip-java-db-update
```

This sample configuration downloads the latest Trivy vulnerability and Java databases and then scans with the stored databases. This prevents multiple database updates while running concurrent scans.

The placeholder `{image}` is replaced by each one of the container images that are being scanned. This is equivalent to the `$(params.image)` placeholder used in the `ImageVulnerabilityScan`.

The placeholder `{output}` is replaced by an auto-generated path to store the results for the scanned image. This is equivalent to the `$(params.scan-results-path)` placeholder used in the `ImageVulnerabilityScan`.

Note

Do not enclose the `{output}` interpolation value in quotes for a Trivy scan.

Enable policy enforcement with Scan 2.0 in a supply chain

This topic tells you how to enable policy enforcement in a supply chain with Supply Chain Security Tools (SCST) - Scan 2.0.

Policy enforcement is not built into SCST - Scan 2.0 and is not in any of the Out of the Box supply chains. You must author a custom supply chain to enable policy enforcement.

To enforce a policy in a supply chain you need a `ClusterImageTemplate` that uses a Tekton `TaskRun` to evaluate the vulnerabilities and enforces the set policy. This topic provides a sample `TaskRun` and a sample `ClusterImageTemplate` for you to edit.

Prepare for the `TaskRun`

The `TaskRun` queries the Metadata Store to get the list of vulnerabilities for the image. Authenticate with the Metadata Store API by obtaining an access token and a certificate:

1. Build an image that contains `curl` and `jq` for the `TaskRun` to use.
2. Get the access token from the Metadata Store by running:

   ```
   ACCESS-TOKEN=$(kubectl get secrets -n metadata-store  metadata-store-read-write
   -client -o yaml \
   | yq .data.token | base64 -d)
   ```

3. Create the secret `metadata-store-access-token-secret.yaml` and include the access token:

   ```
   kind: Secret
   apiVersion: v1
   metadata:
     name: metadata-store-access-token
   stringData:
     accessToken: ACCESS-TOKEN
   ```

   Where `ACCESS-TOKEN` is the access token

4. Get the Certificate Authority (CA) certificate from the Metadata Store by running:

```
MDS_CA_CERT=$(kubectl get secret -n metadata-store ingress-cert -o json | jq -r
".data.\"ca.crt\"" \
| base64 -d)
```

5. Create the secret `metadata-store-cert-secret.yaml` and include the certificate:

```
kind: Secret
apiVersion: v1
metadata:
  name: metadata-store-cert
stringData:
  caCrt: |
    METADATA-STORE-CA-CERT
```

   Where `METADATA-STORE-CA-CERT` is the Metadata Store CA certificate

6. Apply the created secrets in the developer namespace:

```
kubectl apply -f metadata-store-access-token-secret.yaml -n DEVELOPER-NAMESPACE
kubectl apply -f metadata-store-cert-secret.yaml -n DEVELOPER-NAMESPACE
```

Edit the `TaskRun` sample to enforce the policy

The following sample `TaskRun` waits until the vulnerability data is available for the image in the Metadata Store. When the data is available, the vulnerabilities are aggregated by severity. The policy that `GATE` sets determines whether `TaskRun` succeeds or fails.

Edit the sample for your needs:

```
apiVersion: tekton.dev/v1
kind: TaskRun
metadata:
  generateName: enforce-policy-task-run-
spec:
  serviceAccountName: SERVICE-ACCOUNT-THAT-CAN-READ-TAP-IMAGES
  params:
    - name: image
      value: IMAGE-WITH-DIGEST-THAT-WAS-SCANNED
  taskSpec:
    steps:
    - name: enforce-policy
      image: TASK-RUN-IMAGE-WITH-CURL-AND-JQ
      script: |
        if [ ${GATE} -eq "none" ]; then
            exit 0
        fi

        IMAGE_DIGEST=$(echo $(params.image) | cut -d "@" -f 2)
        while true; do
          response_code=$(curl https://$METADATA_STORE_URL/api/v1/images/${IMAGE_DIGES
T} -H "Authorization: Bearer ${ACCESS_TOKEN}" -H 'accept: application/json' --cacert /
var/cert/caCrt -o vulnerabilities.json -w "%{http_code}")
          if [ $response_code -eq 200 ]; then
            echo "Vulnerabilities data is available in AMR"
            break
          else
            echo "Vulnerabilities data is not available in AMR, waiting..."
            sleep 10
          fi
        done
```

```
        critical=$(cat vulnerabilities.json | jq '[.Packages[].Vulnerabilities[] | sel
ect(.Ratings[].Severity | contains("Critical"))] | unique | length')
        high=$(cat vulnerabilities.json | jq '[.Packages[].Vulnerabilities[] | select
(.Ratings[].Severity | contains("High"))] | unique | length')
        medium=$(cat vulnerabilities.json | jq '[.Packages[].Vulnerabilities[] | selec
t(.Ratings[].Severity | contains("Medium"))] | unique | length')
        low=$(cat vulnerabilities.json | jq '[.Packages[].Vulnerabilities[] | select(.
Ratings[].Severity | contains("Low"))] | unique | length')
        vulnerabilitiesCount=0
        case $GATE in
          low)
            vulnerabilitiesCount=$(($low+$medium+$high+$critical))
            ;;
          medium)
            vulnerabilitiesCount=$(($medium+$high+$critical))
            ;;

          high)
            vulnerabilitiesCount=$(($high+$critical))
            ;;

          critical)
            vulnerabilitiesCount=$(($critical))
            ;;
        esac
        echo "Vulnerabilities: ${vulnerabilitiesCount}"
        if [ ${vulnerabilitiesCount} -gt 0 ];then
          exit 1
        fi
      env:
      - name: GATE
        value: "critical"
      - name: METADATA_STORE_URL
        value: METADATA-STORE-URL-VALUE
      - name: ACCESS_TOKEN
        valueFrom:
          secretKeyRef:
            name: METADATA-STORE-ACCESS-TOKEN
            key: accessToken
      volumeMounts:
      - name: cert
        mountPath: /var/cert
    volumes:
    - name: cert
      secret:
        secretName: SECRET-CONTAINING-METADATA-STORE-CERT
```

Where:

- `GATE` is an environment variable that sets the threshold for severity in the policy. The accepted values are `low`, `medium`, `high`, and `critical`. For example, if the `GATE` is set to `high` then the `TaskRun` fails if it finds `high` or `critical` vulnerabilities for the image. If the `GATE` is set to `none`, no policy is enforced and `TaskRun` succeeds.
- `METADATA-STORE-URL-VALUE` is the URL for reaching the Metadata Store. In a single-cluster deployment, the value is `metadata-store-app.metadata-store.svc.cluster.local:8443`. In a multicluster deployment, the value is `metadata-store.VIEW-CLUSTER-INGRESS-DOMAIN`.
- `IMAGE-WITH-DIGEST-THAT-WAS-SCANNED` is the image that was built and scanned in the previous steps of the supply chain. The environment variable value is set to `#@ data.values.image` while embedding the `TaskRun` in the `ClusterImageTemplate`. Template this value to enable it be passed through the supply chain.
- `SERVICE-ACCOUNT-THAT-CAN-READ-TAP-IMAGES` is a service account in the developer namespace that has access to read Tanzu Application Platform images. `TaskRun` uses this

service account to pull images for its execution steps.

- `TASK-RUN-IMAGE-WITH-CURL-AND-JQ` is any image that contains `curl` and `jq` commands.
- `METADATA-STORE-ACCESS-TOKEN` is the secret that contains the Metadata Store read access token.
- `SECRET-CONTAINING-METADATA-STORE-CERT` is the name of the secret that contains the Metadata Store certificate.

Include the policy `ClusterImageTemplate` in the newly authored supply chain

To include the policy `ClusterImageTemplate` in the newly authored supply chain:

1. Create `policy-cluster-image-template.yaml` by embedding the updated `TaskRun` in a `ClusterImageTemplate`. Set the values for environment variables and properties you used when editing the TaskRun sample to enforce the policy:

```
#@ load("@ytt:data", "data")
---
apiVersion: carto.run/v1alpha1
kind: ClusterImageTemplate
metadata:
  name: scan-policy-template
spec:
  imagePath: spec.params[?(@.name=="image")].value
  healthRule:
    multiMatch:
      healthy:
        matchConditions:
          - type: Succeeded
            status: "True"
      unhealthy:
        matchConditions:
          - type: Succeeded
            status: "False"
  ytt: |
    #@ load("@ytt:data", "data")
    #@ load("@ytt:template", "template")
    ---
    apiVersion: tekton.dev/v1
    kind: TaskRun
    metadata:
      name: enforce-policy
    spec:
      serviceAccountName: scanner
      taskSpec:
        steps:
        - name: enforce-policy
          image: dev.local:5000/taskrun-image:latest
          script: |
          ....
            IMAGE_DIGEST=$(echo ${IMAGE} | cut -d "@" -f 2)
          ....
          env:
          ...
          - name: IMAGE
            value: #@ data.values.image # <------ template the image so that it
can flow through the supply chain
          ....
```

2. Create a new supply chain named `custom-supply-chain.yaml` by following the steps in Author your supply chains.

   The scan step generates the vulnerability data that the policy step queries the Metadata Store for. Therefore the policy step must be after the scan step and must take the image produced by the scan step as an input image. You can place any step that requires an image as an input after the policy step.

```
---
apiVersion: carto.run/v1alpha1
kind: ClusterSupplyChain
metadata:
  name: CUSTOM-SUPPLY-CHAIN-NAME
spec:
  selectorMatchExpressions:
    - key: 'apps.tanzu.vmware.com/workload-type'
      operator: In
      values:
      - web
      - server
      - worker
  selectorMatchFields:
    - key: spec.image
      operator: Exists

  params:
    - name: image_scanning_service_account_publisher
      value: scanner
    - name: image_scanning_service_account_scanner
      default: report-publisher
    - name: image_scanning_workspace_size
      default: 4Gi

  resources:
  - name: image-provider
    templateRef:
      kind: ClusterImageTemplate
      name: image-provider-template
    params:
      - name: serviceAccount
        default: scanner

  - name: image-scanner
    templateRef:
      kind: ClusterImageTemplate
      name: image-vulnerability-scan-trivy
    params:
      - name: registry
        default:
          server: dev.registry.tanzu.vmware.com
          repository: tanzu-image-signing/test-policy
    images:
      - resource: image-provider
        name: image

  - name: policy # policy cluster image template
    templateRef:
      kind: ClusterImageTemplate
      name: scan-policy-template
    params:
      - name: serviceAccount
        default: scanner
    images:
    - resource: image-scanner
```

```
      name: image
    ... # supply chain continues
```

Apply the template, supply chain, and workload

To apply the template, supply chain, and workload:

1. Apply the generated `ClusterImageTemplate` and `ClusterSupplyChain` by running:

   ```
   kubectl apply -f policy-cluster-image-template.yaml
   kubectl apply -f custom-supply-chain.yaml
   ```

2. Create a workload in the developer namespace that can trigger the supply chain. For more information about selectors and how to use them with a custom supply chain, see Providing your own supply chain.

Troubleshoot the policy

If the policy is still waiting to find the vulnerabilities data for the image in the Metadata Store:

1. Verify that the observer is healthy and running.
2. Verify that the observer registered the controller to monitor the `ImageVulnerabilityScan` kind. For more information about troubleshooting the observer, see Troubleshooting Artifact Metadata Repository.

Supply Chain Security Tools - Scan 2.0 Observability

This topic guides you through observing Supply Chain Security Tools (SCST) - Scan 2.0. This helps you understand each step of scanning.

Scanning Steps

This section describes each of the scanning steps and corresponding observability methods.

- To watch the status of the scanning custom resources and child resources:

  ```
  kubectl get -l imagevulnerabilityscan pipelinerun,taskrun,pod
  kubectl get imagevulnerabilityscan
  ```

- View the status, reason, and urls:

  ```
  kubectl get imagevulnerabilityscan -o wide
  ```

- View the complete status and events of scanning custom resources:

  ```
  kubectl describe imagevulnerabilityscan IMAGE-VULNERABILITY-SCAN-NAME
  ```

  Where `IMAGE-VULNERABILITY-SCAN-NAME` is the name of an `ImageVulnerabilityScan` resource you want to inspect.

- List the child resources of a scan:

  ```
  kubectl get -l imagevulnerabilityscan=$NAME pipelinerun,taskrun,pod
  ```

- Get the logs of the controller:

```
kubectl logs -f deployment/app-scanning-controller-manager -n app-scanning-syst
em -c manager
```

Troubleshooting Supply Chain Security Tools - Scan 2.0

This topic helps you troubleshoot Supply Chain Security Tools (SCST) - Scan 2.0.

Overview

When Scan 2.0 creates an ImageVulnerabilityScan, the following resources are also created:

- Tekton `PipelineRun` with the following `Tasks`:
  - workspace-setup-task
  - scan-task
  - publish-task
- Tekton `TaskRun` corresponding to each `Task`
- `Pod` corresponding to each `TaskRun`

Viewing resources

- To view all resources:

  ```
  kubectl get imagevulnerabilityscans,pipelineruns,taskruns,pods -n DEV-NAMESPACE
  ```

  Where `DEV-NAMESPACE` is the name of your developer namespace.

- To verify which resources are failing, proceed to the following debugging sections:

  ```
  NAME                                                                SUCCEEDED
  REASON
  imagevulnerabilityscan.app-scanning.apps.tanzu.vmware.com/my-scan   False
  Failed

  NAME                                  SUCCEEDED   REASON      STARTTIME   COMP
  LETIONTIME
  pipelinerun.tekton.dev/my-scan-5kllf   False       Failed      2m10s       85s

  NAME                                                    SUCCEEDED   REASON
  STARTTIME   COMPLETIONTIME
  taskrun.tekton.dev/my-scan-5kllf-publish-task           False       Failed
  94s         85s
  taskrun.tekton.dev/my-scan-5kllf-scan-task              True        Succeeded
  2m1s        94s
  taskrun.tekton.dev/my-scan-5kllf-workspace-setup-task   True        Succeeded
  2m9s        2m1s

  NAME                                        READY   STATUS      RESTARTS   AGE
  pod/my-scan-5kllf-publish-task-pod          0/4     Completed   1          94s
  pod/my-scan-5kllf-scan-task-pod             0/4     Completed   1          2m
  pod/my-scan-5kllf-workspace-setup-task-pod  0/2     Completed   1          2m1
  0s
  ```

Debugging commands

The following sections describe commands you run to get logs and details about scanning errors.

Debugging resources

If a resource fails or has errors, inspect the resource. If multiple resources are involved, inspecting them all can provide a broader understanding. For example, inspecting the corresponding `TaskRun` to a failed `Pod`.

To get status conditions on a resource:

```
kubectl describe RESOURCE RESOURCE-NAME -n DEV-NAMESPACE
```

Where:

- `RESOURCE` is one of the following: `ImageVulnerabilityScan`, `PipelineRun`, `TaskRun`, or `Pod`.
- `RESOURCE-NAME` is the name of the `RESOURCE`.
- `DEV-NAMESPACE` is the name of your developer namespace.

Debugging scan pods

You can use the following methods to debug scan pods:

- To get error logs from a pod when scan pods fail:

  ```
  kubectl logs SCAN-POD-NAME -n DEV-NAMESPACE
  ```

  Where `SCAN-POD-NAME` is the name of the scan pod.

  For information about debugging Kubernetes pods, see the Kubernetes documentation.

  A scan run that has an error can indicate that one of the following step containers has a failure:

  - `step-workspace-setup`
  - `step-write-certs`
  - `step-cred-helper`
  - `step-SCANNER`
  - `step-publisher`
  - `sidecar-sleep`

  Where `step-SCANNER` is your scanner step.

- To verify which step container had a failed exit code:

  ```
  kubectl get taskrun TASKRUN-NAME -o json | jq .status
  ```

  Where `TASKRUN-NAME` is the name of the TaskRun.

- To inspect a specific step container in a pod:

  ```
  kubectl logs scan-pod-name -n DEV-NAMESPACE -c step-container-name
  ```

  Where `DEV-NAMESPACE` is your developer namespace.

  For information about debugging a TaskRun, see the Tekton documentation.

- To debug inside of the scan-task pod: Add an additional step with a `sleep` command after your scanner step in the ImageVulnerabilityScan. For example:

  ```
  ...
  spec:
  ```

```
  ...
  steps:
  - name: SCANNER-STEP
    ...
  - name: view
    image: busybox:latest
    args:
    - -c
    - sleep 6000
```

This keeps the pod in a running state so that you can exec into it. Re-run the scan and then exec into the pod:

```
    kubectl exec SCAN-TASK-POD-NAME -n DEV-NAMESPACE -c step-view --stdin --tty
-- sh
```

Where `SCAN-TASK-POD-NAME` is the name of your scan-task pod.

Viewing the Scan-Controller manager logs

You can run these commands to view the Scan-Controller manager logs:

- Retrieve scan-controller manager logs:

  ```
  kubectl logs deployment/app-scanning-controller-manager -n app-scanning-system
  ```

- Tail scan-controller manager logs:

  ```
  kubectl logs -f deployment/app-scanning-controller-manager -n app-scanning-syst
  em
  ```

Troubleshooting issues

Volume permission error

If you encounter a permission error for accessing, opening, and writing to the files inside cluster volume, such as:

```
unsuccessful cred copy: ".git-credentials" from "/tekton/creds" to "/home/app-scannin
g": unable to open destination: open /home/app-scanning/.git-credentials: permission d
enied
```

Ensure that the problematic step runs with the proper user and group ids.

Incompatible Tekton version

Tanzu Application Platform `v1.7.0` or later includes `app-scanning.apps.tanzu.vmware.com` version `0.2.0` and Tekton Pipelines version `0.50.1`. The `app-scanning.apps.tanzu.vmware.com` package is incompatible with previous versions of Tekton Pipelines as v1 CRDs were not enabled. You must upgrade Tanzu Application Platform to `v1.7.0` or later before upgrading `app-scanning.apps.tanzu.vmware.com`.

If you did not upgrade Tanzu Application Platform before upgrading `app-scanning.apps.tanzu.vmware.com`, you can encounter ImageVulnerabilityScans not progressing:

```
NAME      SUCCEEDED   REASON
my-scan
```

To resolve this issue:

1. Confirm that the issue is due to installing an incompatible Tekton version by viewing the controller manager logs by running:

   ```
   kubectl -n app-scanning-system logs -f deployment/app-scanning-controller-manag
   er -c manager
   ```

   If you encounter the following error, proceed to the next step:

   ```
   ERROR  controller-runtime.source.EventHandler  failed to get informer from cach
   e  {"error": "failed to get API group resources: unable to retrieve the complet
   e list of server APIs: tekton.dev/v1: the server could not find the requested r
   esource"}
   ```

2. Upgrade Tanzu Application Platform to `v1.7.0` or later. See Upgrade your Tanzu Application Platform.

Scan results empty

The publish-task task fails if the `scan-results-path` (default value of `/workspace/scan-result`) is empty. To confirm, view the logs of the publish-task pod:

```
kubectl logs PUBLISH-TASK-POD-NAME -c step-publisher -n DEV-NAMESPACE
```

Where `PUBLISH-TASK-POD-NAME` is the name of your publish-task pod.

```
2023/08/22 17:09:49 results folder /workspace/scan-results is empty
```

To resolve this issue, you can debug within the scan-task pod by following the instructions under Debugging scan pods. You must use an image with both a shell and your scanner CLI image to run the `sleep` command and troubleshoot your scanner commands from within the container.

Scanning in a cluster with restricted Kubernetes Pod Security Standards

As part of compliance with the restricted profile for Kubernetes Pod Security Standards, you must set the `securityContext` of containers and initContainers. When a pod does not meet pod Security Standards, it is not created and vulnerability scanning cannot proceed. For more information, see the Kubernetes documentation.

You might see an error message similar to the following when describing the TaskRun:

```
pods "trivy-ivs-abcd-scan-task-pod" is forbidden: violates PodSecurity "restricted:lat
est": allowPrivilegeEscalation != false (container "prepare" must set securityContext.
allowPrivilegeEscalation=false), unrestricted capabilities (container "prepare" must s
et securityContext.capabilities.drop=["ALL"]), seccompProfile (pod or container "prepa
re" must set securityContext.seccompProfile.type to "RuntimeDefault" or "Localhost").
Maybe invalid TaskSpec. ScanPodError PodNotFound: no pod found
```

To resolve this issue:

1. Update your Tekton Pipelines package configuration in your `tap-values.yaml` with the following changes:

   ```
   tekton_pipelines:
       feature_flags:
           set_security_context: "true"
   ```

   Setting the `securityContext` resolves the `prepare` initContainer violation.

2. Update your Tanzu Application Platform installation by running:

```
tanzu package installed update tap -p tap.tanzu.vmware.com -v TAP-VERSION  --va
lues-file tap-values.yaml -n tap-install
```

Where `TAP-VERSION` is the version of Tanzu Application Platform installed.

3. Re-run the scan.

Supply Chain Security Tools - Scan 2.0 with Tanzu Supply Chain (Beta)

This topic provides an overview of using Supply Chain Security Tools (SCST) - Scan 2.0 with Tanzu Supply Chain (Beta). This section is only applicable if you are evaluating the beta release of Tanzu Supply Chain.

Integrating into a Tanzu Supply Chain

The SCST - Scan 2.0 component defines how to scan a container image with a scan solution by using the generic Kubernetes custom resource `ImageVulnerabilityScan`. This provides a generic interface that allows you to declare how Tanzu Application Platform executes a scan on a container image for a container image scan solution.

To run an `ImageVulnerabilityScan` in a Tanzu Supply Chain:

- Construct a Supply Chain using the Tanzu CLI.
- Create a Workload.

Getting started with SCST - Scan 2.0 with Tanzu Supply Chain

To use SCST - Scan 2.0 in a Tanzu Supply Chain, see Create Tanzu Supply Chain with SCST - Scan 2.0.

Create Tanzu Supply Chain with SCST - Scan 2.0

This section tells you how to create a Tanzu Supply Chain with SCST - Scan 2.0.

- Install SCST - Scan 2.0
- Set up the Supply Chain Component
- Create a Supply Chain that uses SCST - Scan 2.0 with a Component
- Create a workload from the Supply Chain

Install Supply Chain Security Tools - Scan 2.0 in a cluster

This topic describes how to install Supply Chain Security Tools (SCST) - Scan 2.0 if are not using a profile. By default, SCST - Scan 2.0 is installed in the build and full profiles.

Note

Follow the steps in this topic if you do not want to use a profile to install SCST - Scan 2.0. For more information about profiles, see Installation profiles in Tanzu Application Platform v1.9.

Prerequisites

SCST - Scan 2.0 requires the following prerequisites:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- Install the Tekton component.
- To store results, install AMR, and AMR Observer. Downstream Tanzu Application Platform services, such as Tanzu Developer Portal and Tanzu CLI, depend on scan results stored in SCST - Store to display correctly. For more information, see Artifact Metadata Repository Observer for Supply Chain Security Tools - Store.

Note

If you are installing SCST - Scan 2.0 in a cluster with restricted Kubernetes Pod Security Standards, you must update configurations for the Tekton Pipelines package. See Scanning in a cluster with restricted Kubernetes Pod Security Standards.

Configure properties

When you install SCST - Scan 2.0, you can configure the following optional properties:

Key	Default	Type	Description
caCertData	""	string	The custom certificates trusted by the scan's connections
docker.import	true	Boolean	Import `docker.pullSecret` from another namespace (requires secretgen-controller). Set to false if the secret is already present.
docker.pullSecret	registries-credentials	string	Name of a Docker pull secret in the deployment namespace to pull the scanner images
scans.maxConcurrentScans	10	integer	Maximum number of scans running at one time. Set to 0 to have no limit.
scans.priorityClassName	""	string	Name of a predefined PriorityClass to apply to scan pods
workspace.storageSize	2Gi	string	Size of the PersistentVolume that the Tekton pipelineruns uses
workspace.storageClass	""	string	Name of the storage class to use while creating the PersistentVolume claims used by Tekton pipelineruns

Note

If the StorageClass you select does not have a node limit but uses the node storage, such as hostpath, the nodes must have large enough disks. For example, if a scan creates a 2Gi volume on a hostpath type storage class, `2Gi * number of AMR images` indicates how much storage this cluster needs overall. `2Gi * number of AMR images / number of nodes` indicates how much storage each node needs.

Install

To install SCST - Scan 2.0:

1. List version information for the package:

```
tanzu package available list app-scanning.apps.tanzu.vmware.com --namespace tap
-install
```

For example:

```
$ tanzu package available list app-scanning.apps.tanzu.vmware.com --namespace t
ap-install
- Retrieving package versions for app-scanning.apps.tanzu.vmware.com...
    NAME                                VERSION              RELEASED-AT
    app-scanning.apps.tanzu.vmware.com  0.1.0              2023-03-01 20:00:00 -
0400 EDT
```

2. (Optional) Make changes to the default installation settings:

Retrieve the configurable settings:

```
tanzu package available get app-scanning.apps.tanzu.vmware.com/VERSION --values
-schema --namespace tap-install
```

Where `VERSION` is your package version number. For example, `0.1.0`.

For example:

```
tanzu package available get app-scanning.apps.tanzu.vmware.com/0.1.0 --values-s
chema --namespace tap-install
| Retrieving package details for app-scanning.apps.tanzu.vmware.com/0.1.0...

  KEY                     DEFAULT                 TYPE     DESCRIPTION
  docker.import           true                    boolean  Import `docker.pullS
ecret` from another namespace (requires
                                                           secretgen-controlle
r). Set to false if the secret will already be present.
  docker.pullSecret       registries-credentials  string   Name of a Docker pul
l secret in the deployment namespace to pull the scanner
                                                           images.
  workspace.storageSize   2Gi                     string   Size of the Persiste
nt Volume to be used by the tekton pipelineruns
  workspace.storageClass                          string   Name of the storage
class to use while creating the Persistent Volume Claims
                                                           used by tekton pipel
ineruns
  caCertData                                      string   The custom certifica
tes to be trusted by the scan's connections
```

To edit any of the default installation settings, create an `app-scanning-values-file.yaml` and append the key-value pairs to be modified to the file. For example:

```
scans:
  workspace:
    storageSize: 200Mi
```

3. Install the package. If you did not edit the default installation settings, you do not need to specify the `--values-file` flag.

```
tanzu package install app-scanning --package-name app-scanning.apps.tanzu.vmwar
e.com \
    --version VERSION \
    --namespace tap-install \
    --values-file app-scanning-values-file.yaml
```

Where `VERSION` is your package version number. For example, `0.1.0`.

For example:

```
tanzu package install app-scanning --package app-scanning.apps.tanzu.vmware.com
\
    --version 0.1.0 \
    --namespace tap-install \
    --values-file app-scanning-values-file.yaml

    Installing package 'app-scanning.apps.tanzu.vmware.com'
    Getting package metadata for 'app-scanning.apps.tanzu.vmware.com'
    Creating service account 'app-scanning-default-sa'
    Creating cluster admin role 'app-scanning-default-cluster-role'
    Creating cluster role binding 'app-scanning-default-cluster-rolebinding'
    Creating package resource
    Waiting for 'PackageInstall' reconciliation for 'app-scanning'
    'PackageInstall' resource install status: Reconciling
    'PackageInstall' resource install status: ReconcileSucceeded
```

Configure service accounts and registry credentials

This section contains instructions for running a standalone `ImageVulnerabilityScan` or using multiple registries.

If the image that you are scanning using a default scanner or your own scanner, and your vulnerability scanner image are located in private registries different from the `Tanzu Application Platform bundles registry`, you must edit your scanner service account to include registry credentials for these registries.

Important

If your use case is listed below, skip this topic and proceed to Enable App Scanning for default Test and Scan supply chains.

- You are running an `ImageVulnerabilityScan` in the context of a supply chain.
- You used the Namespace Provisioner to provision your developer namespace. For more information, see the Namespace Provisioner documentation.

To configure service accounts and registry credentials, SCST - Scan 2.0 requires the following access:

Registry	Permission	Service Account	Example
Tanzu Application Platform bundles registry	Read	scanner	`registry.tanzu.vmware.com`
Target image registry	Read	scanner	`your-registry.io`
Vulnerability scanner image registry	Read	scanner	`your-registry.io`
Scan results location registry	Write	publisher	`your-registry.io`

Where:

- `Tanzu Application Platform bundles registry` is the registry containing the Tanzu Application Platform bundles. This is the registry from the Relocate images to a registry step or `registry.tanzu.vmware.com`.
- `Target image registry` is the registry containing the image to scan. This registry credential is required if you are scanning a private image. The `image to scan is` called the `target`

`image` or `TARGET-IMAGE`.

- `Vulnerability scanner image registry` is the registry containing your vulnerability scanner image. This is only needed if you are bringing your own scanner and your vulnerability scanner image is located in a private registry different from the `Tanzu Application Platform bundles registry`.
- `Scan results location registry` is the registry where scan results are published.

To configure service accounts and registry credentials:

1. Create a secret `scanning-tap-component-read-creds` with read access to the registry containing the Tanzu Application Platform bundles. This pulls the SCST - Scan 2.0 images. If you previously relocated the Tanzu Application Platform bundles to your own registry, you can also place your vulnerability scanner image in this registry.

   ```
   read -s TAP_REGISTRY_PASSWORD
   kubectl create secret docker-registry scanning-tap-component-read-creds \
     --docker-username=TAP-REGISTRY-USERNAME \
     --docker-password=$TAP_REGISTRY_PASSWORD \
     --docker-server=TAP-REGISTRY-URL \
     -n DEV-NAMESPACE
   ```

   Where `DEV-NAMESPACE` is the developer namespace where scanning occurs.

2. If you are scanning a private target image, create a secret `target-image-read-creds` with read access to the registry containing that target image.

   

   Important

   If you followed the directions for Install Tanzu Application Platform, you can skip this step and use the `targetImagePullSecret` secret with your service account as referenced in your `tap-values.yaml`. See Full profile.

   ```
   read -s REGISTRY_PASSWORD
   kubectl create secret docker-registry target-image-read-creds \
     --docker-username=REGISTRY-USERNAME \
     --docker-password=$REGISTRY_PASSWORD \
     --docker-server=REGISTRY-URL \
     -n DEV-NAMESPACE
   ```

3. Create a secret `write-creds` with write access to the registry for the scanner to upload the scan results to.

   ```
   read -s WRITE_PASSWORD
   kubectl create secret docker-registry write-creds \
     --docker-username=WRITE-USERNAME \
     --docker-password=$WRITE_PASSWORD \
     --docker-server=DESTINATION-REGISTRY-URL \
     -n DEV-NAMESPACE
   ```

4. (Optional) If you are bringing your own vulnerability scanner and your vulnerability scanner image is located in a private registry different from the registry containing your Tanzu Application Platform bundles, you must create a secret `vulnerability-scanner-image-read-creds` with read access to the registry.

   ```
   read -s WRITE_PASSWORD
   kubectl create secret docker-registry vulnerability-scanner-image-read-creds \
     --docker-username=WRITE-USERNAME \
     --docker-password=$WRITE_PASSWORD \
   ```

```
  --docker-server=REGISTRY-URL \
  -n DEV-NAMESPACE
```

5. Create a `scanner-sa.yaml` file containing the service account `scanner` which enables SCST - Scan 2.0 to pull both the vulnerability scanner image and target image. Attach the one or more read secrets created earlier pulling the Tanzu Application Platform bundles, and optionally, your vulnerability scanner image under `imagePullSecrets`. Attach the read secret created earlier for your target image under `secrets`.

   ```
   apiVersion: v1
   kind: ServiceAccount
   metadata:
     name: scanner
     namespace: DEV-NAMESPACE
   imagePullSecrets:
   - name: scanning-tap-component-read-creds
   - name: vulnerability-scanner-image-read-creds # optional
   secrets:
   - name: target-image-read-creds
   ```

   Where:

   - `imagePullSecrets.name` includes the name of the secret used to pull the scan component from the registry. If you are bringing your own vulnerability scanner and the vulnerability scanner image is located in a separate private registry, you must also include the name of the secret with those registry credentials.
   - `secrets.name` is the name of the secret used to pull the target image to scan. This is required if the image you are scanning is private.

6. Apply the service account to your developer namespace by running:

   ```
   kubectl apply -f scanner-sa.yaml
   ```

7. Create a `publisher-sa.yaml` file containing the service account `publisher` which enables SCST - Scan 2.0 to push the scan results to a user specified registry.

   ```
   apiVersion: v1
   kind: ServiceAccount
   metadata:
     name: publisher
     namespace: DEV-NAMESPACE
   imagePullSecrets:
   - name: scanning-tap-component-read-creds
   secrets:
   - name: write-creds
   ```

   Where:

   - `imagePullSecrets.name` is the name of the secret used to pull the scan component image from the registry.
   - `secrets.name` is the name of the secret used to publish the scan results.

8. Apply the service account to your developer namespace by running:

   ```
   kubectl apply -f publisher-sa.yaml
   ```

(Optional) Set up your registry retention policy

Although Tanzu Application Platform ingests scan artifacts into the Metadata Store, and stores information such as packages and parsed vulnerabilities, only a pointer to the original SBOM location is stored. The original SBOM generated by the scan is not preserved within the Metadata Store. VMware recommends that you keep these original artifacts according to your organization's archival requirements.

If the registry specified to push scan results to support retention policies, you can configure the registry to delete old scan results automatically, depending on your archival requirements. Scan result artifacts accumulate over time and can quickly consume hard disk space.

For information about configuring Harbor tag retention rules, see the Harbor documentation. For example, you can configure Harbor to retain the most recently pushed # artifacts or retain the artifacts pushed within the last # days.

Retention policy setup differs between registry providers. Confirm with your specific registry's documentation about the configuration options.

Set up the Supply Chain Component

This topic describes tells you how to install the Trivy Supply Chain Component, and create a Custom Supply Chain Component by using SCST - Scan 2.0.

Install Trivy Supply Chain Component

This section describes how to install the Trivy Supply Chain Component that uses SCST - Scan 2.0.

1. List version information for the Trivy Supply Chain Component package by running.

   ```
   tanzu package available list trivy.app-scanning.component.apps.tanzu.vmware.com
   --namespace tap-install
   ```

   For example:

   ```
   $ tanzu package available list trivy.app-scanning.component.apps.tanzu.vmware.c
   om --namespace tap-install

   NAME                                                VERSION
   RELEASED-AT
   trivy.app-scanning.component.apps.tanzu.vmware.com  TRIVY-COMPONENT-VERSION
   2024-01-26 12:35:39 -0500 EST
   ```

2. Install the Trivy Supply Chain Component package by running.

   ```
   tanzu package install trivy-app-scanning-component -p trivy.app-scanning.compon
   ent.apps.tanzu.vmware.com \
       --version TRIVY-COMPONENT-VERSION \
       --namespace tap-install
   ```

Create a Custom Scanning Component

This section describes how to create a Custom Scanning Supply Chain Component that uses SCST - Scan 2.0. For more details about how to create a Component, see Tanzu Supply Chain docs.

1. Retrieve the component YAML of the Trivy Supply Chain Component by running.

   ```
   kubectl get component trivy-image-scan-1.0.0 -n trivy-app-scanning-catalog -o y
   aml > component.yaml
   ```

2. Edit the following lines in `component.yaml`:

```
apiVersion: supply-chain.apps.tanzu.vmware.com/v1alpha1
kind: Component
metadata:
  name: trivy-image-scan-1.0.0 # change to SCANNER-image-scan-1.0.0
  namespace: trivy-app-scanning-catalog # change to DEV-NAMESPACE
...
  description: Performs a trivy image scan using the scan 2.0 components # chan
ge trivy to SCANNER
  ...
    - name: image-scanning-cli
      value: # change to registry url of scanner image
    ...
    - name: image-scanning-steps-env-vars
      value: '[{"name":"<Name of Env var>","value":"<value of Env var>"}]' # in
sert env vars inside nested {}
    ...
    pipelineRef:
      name: trivy-image-scan-v2 # SCANNER-image-scan-v2. Replace with the name
of the pipeline created in the next step.
```

3. Remove the following fields from `component.yaml`:

```
metadata:
  annotations:
    ...
  creationTimestamp:
  generation:
  labels:
    ...
  resourceVersion:
  uid:
```

4. Customize a pipeline by retrieving the YAML of the Trivy Supply Chain Component's Pipeline.

    1. Retrieve pipeline YAML by running:

    ```
    kubectl get pipeline trivy-image-scan-v2 -n trivy-app-scanning-catalog -o
    yaml > pipeline.yaml
    ```

    2. Edit the following lines in the `pipeline.yaml`:

    ```
    apiVersion: tekton.dev/v1
    kind: Pipeline
    metadata:
      name: trivy-image-scan-v2 # change to SCANNER-image-scan-v2
    spec:
      description: Scans your image for vulnerabilities using Trivy # change
    Trivy to SCANNER
    ...
            resourceSpec:
              apiVersion: app-scanning.apps.tanzu.vmware.com/v1alpha1
              kind: ImageVulnerabilityScan
              metadata:
                annotations:
                  app-scanning.apps.tanzu.vmware.com/scanner-name: Trivy # ch
    ange to SCANNER
                ...
                steps:
                - args:
                  - # insert array of steps to run for SCANNER
                ...
    ```

```
              name: trivy-generate-report # change to any SCANNER
            ...
```

Where `SCANNER` is the name of the scanner from the scanning component

3. Remove the following fields from the `pipeline.yaml`:

```
metadata:
  annotations:
    ...
  creationTimestamp:
  generation:
  labels:
    ...
  resourceVersion:
  uid:
```

5. Apply the custom component and pipeline by running:

```
kubectl apply -f component.yaml -n DEV-NAMESPACE
kubectl apply -f pipeline.yaml -n DEV-NAMESPACE
```

6. (Optional) If you created your own component, it requires the following label so that it can be observed by Tanzu Supply Chain:

```
labels:
  supply-chain.apps.tanzu.vmware.com/catalog: tanzu
```

View components

This section tells you how to view the available components that were installed or applied.

```
kubectl get components -A -l "supply-chain.apps.tanzu.vmware.com/catalog=tanzu"
```

Example output:

```
$ kubectl get components -A -l "supply-chain.apps.tanzu.vmware.com/catalog=tanzu"

NAMESPACE                    NAME                               RESUMPTIONS   READY   R

```

Create a Supply Chain that uses SCST - Scan 2.0 with a Component

This topic tels you how to create a Tanzu Supply Chain with SCST - Scan 2.0, which replaces the previous solution for Supply Chain Choreographer for Tanzu.

Prerequisites

- Tanzu Supply Chain packages
    - Tanzu Supply Chain packages
    - Managed Resource Controller

  For more information, see Packages.
- Tanzu Supply Chain components
    - Source
    - Buildpack
    - Trivy Scanning
- Tanzu Application Platform packages
    - SCST - Scan 2.0
    - Tekton
- Tanzu CLI plug-ins
    - Tanzu Workload CLI plug-in
    - Tanzu Supply Chain CLI plug-in

  For more information see, Install the Tanzu Supply Chain CLI plug-ins.

Create a Supply Chain with SCST - Scan 2.0 and a Component

This section tells you how to create a supply chain with SCST - Scan 2.0 by using either a Trivy Supply Chain Component or a Custom Scanning Component.

Using Trivy Supply Chain Component
Complete the following steps:

1. Initialize Tanzu Supply Chain by running:

   ```
   tanzu supplychain init --group example.com
   ```

   Example output:

   ```
   $ tanzu supplychain init --group example.com
   Initializing group example.com
   Creating directory structure
   ```

```
├─ supplychains/
├─ components/
├─ pipelines/
├─ tasks/
└─ config.yaml

Writing group configuration to config.yaml
```

2. Generate a Supply Chain by running:

```
tanzu supplychain generate --kind TrivySC \
--description Trivy \
--component source-git-provider-1.0.0 \
--component buildpack-build-1.0.0 \
--component trivy-image-scan-1.0.0
```

Example output:

```
$ tanzu supplychain generate --kind TrivySC \
 --description Trivy \
 --component source-git-provider-1.0.0 \
 --component buildpack-build-1.0.0 \
 --component trivy-image-scan-1.0.0

✓ Successfully fetched all component dependencies
Created file supplychains/trivysc.yaml
Created file components/buildpack-build-1.0.0.yaml
Created file components/source-git-provider-1.0.0.yaml
Created file components/trivy-image-scan-1.0.0.yaml
Created file pipelines/buildpack-build.yaml
Created file pipelines/source-git-provider.yaml
Created file pipelines/trivy-image-scan-v2.yaml
Created file tasks/calculate-digest.yaml
Created file tasks/check-builders.yaml
Created file tasks/prepare-build.yaml
Created file tasks/source-git-check.yaml
Created file tasks/source-git-clone.yaml
Created file tasks/store-content-oci.yaml
```

Using Custom Scanning Component

Complete the following steps:

1. Initialize Tanzu Supply Chain by running:

```
tanzu supplychain init --group example.com
```

Example output:

```
$ tanzu supplychain init --group example.com
Initializing group example.com
Creating directory structure
├─ supplychains/
├─ components/
├─ pipelines/
├─ tasks/
└─ config.yaml

Writing group configuration to config.yaml
```

2. Generate a Supply Chain by running:

```
tanzu supplychain generate --kind CUSTOM-KIND-WORKLOAD \
--description DESCRIPTION-OF-SCANNER \
```

```
--component source-git-provider-1.0.0 \
--component buildpack-build-1.0.0 \
--component SCANNING-COMPONENT-NAME
```

Where `SCANNING-COMPONENT-NAME` is the name of the Custom Scanning Component.

For more information about how to construct a Supply Chain by using the Tanzu CLI, see Construct a Supply Chain using the CLI.

For more details about how to create a Supply Chain, see Build your first Supply Chain.

Apply Supply Chain

Generating the supply chain created the following directory structure:

```
├─ supplychains/
├─ components/
├─ pipelines/
├─ tasks/
```

Apply these directories to the namespace where the workload will run by running.

```
kubectl apply -R -f components -f supplychains -f tasks -f pipelines -n DEV-NAMESPACE
```

Where `DEV-NAMESPACE` is the same namespace where the intended workload will be.

Create a Workload from the Supply Chain

This topic tells you how to create and apply a workload from a Supply Chain, how to observe a workload, and how to verify the scanning performed in a workload.

Define a workload

This section tells you how to create a workload from an existing Supply Chain that was created by using SCST - Scan 2.0 and one of the following:

- Trivy Supply Chain Component
- Custom Scanning Component

You can define a workload in YAML or use the Tanzu Workload CLI plug-in.

Using YAML

Run:

```
kind: KIND
apiVersion: API-VERSION
metadata:
  name: WORKLOAD-NAME
spec:
  registry:
    repository: REGISTRY-REPOSITORY
    server: REGISTRY-SERVER
  source:
    git:
      branch: GIT-BRANCH
      url: GIT-URL
    subPath: GIT-SUBPATH
```

Where:

- `KIND` is the kind defined in the Trivy Supply Chain Component or Custom Scanning Component. The kind can be found in the supplychain YAML in the supplychains directory.
- `API-VERSION` is defined in the Create a Supply Chain with SCST - Scan 2.0 and Trivy Supply Chain Component or Create Supply Chain with SCST - Scan 2.0 and Custom Scanning Component. `API-VERSION` is the `group` and `version` found in the supplychain YAML in the supplychains directory.
- `REGISTRY-REPOSITORY` is the registry repository used for the scan results location.
- `REGISTRY-SERVER` is the registry server used for the scan results location.
- `GIT-URL` is the Git repository URL to clone from for the source component.
- `GIT-BRANCH` is the Git branch reference to watch for the new source.
- `GIT-SUBPATH` is the path where the source code is located.

For more information about any of the `GIT-*` values, see Source Git Provider.

Using Tanzu Workload CLI plug-in

Run:

```
tanzu workload generate NAME --kind KIND
```

Where `KIND` is the kind API resource defined in the Trivy Supply Chain Component or Custom Scanning Component.

This renders a sample workload YAML that you can configure and put in a `workload.yaml`.

Create a workload

Using the `workload.yaml` created in the previous section, create the workload:

```
tanzu workload create --file workload.yaml --namespace DEV-NAMESPACE
```

Where `DEV-NAMESPACE` is the same namespace where the intended workload will be.

Observe a workload

This section shows you how to use the Tanzu Workload CLI plug-in to observe a workload.

1. List workloads in the cluster by running:

   ```
   tanzu workload list -n DEV-NAMESPACE
   ```

   Where `DEV-NAMESPACE` is the namespace where the workload is.

   Example output:

   ```
   $ tanzu workload list -n grype-app-scanning-catalog

   Listing workloads from all namespaces

     NAMESPACE                   NAME                          KIND
   VERSION   AGE
     grype-app-scanning-catalog  golang-app-grype-test  grypescs.example.com  v1al
   pha1  35m
   ```

```
  To see more details about a workload, use 'tanzu workload get workload-name --kind workload-kind'
```

2. View workload details by running:

   ```
   tanzu workload get Sample WORKLOAD-NAME
   ```

   Example output:

   ```
   $ tanzu workload get golang-app-grype-test  -n grype-app-scanning-catalog
     Overview
     name:       golang-app-grype-test
     kind:       grypescs.example.com/golang-app-grype-test
     namespace:  grype-app-scanning-catalog
     age:        37m

     Runs:
     ID                                    STATUS     DURATION  AGE
     golang-app-grype-test-run-btlvx  Succeeded  4m13s     37m

     To view a run information, use 'tanzu workload run get run-id'
   ```

   For more information, How to observe the Runs of your Workload.

Check the workload scan results

Get the `ImageVulnerabilityScan` name by looking in the namespace it was created in:

```
kubectl get ivs -n DEV-NAMESPACE
```

Example output:

```
NAMESPACE                   NAME                          SUCCEEDED   REASON      AGE
dev-namespace               golang-app-test-123-bbrpz     True        Succeeded   4m52s
```

For information about how to retrieve scan results by using the `ImageVulnerabilityScan` name, see Retrieve scan results.

For more information about how to create a workload, see Work with Workloads.

Supply Chain Security Tools - Scan 2.0 Observability

This topic guides you through observing Supply Chain Security Tools (SCST) - Scan 2.0. This helps you understand each step of scanning.

Scanning Steps

This section describes each of the scanning steps and corresponding observability methods.

- To watch the status of the scanning custom resources and child resources:

  ```
  kubectl get -l imagevulnerabilityscan pipelinerun,taskrun,pod
  kubectl get imagevulnerabilityscan
  ```

- View the status, reason, and urls:

  ```
  kubectl get imagevulnerabilityscan -o wide
  ```

- View the complete status and events of scanning custom resources:

```
kubectl describe imagevulnerabilityscan IMAGE-VULNERABILITY-SCAN-NAME
```

Where `IMAGE-VULNERABILITY-SCAN-NAME` is the name of an `ImageVulnerabilityScan` resource you want to inspect.

- List the child resources of a scan:

```
kubectl get -l imagevulnerabilityscan=$NAME pipelinerun,taskrun,pod
```

- Get the logs of the controller:

```
kubectl logs -f deployment/app-scanning-controller-manager -n app-scanning-syst
em -c manager
```

Troubleshooting Supply Chain Security Tools - Scan 2.0

This topic helps you troubleshoot Supply Chain Security Tools (SCST) - Scan 2.0.

Overview

When Scan 2.0 creates an ImageVulnerabilityScan, the following resources are also created:

- Tekton `PipelineRun` with the following `Tasks`:
  - workspace-setup-task
  - scan-task
  - publish-task
- Tekton `TaskRun` corresponding to each `Task`
- `Pod` corresponding to each `TaskRun`

Viewing resources

- To view all resources:

```
kubectl get imagevulnerabilityscans,pipelineruns,taskruns,pods -n DEV-NAMESPACE
```

Where `DEV-NAMESPACE` is the name of your developer namespace.

- To verify which resources are failing, proceed to the following debugging sections:

```
NAME                                                                SUCCEEDED
REASON
imagevulnerabilityscan.app-scanning.apps.tanzu.vmware.com/my-scan   False
Failed

NAME                                    SUCCEEDED   REASON      STARTTIME   COMP
LETIONTIME
pipelinerun.tekton.dev/my-scan-5kllf    False       Failed      2m10s       85s

NAME                                                    SUCCEEDED   REASON
STARTTIME   COMPLETIONTIME
taskrun.tekton.dev/my-scan-5kllf-publish-task           False       Failed
94s         85s
taskrun.tekton.dev/my-scan-5kllf-scan-task              True        Succeeded
2m1s        94s
taskrun.tekton.dev/my-scan-5kllf-workspace-setup-task   True        Succeeded
2m9s        2m1s
```

```
NAME                                          READY   STATUS      RESTARTS   AGE
pod/my-scan-5kllf-publish-task-pod            0/4     Completed   1          94s
pod/my-scan-5kllf-scan-task-pod               0/4     Completed   1          2m
pod/my-scan-5kllf-workspace-setup-task-pod    0/2     Completed   1          2m10s
```

Debugging commands

The following sections describe commands you run to get logs and details about scanning errors.

Debugging resources

If a resource fails or has errors, inspect the resource. If multiple resources are involved, inspecting them all can provide a broader understanding. For example, inspecting the corresponding `TaskRun` to a failed `Pod`.

To get status conditions on a resource:

```
kubectl describe RESOURCE RESOURCE-NAME -n DEV-NAMESPACE
```

Where:

- `RESOURCE` is one of the following: `ImageVulnerabilityScan`, `PipelineRun`, `TaskRun`, or `Pod`.
- `RESOURCE-NAME` is the name of the `RESOURCE`.
- `DEV-NAMESPACE` is the name of your developer namespace.

Debugging scan pods

You can use the following methods to debug scan pods:

- To get error logs from a pod when scan pods fail:

  ```
  kubectl logs SCAN-POD-NAME -n DEV-NAMESPACE
  ```

  Where `SCAN-POD-NAME` is the name of the scan pod.

  For information about debugging Kubernetes pods, see the Kubernetes documentation.

  A scan run that has an error can indicate that one of the following step containers has a failure:

  - `step-workspace-setup`
  - `step-write-certs`
  - `step-cred-helper`
  - `step-SCANNER`
  - `step-publisher`
  - `sidecar-sleep`

  Where `step-SCANNER` is your scanner step.

- To verify which step container had a failed exit code:

  ```
  kubectl get taskrun TASKRUN-NAME -o json | jq .status
  ```

  Where `TASKRUN-NAME` is the name of the TaskRun.

- To inspect a specific step container in a pod:

```
kubectl logs scan-pod-name -n DEV-NAMESPACE -c step-container-name
```

Where `DEV-NAMESPACE` is your developer namespace.

For information about debugging a TaskRun, see the Tekton documentation.

- To debug inside of the scan-task pod: Add an additional step with a `sleep` command after your scanner step in the ImageVulnerabilityScan. For example:

```
...
spec:
  ...
  steps:
  - name: SCANNER-STEP
    ...
  - name: view
    image: busybox:latest
    args:
    - -c
    - sleep 6000
```

This keeps the pod in a running state so that you can exec into it. Re-run the scan and then exec into the pod:

```
    kubectl exec SCAN-TASK-POD-NAME -n DEV-NAMESPACE -c step-view --stdin --tty
-- sh
```

Where `SCAN-TASK-POD-NAME` is the name of your scan-task pod.

Viewing the Scan-Controller manager logs

You can run these commands to view the Scan-Controller manager logs:

- Retrieve scan-controller manager logs:

```
kubectl logs deployment/app-scanning-controller-manager -n app-scanning-system
```

- Tail scan-controller manager logs:

```
kubectl logs -f deployment/app-scanning-controller-manager -n app-scanning-syst
em
```

Troubleshooting issues

Volume permission error

If you encounter a permission error for accessing, opening, and writing to the files inside cluster volume, such as:

```
unsuccessful cred copy: ".git-credentials" from "/tekton/creds" to "/home/app-scannin
g": unable to open destination: open /home/app-scanning/.git-credentials: permission d
enied
```

Ensure that the problematic step runs with the proper user and group ids.

Incompatible Tekton version

Tanzu Application Platform `v1.7.0` or later includes `app-scanning.apps.tanzu.vmware.com` version `0.2.0` and Tekton Pipelines version `0.50.1`. The `app-scanning.apps.tanzu.vmware.com` package is incompatible with previous versions of Tekton Pipelines as v1 CRDs were not enabled. You must

upgrade Tanzu Application Platform to `v1.7.0` or later before upgrading `app-scanning.apps.tanzu.vmware.com`.

If you did not upgrade Tanzu Application Platform before upgrading `app-scanning.apps.tanzu.vmware.com`, you can encounter ImageVulnerabilityScans not progressing:

```
NAME      SUCCEEDED   REASON
my-scan
```

To resolve this issue:

1. Confirm that the issue is due to installing an incompatible Tekton version by viewing the controller manager logs by running:

   ```
   kubectl -n app-scanning-system logs -f deployment/app-scanning-controller-manag
   er -c manager
   ```

   If you encounter the following error, proceed to the next step:

   ```
   ERROR  controller-runtime.source.EventHandler  failed to get informer from cach
   e  {"error": "failed to get API group resources: unable to retrieve the complet
   e list of server APIs: tekton.dev/v1: the server could not find the requested r
   esource"}
   ```

2. Upgrade Tanzu Application Platform to `v1.7.0` or later. See Upgrade your Tanzu Application Platform.

Scan results empty

The publish-task task fails if the `scan-results-path` (default value of `/workspace/scan-result`) is empty. To confirm, view the logs of the publish-task pod:

```
kubectl logs PUBLISH-TASK-POD-NAME -c step-publisher -n DEV-NAMESPACE
```

Where `PUBLISH-TASK-POD-NAME` is the name of your publish-task pod.

```
2023/08/22 17:09:49 results folder /workspace/scan-results is empty
```

To resolve this issue, you can debug within the scan-task pod by following the instructions under Debugging scan pods. You must use an image with both a shell and your scanner CLI image to run the `sleep` command and troubleshoot your scanner commands from within the container.

Scanning in a cluster with restricted Kubernetes Pod Security Standards

As part of compliance with the restricted profile for Kubernetes Pod Security Standards, you must set the `securityContext` of containers and initContainers. When a pod does not meet pod Security Standards, it is not created and vulnerability scanning cannot proceed. For more information, see the Kubernetes documentation.

You might see an error message similar to the following when describing the TaskRun:

```
pods "trivy-ivs-abcd-scan-task-pod" is forbidden: violates PodSecurity "restricted:lat
est": allowPrivilegeEscalation != false (container "prepare" must set securityContext.
allowPrivilegeEscalation=false), unrestricted capabilities (container "prepare" must s
et securityContext.capabilities.drop=["ALL"]), seccompProfile (pod or container "prepa
re" must set securityContext.seccompProfile.type to "RuntimeDefault" or "Localhost").
Maybe invalid TaskSpec. ScanPodError PodNotFound: no pod found
```

To resolve this issue:

1. Update your Tekton Pipelines package configuration in your `tap-values.yaml` with the following changes:

   ```
   tekton_pipelines:
       feature_flags:
           set_security_context: "true"
   ```

   Setting the `securityContext` resolves the `prepare` initContainer violation.

2. Update your Tanzu Application Platform installation by running:

   ```
   tanzu package installed update tap -p tap.tanzu.vmware.com -v TAP-VERSION  --va
   lues-file tap-values.yaml -n tap-install
   ```

   Where `TAP-VERSION` is the version of Tanzu Application Platform installed.

3. Re-run the scan.

Overview of Supply Chain Security Tools for Tanzu – Store

This topic gives you an overview of Supply Chain Security Tools (SCST) – Store.

SCST - Store stores the metadata generated by supplies chains in Tanzu Application Platform. It is made up of two services: Artifact Metadata Repository (AMR) and the Metadata Store.

Artifact Metadata Repository

AMR includes both AMR Observer and AMR CloudEvent Handler.

AMR Observer

AMR Observer is a set of managed controllers that watches for relevant updates on resources of interest. When relevant events are observed, a CloudEvent is generated and sent to AMR CloudEvent Handler. By design, you can deploy this component on Full, Build, and Run profile clusters.

AMR CloudEvent Handler

AMR CloudEvent Handler receives CloudEvents and stores relevant information in Artifact Metadata Repository or the Metadata Store. By design, you can deploy this component on Full and View profile clusters.

Additional resources

- Artifact Metadata Repository architecture
- Configure Artifact Metadata Repository
- AMR GraphQL Query

The Metadata Store

For more information about the Metadata Store, see Overview of the Metadata Store.

Overview of Supply Chain Security Tools for Tanzu – Store

This topic gives you an overview of Supply Chain Security Tools (SCST) – Store.

SCST - Store stores the metadata generated by supplies chains in Tanzu Application Platform. It is made up of two services: Artifact Metadata Repository (AMR) and the Metadata Store.

Artifact Metadata Repository

AMR includes both AMR Observer and AMR CloudEvent Handler.

AMR Observer

AMR Observer is a set of managed controllers that watches for relevant updates on resources of interest. When relevant events are observed, a CloudEvent is generated and sent to AMR CloudEvent Handler. By design, you can deploy this component on Full, Build, and Run profile clusters.

AMR CloudEvent Handler

AMR CloudEvent Handler receives CloudEvents and stores relevant information in Artifact Metadata Repository or the Metadata Store. By design, you can deploy this component on Full and View profile clusters.

Additional resources

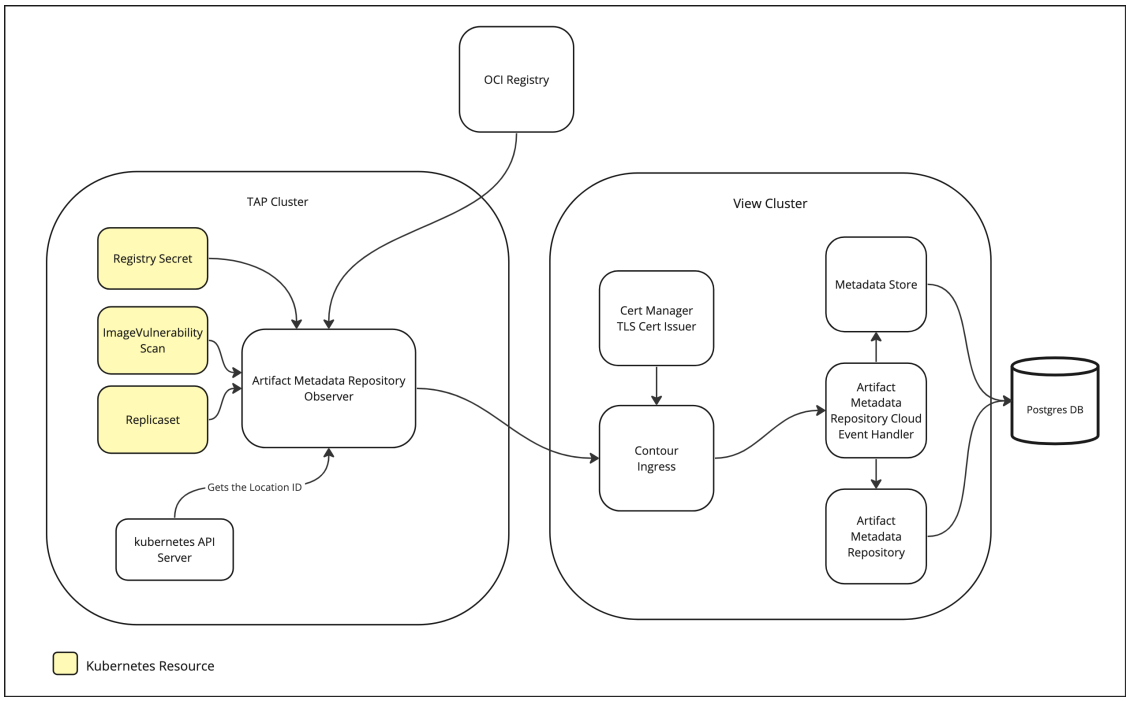
- Artifact Metadata Repository architecture
- Configure Artifact Metadata Repository
- AMR GraphQL Query

The Metadata Store

For more information about the Metadata Store, see Overview of the Metadata Store.

Artifact Metadata Repository architecture

This topic gives you an overview of the Artifact Metadata Repository (AMR) architecture.



AMR Observer

The full, build, and run clusters include AMR Observer. AMR Observer communicates with the Kubernetes API Server to obtain the cluster's location ID, which is the globally unique identifier (GUID) of the `kube-system` namespace. After AMR Observer retrieves the location ID, AMR Observer emits a CloudEvent to AMR CloudEvent Handler, including any operator-defined metadata. This CloudEvent registers the location, and subsequent CloudEvents from that cluster use the same location reference in the source field. This mechanism helps AMR track artifacts with their associated location.

Watched resources

AMR Observer consists of managed controllers that watch resources. In Tanzu Application Platform v1.9, AMR Observer watches for:

AMR Observer Supported Resources	**-**
ImageVulnerabilityScans	app-scanning.apps.tanzu.vmware.com/v1alpha1
Pods	v1
GitRepository	source.toolkit.fluxcd.io/v1
OCIRepository	source.toolkit.fluxcd.io/v1beta2
ImageRepository	source.apps.tanzu.vmware.com/v1alpha1
MavenArtifacts	source.apps.tanzu.vmware.com/v1alpha1
Build	kpack.io/v1alpha2
TaskRun	tekton.dev/v1beta1

ImageVulnerabilityScans

AMR Observer watches the `ImageVulnerabilityScan` Custom Resources for completed scans. When a scan finishes, AMR Observer uses the `registry secret` and the location information from the `ImageVulnerabilityScan` Custom Resources to fetch the Software Bill of Materials (SBOM) report. After obtaining the SBOM report, AMR Observer wraps it in a CloudEvent and emits it to the AMR CloudEvent Handler. The AMR CloudEvent Handler persists this event in the Metadata Store.

Configure Artifact Metadata Repository

This topic tells you how to configure Artifact Metadata Repository (AMR).

AMR Observer

You can obtain the Tanzu Application Platform values schema by running:

```
tanzu package available get amr-observer.apps.tanzu.vmware.com/${VERSION} --values-sch
ema --namespace tap-install
```

The following example is an AMR Observer configuration, located under the `amr` key in the Tanzu Application Platform values file:

```
amr:
  observer:
    location: |
```

```
      labels:
      - key: env
        value: prod
    resync_period: "10h"
    ca_cert_data: |
      -----BEGIN CERTIFICATE-----
      Custom CA certificate for AMR CloudEvent Handler's HTTPProxy with custom TLS cer
ts
      -----END CERTIFICATE-----
    cloudevent_handler:
      endpoint: "https://amr-cloudevent-handler.DOMAIN"
      liveness_period_seconds: 10
    auth:
      kubernetes_service_accounts:
        enable: true
        autoconfigure: true
        secret:
          ref: "amr-observer-edit-token"
          value: ""
    max_concurrent_reconciles:
      image_vulnerability_scans: 1
```

Where `DOMAIN` is the domain you want to target.

Configuration options:

- `amr.observer.location`
    - Default: ""
    - Location is the multiline string configuration for the location content.
    - The YAML string can contain a single field:
    - `labels`: Consists of an array for key and value pairing. Useful for adding searchable and identifiable metadata. For enabling DORA functionality, it is important to have a label named `env`. For more information, see DORA metrics in Tanzu Developer Portal.
- `amr.observer.resync_period`
    - Default: “10h”
    - `resync_period` decides the minimum frequency at which watched resources reconcile. A lower period corrects entropy more quickly, but reduce responsiveness to change if there are many watched resources. Change this value only if you know what you are doing. Defaults to 10 hours if unset.
- `amr.observer.ca_cert_data` or `shared.ca_cert_data`
    - Default: ""
    - `ca_cert_data` adds certificates to the truststore that amr-observer uses.

    ```
    kubectl -n metadata-store get secrets/amr-cloudevent-handler-ingress-cert -o js
    onpath='{.data."crt.ca"}' | base64 -d
    ```

- `amr.observer.cloudevent_handler.endpoint`
    - Default: `http://amr-cloudevent-handler.metadata-store.svc.cluster.local:80`
    - The URL of the AMR CloudEvent Handler endpoint.
    - On the view or full Tanzu Application Platform profile cluster, obtain the AMR CloudEvent Handler ingress address to configure this property:

```
kubectl -n metadata-store get httpproxies.projectcontour.io amr-cloudevent-hand
ler-ingress -o jsonpath='{.spec.virtualhost.fqdn}'
```

Note

Ensure that you set the correct protocol. If there is TLS, you must prepend `https://`. If there is no TLS, you must prepend `http://`.

- `amr.observer.cloudevent_handler.liveness_period_seconds`
  - Default: `10`
  - The period in seconds between executed health checks to the AMR CloudEvent Handler endpoint.
- `amr.observer.auth.kubernetes_service_accounts`
  - `.enable`
  - Default: `true`
  - Include an Authorization header when communicating with AMR CloudEvent Handler.
  - `.autoconfigure`
  - Default: `true`
  - Delegate creation of authentication token secret to the artifact metadata repository. Only applicable on Full and View clusters.
  - `.secret`
  - The secret with the access token for communicating with the cloudevent-handler
  - `.ref`
    - Default: ""
    - Secret name which contains the access token.
  - `.value`
    - Default: ""
    - Secret as a plain text string. This allows integrating with Tanzu Mission Control (TMC) secret imports.
- `amr.observer.deployed_through_tmc`
  - Default: `null`
  - Tanzu Application Platform multicluster deployment happens through TMC when you set `deployed_through_tmc` to true.
- `amr.observer.max_concurrent_reconciles`
  - Configure maximum concurrent reconciles for controllers.
  - `.image_vulnerability_scans`
  - Default: `1`
  - Maximum concurrent reconciles for observing ImageVulnerabilityScans.
- When deploying with TMC, `MultiClusterPropertyCollector` overwrites existing Observer package configuration values. For the workaround, see the known issue.

AMR GraphQL

- `amr.graphql.auth.kubernetes_service_accounts``
  - `.enable`
  - Default: true
  - Enable authentication for artifact metadata repository GraphQL server. By default it is set to true.
  - `.autoconfigure`
  - Default: `true`
  - Delegate creation of authentication token secret to the artifact metadata repository. By default it is set to true.

AMR CloudEvent Handler

- `amr.cloudevent_handler.auth.kubernetes_service_accounts`
  - `.enable`
  - Default: true
  - Enable authentication and authorization for services accessing Artifact Metadata Repository.
  - `.autoconfigure`
  - Default: `true`
  - Delegate creation of authentication token secret to the artifact metadata repository. By default it is set to true.

Authentication and authorization

This topic tells you how to authenticate and authorize the Artifact Metadata Repository (AMR).

Overview

The following are included in authentication and authorization:

- High-level design
- Kubernetes service account automatic configuration
- User-defined kubernetes service account configuration
- Cloudevent user-defined service account
- Configuring AMR Observer with the CloudEvent Handler service account access token

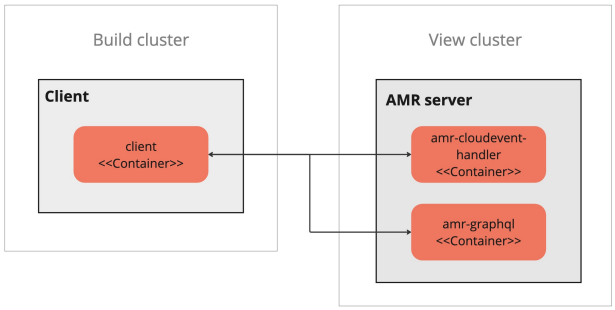
High-level design

The Artifact Metadata Repository (AMR) deploys the following Kubernetes services which expose http endpoints:

- Cloudevent-handler
- GraphQL

Both Cloudevent-handler and GraphQL are in the same cluster. In a multicluster Tanzu Application Platform deployment, they're in the view cluster and the clients can be from any cluster. This topic

shows the client in the build cluster in our examples.

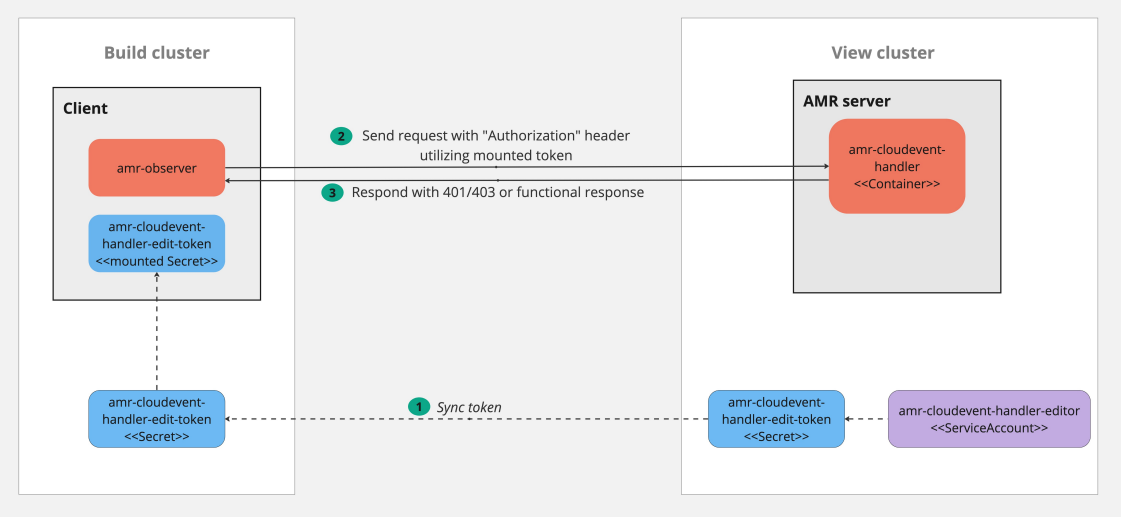


The client sends requests to either service depending on their current task. The cloudevent-handler ingests events from the client and stores it in a database. The GraphQL server answers queries from the client and returns data from the database. Other than those points, the two are treated the same in this design. They both use the same authentication and authorization solution. This topic simplifies the explanation by only showing the cloudevent-handler.

Kubernetes RBAC

The server implements support for authentication using Kubernetes RBAC. This includes requiring the client to send a token from a Kubernetes service account token bound to a Kubernetes role.

1. The administrator creates a service account, role/clusterrole, and role binding in the cluster where the cloudevent-handler is deployed in the View cluster. The role declares what permissions the client has:
    - For the AMR **Observer** the supported permissions are `update`, resource `*`, group `cloudevents.amr.apps.tanzu.vmware.com`. No resourceNames are supported. That translates to “write for all resources” for the CloudEvents API.
    - For **GraphQL** service the supported permissions are `get`, resource `*` and group `graphql.amr.apps.tanzu.vmware.com`. No resourceNames are supported. That translates to “read all” from the GraphQL API.
2. The administrator copies the service account token and puts it in the client cluster where the client container can read it. For example, the client can get the token mounted as a Kubernetes secret.
3. The client sends a request to AMR, and puts the service account token in the http header `Authorization: Bearer <token>`.
4. The cloudevent-handler reads the token and conduct a **TokenReview**.
5. The cloudevent-handler does a **SubjectAccessReview** using the userinfo returned from TokenReview and the resource information as described in #1.
6. The SubjectAccessReview looks, according to the Kubernetes RBAC system, for any Role/ClusterRole associations by using bindings to find a match between the assigned roles to the specific service account and the requested resource information.



Kubernetes service account automatic configuration

This topic tells you about the resources that you create for Kubernetes service account automatic configuration for AMR authentication and authorization.

Overview

This topic describes which resources play a role in the default configuration and how to troubleshoot. For more information about the resources, for example, if you use means to manage your service accounts or have other requirements related to roles and bindings, see User-defined kubernetes service account configuration

The package-level configuration has a component top level key (TLK) prefix and this topic describes how Tanzu Application Platform configurations can influence this prefix.

Observer

Observer configuration in the Tanzu Application Platform context has the prefix TLK `amr.observer`. For authentication and authorization, the Tanzu Application Platform profiles influence automatic configuration. Observer can only automatically configure itself when co-located with the CloudEvent Handler, which is in the `full` or `view` profile. If this is not the case `auth.kubernetes_service_accounts.autoconfigure` is set to false at installation.

If `auth.kubernetes_service_accounts.enable` and `auth.kubernetes_service_accounts.autoconfigure` are true, the observer package creates the following resources to set up authentication automatically in the `amr-observer-system` namespace:

- a `ServiceAccount` named `amr-observer-editor` that observer uses to send requests to the CloudEvent Handler
- a `Secret` named `amr-observer-edit-token` of type `kubernetes.io/service-account-token` which generates a long-lived token for the service account
- a `ClusterRole` named `tanzu:amr:observer:edit` defining the necessary `update` permissions for all resources in `cloudevents.amr.apps.tanzu.vmware.com`
- a `ClusterRoleBinding` named `tanzu:amr:observer:editor` binding the defined role to the service account

If `auth.kubernetes_service_accounts.autoconfigure` is set to false, you must configure the observer package with all the above resources manually. For information about how to set up the observer, see User-defined Kubernetes service account configuration.

CloudEvent Handler

You can find the CloudEvent Handler configuration in the Tanzu Application Platform context under the TLK `amr.cloudevent_handler`. This prefix is not stripped in this case.

On the package level, if `amr.cloudevent_handler.auth.kubernetes_service_accounts.enable` and `amr.cloudevent_handler.auth.kubernetes_service_accounts.autoconfigure` are true, the package creates the following resources to set up authentication automatically in the `metadata-store` namespace:

- a `ServiceAccount` named `amr-cloudevent-handler-editor` that clients use to send requests to the CloudEvent Handler
- a `Secret` named `amr-cloudevent-handler-edit-token` of type `kubernetes.io/service-account-token` which generates a long-lived token for the service account
- a `ClusterRole` named `tanzu:amr:cloudevent-handler:edit` defining the necessary `update` permissions for all resources in `cloudevents.amr.apps.tanzu.vmware.com`
- a `ClusterRoleBinding` named `tanzu:amr:cloudevent-handler:editor` binding the defined role to the service account

GraphQL handler

You can find the GraphQL configuration in the Tanzu Application Platform context under the TLK `amr.graphql`. This prefix is not stripped in this case.

If `amr.graphql.auth.kubernetes_service_accounts.enable` and `amr.graphql.auth.kubernetes_service_accounts.autoconfigure` are true, the package creates the following resources to set up authentication automatically in the `metadata-store` namespace:

- a `ServiceAccount` named `amr-graphql-viewer` that clients use to send requests to the graphql interface
- a `Secret` named `amr-graphql-view-token` of type `kubernetes.io/service-account-token` which generates a long-lived token for the service account
- a `ClusterRole` named `tanzu:amr:graphql:view` defining the necessary `get` permissions for all resources in `graphql.amr.apps.tanzu.vmware.com`
- a `ClusterRoleBinding` named `tanzu:amr:graphql:viewer` binding the defined role to the service account

User-defined Kubernetes service account configuration

This topic tells you how to configure a user-defined Kubernetes service account.

Overview

To configure a Kubernetes service account authentication for AMR Observer, CloudEvent Handler or GraphQL clients must have the required permissions, resources, and groups in the following sections.

Clients to CloudEvent Handler

Clients to the CloudEvent Handler, such as Observer, must have the permission `update`, resource `*`, and group `cloudevents.amr.apps.tanzu.vmware.com`. `resourceNames` are not supported. That translates to write for all resources for the CloudEvents API.

For example:

```
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: tanzu:amr:observer:editor
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: tanzu:amr:observer:edit
subjects:
  - kind: ServiceAccount
    name: amr-observer-editor
    namespace: amr-observer-system

---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: tanzu:amr:observer:edit
rules:
  - apiGroups: ["cloudevents.amr.apps.tanzu.vmware.com"]
    resources: ["*"]
    verbs: ["update"]

---
apiVersion: v1
kind: ServiceAccount
metadata:
  name: amr-observer-editor
  namespace: amr-observer-system
  annotations:
automountServiceAccountToken: false

---
apiVersion: v1
kind: Secret
type: kubernetes.io/service-account-token
metadata:
  name: amr-observer-editor-token
  namespace: amr-observer-system
  annotations:
    kubernetes.io/service-account.name: amr-observer
```

If you saved this to a `observer-rbac.yaml` file, run `kubectl apply -f observer-rbac.yaml` to set everything up. If you prefer short lived service account tokens, remove the secret from the file beforehand. After creating the resources, run `kubectl create token amr-observer-editor-token -n amr-observer-system` to create a token.

To configure custom service accounts even if automatic configuration is on, you must edit the resource naming.

Clients to GraphQL

Clients to the AMR GraphQL interface must have the permission `get`, resource `*`, and group `graphql.amr.apps.tanzu.vmware.com`. `resourceNames` are not supported. That translates to “get for all resources for the GraphQL API”.

For example:

```
---
apiVersion: rbac.authorization.k8s.io/v1
```

```
kind: ClusterRoleBinding
metadata:
  name: tanzu:amr:graphql:viewer
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: tanzu:amr:graphql:view
subjects:
  - kind: ServiceAccount
    name: amr-graphql-viewer
    namespace: metadata-store
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: tanzu:amr:graphql:view
rules:
  - apiGroups: ["graphql.amr.apps.tanzu.vmware.com"]
    resources: ["*"]
    verbs: ["get"]
---
apiVersion: v1
kind: ServiceAccount
metadata:
  name: amr-graphql-viewer
  namespace: metadata-store
  annotations:
    kapp.k14s.io/change-group: amr-graphql-viewer.metadata-store.apps.tanzu.vmware.co
m/service-account
automountServiceAccountToken: false
---
apiVersion: v1
kind: Secret
type: kubernetes.io/service-account-token
metadata:
  name: amr-graphql-view-token
  namespace: metadata-store
  annotations:
    kubernetes.io/service-account.name: amr-graphql-viewer
```

If you saved this to a `graphql-client-rbac.yaml` file, run `kubectl apply -f graphql-client-rbac.yaml` to set everything up. If you prefer short lived service account tokens, remove the secret from the file beforehand. After creating the resources, run `kubectl create token amr-graphql-view-token -n metadata-store` to create a token.

To configure custom service accounts even if automatic configuration is on, you must edit the resource naming.

Run query with GraphQL

This topic tells you how to connect to the GraphQL playground and how to run some queries.

Connect to AMR GraphQL

There are two ways you can perform GraphQL queries:

- Use the GraphQL playground
- Use curl

Use the GraphQL playground
Complete the following steps to perform GraphQL queries:

1. Enable ingress. VMware recommends enabling ingress. The Supply Chain Security Tools for Tanzu – Store and Artifact Metadata Repository (AMR) packages share the same ingress configuration. For information about enabling ingress, see Ingress support for Supply Chain Security Tools - Store.
2. Retrieve the access token. Run:

   ```
   kubectl -n metadata-store get secret amr-graphql-view-token -o json | jq -r
   ".data.token" | base64 -d
   ```

3. To connect to the AMR GraphQL playground, visit `https://amr-graphql.INGRESS-DOMAIN/play`.

   Where `INGRESS-DOMAIN` is the domain of the ingress you want to use.

4. In the **Headers** tab at the bottom of the query window, add a JSON block containing the following authentication header:

   ```
   {
     "Authorization": "Bearer ACCESS-TOKEN"
   }
   ```

   Where `ACCESS-TOKEN` is the AMR GraphQL access token.

   You can use this to write and execute your own GraphQL queries to fetch data from the AMR.

Use curl

Write and execute GraphQL queries to fetch data from the AMR. This procedure uses curl to query the AMR GraphQL endpoint, but you can use other similar tools to access the endpoint:

1. Enable ingress. VMware recommends enabling ingress. The Supply Chain Security Tools for Tanzu – Store and Artifact Metadata Repository (AMR) packages share the same ingress configuration. For information about enabling ingress, see Ingress support for Supply Chain Security Tools - Store.
2. To connect to the AMR GraphQL by using curl after you enable ingress, you first need the AMR GraphQL access token and its CA certificate. Run:

   ```
   kubectl get secret ingress-cert -n metadata-store -o json | jq -r '.data."ca.
   crt"' | base64 -d > /tmp/graphql-ca.crt
   ```

3. After the token and certificate are retrieved, use curl to perform GraphQL queries. Run:

   ```
   curl "https://amr-graphql.INGRESS-DOMAIN/query" \
     --cacert FILE-LOCATION \
     -H "Authorization: Bearer ACCESS-TOKEN" \
     -H 'accept: application/json' \
     -H 'content-type: application/json' \
     --data-raw '{"query":"query getAppAcceleratorRuns { appAcceleratorRuns(firs
   t: 250){ nodes { guid name namespace timestamp } pageInfo{ endCursor hasNextP
   age } } }"}' | jq .
   ```

   Where:

   - `INGRESS-DOMAIN` is the domain of the ingress you want to use.
   - `ACCESS-TOKEN` is the AMR GraphQL access token
   - `FILE-LOCATION` is the file containing the AMR GraphQL CA certificate, for example, `/tmp/graphql-ca.crt`

Query for AppAcceleratorRuns (alpha)

This section tells you about GraphQL query arguments, and lists the fields available for `AppAcceleratorRuns` and `AppAcceleratorFragments`.

AppAcceleratorRuns query arguments

You can specify the following arguments when querying for `AppAcceleratorRuns`. If you don't specify an argument the query will return all AppAcceleratorRuns. `query` expects an object that specifies additional arguments to query.

Argument	Description	Example
`guid`	String value unique identifier for each AppAcceleratorRuns.	`appAcceleratorRuns(query:{guid: "d2934b09-5d4c-45da-8eb1-e464f218454e"})`
`source`	String representing the client used to run the accelerator. Supported values include `TAP-GUI`, `VSCODE`, and `INTELLIJ`.	`appAcceleratorRuns(query:{source: "TAP-GUI"})`
`username`	String representing the user name of the person who runs the accelerator, as captured by the client UI.	`appAcceleratorRuns(query:{username: "test.user"})`
`namespace` and `name`	Strings representing the accelerator that was used to create an application.	`appAcceleratorRuns(query:{name: "tanzu-java-web-app"})`
`appAcceleratorRepoURL`, `appAcceleratorRevision`, and `appAcceleratorSubpath`	Location in VCS (Version Control System) of the accelerator sources used.	`appAcceleratorRuns(query: {appAcceleratorRepoURL: "https://github.com/vmware-tanzu/application-accelerator-samples.git", appAcceleratorRevision: "v1.6"`
`timestamp`	String representation of the time the accelerator ran. You can query for runs that happened `before` or `after` a particular instant.	`appAcceleratorRuns(query: {timestamp: {after: "2023-10-11T13:40:46.952Z"}})`

AppAcceleratorRuns fields

You can choose the following fields to return in the GraphQL query. You must specify at least one field.

- `guid`: String value unique identifier for each AppAcceleratorRuns.
- `source`: String representing the client used to run the accelerator.
- `username`: String representing the user name of the person who ran the accelerator.
- `namespace` and `name`: Strings representing the accelerator that was used to create an application.
- `appAcceleratorRepoURL`, `appAcceleratorRevision`, and `appAcceleratorSubpath`: Location in VCS of the accelerator sources used.
- `timestamp`: String representation of the time the accelerator ran.
- `appAcceleratorSource`: VCS information of the sources of the accelerator used, but navigable as a commit.
- `appAcceleratorFragments`: A one-to-many container of nodes representing the fragment versions used in each `AppAcceleratorRuns`. Fragment nodes share many of the fields with

`AppAcceleratorRuns`, with the same semantics but applied to the particular fragment. These include:

- `namespace` and `name`: Strings representing the identity of the fragment.
- `appAcceleratorFragmentSourceRepoURL` , `appAcceleratorFragmentSourceRevision`, and `appAcceleratorFragmentSourceSubpath`: Location in VCS of the sources of the fragment used
- `appAcceleratorFragmentSource`: VCS information of the sources of the fragment, but navigable as a commit.

Sample Application Accelerator queries

- Get the list of all Application Accelerator runs, with the fragments used for each.

```
query getAllAcceleratorRuns {
  appAcceleratorRuns {
    nodes {
      name
      appAcceleratorFragments {
        nodes {
          name
        }
      }
    }
  }
}
```

Install Artifact Metadata Repository CloudEvent Handler

This topic tells you how to install the Artifact Metadata Repository (AMR) CloudEvent Handler.

Switching Context

If AMR CloudEvent Handler is installed on a separate cluster, such as with a view profile cluster, it is important that you target the correct cluster when updating. Ensure that the correct cluster is targeted before updating package values.

```
# 1. Switch context to view profile cluster
kubectl config use-context VIEW-CLUSTER-NAME

# 2. Update the tap-values.yaml in an editor according to the desired configuration

# 3. Update the installed TAP package on the cluster
tanzu package installed update tap --values-file tap-values.yaml -n tap-install
```

Where `VIEW-CLUSTER-NAME` is the name of the view profile cluster you want to use.

Install

The AMR CloudEvent Handler is installed by default in the Tanzu Application Platform Full and View profiles.

Artifact Metadata Repository Observer for Supply Chain Security Tools - Store

This topic tells you how to install Artifact Metadata Repository (AMR) Observer for Supply Chain Security Tools (SCST) - Store.

Prerequisites

The AMR Observer is deployed by default on the Tanzu Application Platform Full, Build and Run profiles.

Switching Context

If Artifact Metadata Repository Observer is installed on a separate cluster from AMR CloudEvent Handler, you must ensure that the correct cluster is targeted before updating package values.

```
# 1. Switch context to cluster with AMR Observer
kubectl config use-context OBSERVER-CLUSTER-NAME

# 2. Update the tap-values.yaml in an editor according to the desired configuration

# 3. Update the installed TAP package on the cluster
tanzu package installed update tap --values-file tap-values.yaml -n tap-install
```

Where `OBSERVER-CLUSTER-NAME` is the name of the cluster you want to use.

Configuring AMR Observer in a multicluster deployment

When you install AMR Observer on a different cluster from the AMR CloudEvent Handler, the following values are required:

- `amr.observer.cloudevent_handler.endpoint` is required for the Observer to send to the AMR CloudEvent Handler.
- `amr.observer.cloudevent_handler.ca_cert_data` or `shared.ca_cert_data` are required for AMR CloudEvent Handlers that use Custom CA certificates to generate the associated TLS certificate for the ingress endpoint.

Note

If SCST - Scan 2.0 is installed after AMR Observer has already been deployed, a deployment you must restart AMR Observer to observe the new ImageVulnerabilityScan Custom Resource that was installed with SCST - Scan 2.0.

```
kubectl -n amr-observer-system rollout restart deployment amr-observer-controller-mana
ger
```

The following log appears if the AMR Observer is observing the ImageVulnerabilityScan Custom Resource:

```
2023-06-28T17:56:43Z  INFO  Starting Controller  {"controller": "imagevulnerabilitysca
n", "controllerGroup": "app-scanning.apps.tanzu.vmware.com", "controllerKind": "ImageV
ulnerabilityScan"}
```

For information about logging, see Troubleshoot - AMR Observer Logs.

See Configuration - AMR Observer.

Installing Artifact Metadata Repository Observer Standalone

1. To install AMR Observer standalone from a Tanzu Application Platform profile, verify the available version:

```
$ tanzu package available list amr-observer.apps.tanzu.vmware.com -n tap-instal
l

NAME                                VERSION        RELEASED-AT
amr-observer.apps.tanzu.vmware.com  0.2.0          2023-10-05 16:17:22 -0400 ED
T
```

2. Look at the package values-schema to create the values file. For more information, see Configuration.

```
$ tanzu package available get amr-observer.apps.tanzu.vmware.com/0.2.0 --values
-schema --namespace tap-install

KEY                                                                    DEFAULT
TYPE     DESCRIPTION
deployed_through_tmc                                                   false
boolean  TAP Multi Cluster deployment will happen through Tanzu Mission Control
when `deployed_through_tmc` is set to true
observer.auth.kubernetes_service_accounts.autoconfigure                true
boolean  Delegate creation of auth token secret to AMR Observer. By default it
is set to true.
observer.auth.kubernetes_service_accounts.enable                       true
boolean  Include Authorization header when communicating with AMR CloudEvent Ha
ndler.
observer.auth.kubernetes_service_accounts.secret.ref                   amr-obse
rver-edit-token                                                string   Secret
name which contains the access token.
observer.auth.kubernetes_service_accounts.secret.value                 ""
string   Secret as a plain text string. This allows integrating with Tanzu Miss
ion Control secret imports.
observer.ca_cert_data                                                  ""
string   ca_cert_data is used to add certificates to the truststore that is use
d by the amr-observer.
observer.cloudevent_handler.endpoint                                   "http://
amr-cloudevent-handler.metadata-store.svc.cluster.local:80"    string   The URL
of the CloudEvent Handler endpoint.
observer.cloudevent_handler.liveness_period_seconds                    10
integer  The period in seconds between executed health checks to the CloudEvent
Handler endpoint.
observer.location                                                      ""
string   location is the multiline string configuration for the location.conf c
ontent.
observer.max_concurrent_reconciles.image_vulnerability_scans           1
integer  Max concurrent reconciles for observing ImageVulnerabilityScans.
observer.resync_period                                                 10h
string   resync_period determines the minimum frequency at which watched resour
ces are reconciled.

A lower period will correct entropy more quickly, but reduce

responsiveness to change if there are many watched resources. Change this value
only if you

know what you are doing. Defaults to 10 hours if unset.
```

3. Install the package using `tanzu package install`.

Troubleshooting Artifact Metadata Repository (AMR)

This topic tells you how to troubleshoot issues with Artifact Metadata Repository (AMR).

Debug AMR

1. Pause reconciliation of the package

```
tanzu package installed pause amr-observer -n tap-install
# OR
kctrl package installed pause -i amr-observer -n tap-install
```

2. Change the zap log level.

```
kubectl -n amr-observer-system \
patch deployment amr-observer-controller-manager \
  --type='json' \
  -p='[{"op": "add",
        "path": "/spec/template/spec/containers/1/args/-",
        "value": "--zap-log-level=3"
      }]'
```

Logs now show `LEVEL(-3)` with the example patch above.

```
$ kubectl -n amr-observer-system logs deployments/amr-observer-controller-manag
er
2023-06-20T15:42:39Z  LEVEL(-3)  httpclient.circuitbreaker  AMR CloudEventHandl
er  {"availability": true, "State": "closed"}
```

3. Unpause reconciliation of the package:

```
tanzu package installed kick amr-observer -n tap-install
# OR
kctrl package installed kick -i amr-observer -n tap-install
```

Health Check

AMR Observer does not send events to AMR CloudEvent Handler if either the AMRCloudEvent Handler, AMR, or MDS isn't working.

Sample log in AMR Observer when HealthCheck is working:

```
2023-06-20T15:51:50Z  INFO  httpclient.circuitbreaker  Received response with status
{"status": "204 No Content"}
2023-06-20T15:51:50Z  INFO  httpclient.circuitbreaker  Successfully sent CloudEvent
```

Sample log in AMR Observer when HealthCheck is failing:

```
2023-06-20T19:01:58Z  INFO  httpclient.circuitbreaker  Received response with status
{"status": "503 Service Unavailable"}
2023-06-20T19:01:58Z  ERROR  httpclient    {"error": "request failed with status 503"}
gitlab.eng.vmware.com/tanzu-image-signing/amr-observer/internal/cloud/event/client.(*C
loudEventClient).logAndReturnError
  /workspace/internal/cloud/event/client/client.go:53
gitlab.eng.vmware.com/tanzu-image-signing/amr-observer/internal/cloud/event/client.(*C
loudEventClient).do
  /workspace/internal/cloud/event/client/client.go:102
gitlab.eng.vmware.com/tanzu-image-signing/amr-observer/internal/cloud/event/client.(*C
loudEventClient).checkCloudEventHandlerAvailability.func1
  /workspace/internal/cloud/event/client/client.go:123
github.com/sony/gobreaker.(*CircuitBreaker).Execute
  /go/pkg/mod/github.com/sony/gobreaker@v0.5.0/gobreaker.go:242
gitlab.eng.vmware.com/tanzu-image-signing/amr-observer/internal/cloud/event/client.(*C
loudEventClient).checkCloudEventHandlerAvailability
  /workspace/internal/cloud/event/client/client.go:117
```

```
gitlab.eng.vmware.com/tanzu-image-signing/amr-observer/internal/cloud/event/client.(*C
loudEventClient).CheckAvailabilityPeriodically
  /workspace/internal/cloud/event/client/client.go:111
```

Sample log in AMR CloudEvent Handler:

```
{"level":"error","ts":"2023-06-20T15:15:04.321672436Z","caller":"amr-persister/main.g
o:99","msg":"AMR is unavailable: Get \"https://amr-graphql-app.metadata-store.svc.clus
ter.local:8443/play\": dial tcp 10.28.116.184:8443: connect: connection refused","stac
ktrace":"<...>"}
```

```
{"level":"error","ts":"2023-06-20T20:13:15.689628865Z","caller":"amr-persister/main.g
o:102","msg":"MDS is unavailable: Get \"https://metadata-store-app.metadata-store.svc.
cluster.local:8443/api/health\": dial tcp 10.28.122.145:8443: connect: connection refu
sed","stacktrace":"..."}
```

Unsupported protocol is used for the `amr.observer.cloudevent_handler.endpoint`.

```
2023-06-28T18:48:31Z  ERROR  httpclient  error sending request to AMR CloudEvent Handl
er  {"error": "Get \"amr-persister.example.com/healthz\": unsupported protocol scheme
\"\""}

...

2023-06-28T18:48:31Z  ERROR  setup  unable to registry location  {"error": "failed to
send, Post \"amr-persister.example.com\": unsupported protocol scheme \"\""}

...

2023-06-28T18:48:31Z  ERROR  httpclient.circuitbreaker  error contacting event handler
{"error": "Get \"amr-persister.example.com/healthz\": unsupported protocol scheme
\"\""}
```

To fix this, use the appropriate `https://` or `http://` prepended protocol.

If the log contains:

```
2023/06/28 19:09:06 No certs appended, using system certs only
2023-06-28T19:09:06Z  INFO  controller-runtime.metrics  Metrics server is starting to
listen  {"addr": "127.0.0.1:8080"}
2023-06-28T19:09:06Z  INFO  setup  Establishing  {"locationId": "d9fa1ee9-ba42-4262-aa
f6-4128f99096b9"}
```

And if the following describe on the pod shows:

```
$ kubectl -n amr-observer-system describe pods "<amr-observer-controller-manager-...>"
```

Sample output:

```
...

Events:
  Type     Reason     Age                    From               Message
  ----     ------     ----                   ----               -------
...

  Warning  Unhealthy  3m35s (x3 over 4m15s)  kubelet            Liveness probe failed:
Get "http://192.168.45.78:8081/healthz": context deadline exceeded (Client.Timeout exc
eeded while awaiting headers)

...
```

```
  Warning  Unhealthy  3m5s (x10 over 4m25s)  kubelet            Readiness probe faile
d: Get "http://192.168.45.78:8081/readyz": context deadline exceeded (Client.Timeout e
xceeded while awaiting headers)
```

This is a symptom of a wrong protocol for `amr.observer.cloudevent_handler.endpoint`. The fix is to use the appropriate `https://` or `http://` prepended protocol depending on the TLS configuration.

AMR Observer Logs

```
kubectl -n amr-observer-system logs deployments/amr-observer-controller-manager
```

The AMR Observer is not observing `ImageVulnerabilityScan` CRD.

```
2023-06-20T15:47:09Z  INFO  ivs.SetupWithManager  Not registering ImageVulnerabilitySc
ans Controller: customresourcedefinitions.apiextensions.k8s.io "imagevulnerabilityscan
s.app-scanning.apps.tanzu.vmware.com" not found"
```

The AMR Observer is observing `ImageVulnerabilityScan` CRD if it is installed.

```
2023-06-28T17:56:43Z  INFO  Starting Controller  {"controller": "imagevulnerabilitysca
n", "controllerGroup": "app-scanning.apps.tanzu.vmware.com", "controllerKind": "ImageV
ulnerabilityScan"}
```

When Observer first starts up, it registers a Location to the Metadata Store. See Configure Artifact Metadata Repository.

```
2023-06-20T15:47:09Z  INFO  setup  Establishing  {"locationId": "f17f073d-dfec-4624-95
3e-a133b694ecad"}
sent: type: vmware.tanzu.apps.location.created.v1
  source: f17f073d-dfec-4624-953e-a133b694ecad
  id: 1667244096281455275
Extensions:
map[]
```

Information about what CA certificates were added to the Observer's HTTP client.

```
2023-06-20T15:47:05Z  INFO  setup  No additional certs read from configured path, cont
inuing with system truststore"  {"path": "/truststore/ca.crt"}
```

No valid CA certificates were found.

```
2023/06/28 18:41:04 No certs appended, using system certs only
```

When the ReplicaSet is observed to be deleted, it attempts to send the result to AMR CloudEvent Handler. There is a known minor issue that even non workload replicaSets are sent during create and delete events. The log shows an error, however, it is a no-op because AMR CloudEvent Handler filters out ReplicaSet CloudEvents without a workload container.

```
result: 204: sent: type: dev.knative.apiserver.resource.delete
  source: f17f073d-dfec-4624-953e-a133b694ecad
2023-06-20T19:01:23Z  INFO  replicaset.sendCloudEvent  received result  {"ceType": "de
v.knative.apiserver.resource.delete", "result": "500: "}
  id: 4565357219078868493
Extensions:
map[kind:ReplicaSet name:amr-graphql-app-7ff9bc58f namespace:metadata-store]
```

There is partial legacy support for Knative ApiServerSource CloudEvents which the Observer leverages which is why there are CloudEvents formatted similarly to Knative APIServerSource being sent.

AMR CloudEvent Handler Logs

```
kubectl -n metadata-store logs deployments/amr-persister
```

When an event is received, there are log entries for an event being handled:

```
{"level":"debug","ts":"2023-06-20T15:47:09.203079201Z","caller":"persister/persisterad
apter.go:76","msg":"Handle single event"}
{"level":"debug","ts":"2023-06-20T15:47:09.203160964Z","caller":"persister/persisterad
apter.go:108","msg":"Handle Event"}
```

When the Observer starts up, it sends the Location CloudEvent and the AMR CloudEvent Handler sends the Location information to the Metadata Store. The log entries contain where the request is sent to, the JSON payload, and the response body returned from the Metadata Store:

```
{"level":"debug","ts":"2023-06-20T15:47:09.203390152Z","caller":"persister/persisterad
apter.go:117","msg":"Registry Location Event"}
{"level":"info","ts":"2023-06-20T15:47:09.20349837Z","caller":"persister/persisteradap
ter.go:279","msg":"Sending request to: https://amr-graphql-app.metadata-store.svc.clus
ter.local:8443/api/v1/locations with payload: {\"alias\":\"f17f073d-dfec-4624-953e-a13
3b694ecad\",\"reference\":\"f17f073d-dfec-4624-953e-a133b694ecad\"}"}
{"level":"info","ts":"2023-06-20T15:47:09.238033374Z","caller":"persister/persisterada

Overview of the Metadata Store

This topic gives you an overview of the Metadata Store.

Overview

The Metadata Store saves software bills of materials (SBoMs) to a database and allows you to query for image, source code, package, and vulnerability relationships. The Metadata Store integrates with Supply Chain Security Tools - Scan to automatically store the resulting source code and image vulnerability reports. The Metadata Store accepts CycloneDX input and outputs in both human-readable and machine-readable formats, including JSON, text, and CycloneDX.

Using the Tanzu Insight CLI plug-in

The Tanzu Insight CLI plug-in is the primary way to view results from the Supply Chain Security Tools (SCST) - Scan of source code and image files. Use it to query by the source code commit, image digest, and CVE identifier to understand security risks.

For information about installing, configuring, and using `tanzu insight`, see Overview of Tanzu Insight plug-in.

Multicluster configuration

You can configure the Metadata Store in a multicluster setup. For more information, see Multicluster setup for Supply Chain Security Tools - Store.

Integrating with Tanzu Developer Portal

By using Supply Chain Choreographer in Tanzu Developer Portal, you can visualize your supply chain. Supply Chain Choreographer uses the Metadata Store to show the packages and vulnerabilities in your source code and images.

Additional documentation

For more information about the API, deployment details and configuration, AWS Relational Database Service (RDS) configuration, other database backup recommendations, and known issues, see Additional documentation.

Configure your target endpoint and certificate for Supply Chain Security Tools - Store

This topic describes how you can configure your target endpoint and certificate for Supply Chain Security Tools (SCST) - Store.

Overview

The connection to Supply Chain Security Tools - Store requires TLS encryption, and the configuration depends on the kind of installation.

For a production environment, VMware recommends that SCST - Store is installed with ingress enabled. The following instructions help set up the TLS connection, assuming that you deployed with ingress enabled.

Using `Ingress`

When using an Ingress setup, SCST - Store creates a specific TLS Certificate for HTTPS communications under the `metadata-store` namespace.

Set the endpoint host to `metadata-store.INGRESS-DOMAIN`, such as `metadata-store.example.domain.com`. Where `INGRESS-DOMAIN` isthe value of the `ingress_domain` property in your deployment yaml.

Note In a multi-cluster setup, a DNS record is **required** for the domain. The below instructions for single cluster setup do not apply, skip to Set Target section.

Single Cluster setup

In a single-cluster setup, a DNS record is still recommended. However, if no accessible DNS record exists for the domain, edit the `/etc/hosts` file to add a local record:

```
ENVOY_IP=$(kubectl get svc envoy -n tanzu-system-ingress -o jsonpath="{.status.loadBal
ancer.ingress[0].ip}")

# Replace with your domain
METADATA_STORE_DOMAIN="metadata-store.example.domain.com"

# Delete any previously added entry
sudo sed -i '' "/$METADATA_STORE_DOMAIN/d" /etc/hosts

echo "$ENVOY_IP $METADATA_STORE_DOMAIN" | sudo tee -a /etc/hosts > /dev/null
```

Set Target

To get the certificate, run:

```
kubectl get secret tap-ingress-selfsigned-root-ca -n cert-manager -o json | jq -r '.da
ta."ca.crt"' | base64 -d > insight-ca.crt
```

Set the target by running:

```
tanzu insight config set-target https://$METADATA_STORE_DOMAIN --ca-cert insight-ca.cr
t
```

Important

The `tanzu insight config set-target` does not initiate a test connection. Use `tanzu insight health` to test connecting using the configured endpoint and CA

certificate. Neither commands test whether the access token is correct. For that you must use the plug-in to add data and query data.

Next Step

- Configure access token

Additional Resources

For information about deploying SCST - Store **without** Ingress, see:

- Using LoadBalancer
- Using NodePort

Configure your access tokens for Supply Chain Security Tools - Store

This topic describes how to configure your access tokens for Supply Chain Security Tools - Store.

The access token is a `Bearer` token used in the http request header `Authorization`. For example, `Authorization: Bearer eyJhbGciOiJSUzI1NiIsImtpZCI6IjhMV0....`

Service accounts are required to have associated access tokens. Before Kubernetes 1.24, service accounts generated access tokens automatically. Since Kubernetes 1.24, a secret must be applied manually.

By default, Supply Chain Security Tools - Store includes a `read-write` service account installed with an access token generated. This service account is cluster-wide. If you want to create your own service accounts, see Create Service Accounts.

Setting the Access Token

When using the `insight` plug-in, you must set the `METADATA_STORE_ACCESS_TOKEN` environment variable, or use the `--access-token` flag. VMware discourages using the `--access-token` flag as the token appears in your shell history.

The following command retrieves the access token from the default `metadata-store-read-write-client` service account and stores it in `METADATA_STORE_ACCESS_TOKEN`:

```
export METADATA_STORE_ACCESS_TOKEN=$(kubectl get secrets metadata-store-read-write-cli
ent -n metadata-store -o jsonpath="{.data.token}" | base64 -d)
```

Additional Resources

- Retrieve access tokens
- Create service accounts
- Create a service account with a custom cluster role

Security details for Supply Chain Security Tools - Store

This topic describes the security details for Supply Chain Security Tools (SCST) - Store.

Application security

TLS encryption

Supply Chain Security Tools - Store requires TLS connection. If certificates are not provided, the application does not start. It supports TLS v1.2 and TLS v1.3. It does not support TLS 1.0, so a downgrade attack cannot happen. TLS 1.0 is prohibited under Payment Card Industry Data Security Standard (PCI DSS).

Cryptographic algorithms

Elliptic Curve:

```
CurveP521
CurveP384
CurveP256
```

Cipher Suites:

```
TLS_AES_128_GCM_SHA256
TLS_AES_256_GCM_SHA384
TLS_ECDHE_ECDSA_WITH_AES_128_GCM_SHA256
TLS_ECDHE_ECDSA_WITH_AES_256_GCM_SHA384
TLS_ECDHE_RSA_WITH_AES_128_GCM_SHA256
TLS_ECDHE_RSA_WITH_AES_256_GCM_SHA384
```

Access controls

SCST - Store uses kube-rbac-proxy as the only entry point to its API. Authentication and Authorization must be completed by using the `kube-rbac-proxy` before its API is accessible.

Authentication

The `kube-rbac-proxy` uses Token Review to verify that the token is valid. `Token Review` is a Kubernetes API to ensure that a trusted vendor issued the access token provided by the user. To issue an access token using Kubernetes, the user can create a Kubernetes Service Account and retrieve the corresponding generated secret for the access token.

To create a service account and use its access token, see the Create Service Account Docs.

Authorization

The `kube-rbac-proxy` uses Subject Access Review to ensure that users access certain operations. `Subject Access Review` is a Kubernetes API that uses Kubernetes RBAC to verify that the user can perform specific actions. See Create Service Account Doc.

There are two supported roles:

- `Read Only` cluster role
- `Read and Write` cluster role

These cluster roles are deployed by default. Additionally, a service account is created and bound to the `Read and Write` cluster role by default. If you do not want this service account, set the `add_default_rw_service_account` property to `false` in the `metadata-store-values.yaml` file durring deployment. See Install SCST - Store.

There is no default service account bound to the `Read Only` cluster role. You must create your service account and cluster role binding to bind to the `Read Only` role.

Important

There is no support for roles with access to only specific types of resources For example, images, packages, and vulnerabilities.

Container security

Non-root user

All containers shipped do not use root user accounts or accounts with root access. Using Kubernetes Security Context ensures that applications do not run with root users.

Security Context for the API server:

```
allowPrivilegeEscalation: false
runAsUser: 65532
fsGroup: 65532
```

Security Context for the PostgreSQL database pod:

```
allowPrivilegeEscalation: false
runAsUser: 999
fsGroup: 999
```

Note

`65532` is the UUID for the nobody user. `999` is the UUID for the PostgreSQL user.

Security scanning

There are two types of security scans that are performed before every release.

Static Application Security Testing (SAST)

A Coverity Scan is run on the source code of the API server, CLI, and all their dependencies. There are no high or critical items outstanding at the time of release.

Software Composition Analysis (SCA)

A Black Duck scan is run on the compiled binary to check for vulnerabilities and license data. There are no high or critical items outstanding at the time of release.

A Grype scan is run against the source code and the compiled container for dependencies vulnerabilities. There are no high or critical items outstanding at the time of release.

Additional documentation for Supply Chain Security Tools - Store

This topic describes additional documentation you can use with Supply Chain Security Tools - Store.

Use and operate

- Multicluster setup
- Developer namespace setup
- Failover, redundancy, and backups

Troubleshooting and logging

- Troubleshooting upgrading
- Log configuration and usage
- Connecting to the Postgres Database

Configuration

- Deployment details and configuration

Access control

- Retrieve access tokens
- Create service accounts
- Create a service account with a custom cluster role

Certificates

- Ingress support
- Using LoadBalancer
- Using NodePort
- Custom certificate configuration
- TLS configuration
- Certificate rotation
- Scanners cluster specific configurations

Database

- Use external postgres database
- AWS RDS postgres configuration
- Database backup recommendations

Other

- Install SCST - Store independent from TAP profiles

Additional documentation for Supply Chain Security Tools - Store

This topic describes additional documentation you can use with Supply Chain Security Tools - Store.

Use and operate

- Multicluster setup

Other

- Install SCST - Store independent from TAP profiles

Connecting to the Postgres Database

To connect to the Postgres Database, you will need the following values: * database name * username * password * database host * database port * database CA certificate

1. To obtain the database name, username, password, and CA cert, run the following commands:

```
db_name=$(kubectl get secret postgres-db-secret -n metadata-store -o json | jq
-r '.data.POSTGRES_DB' | base64 -d)
db_username=$(kubectl get secret postgres-db-secret -n metadata-store -o json |
jq -r '.data.POSTGRES_USER' | base64 -d)
db_password=$(kubectl get secret postgres-db-secret -n metadata-store -o json |
jq -r '.data.POSTGRES_PASSWORD' | base64 -d)

db_ca_dir=$(mktemp -d -t ca-cert-XXXX)
db_ca_path="$db_ca_dir/ca.crt"
```

```
kubectl get secrets postgres-db-tls-cert -n metadata-store -o json | jq -r '.da
ta."ca.crt"' | base64 -d > $db_ca_path
```

If the password was auto-generated, the above `password` command will return an empty string. Instead, run the following command:

```
db_password=$(kubectl get secret postgres-db-password -n metadata-store -o json
| jq -r '.data.DB_PASSWORD' | base64 -d)
```

2. In a separate terminal, run the following command:

```
kubectl port-forward service/metadata-store-db 5432:5432 -n metadata-store
```

Set the database host and port values on the first terminal with the following:

```
db_host="localhost"
db_port=5432
```

To port forward to a different local port number, use the following command template:

```
kubectl port-forward service/metadata-store-db <LOCAL_PORT>:5432 -n metadata-st
ore
```

With this setup, you can now connect to the database and make queries like the following example:

```
psql "host=$db_host port=$db_port user=$db_username dbname=$db_name sslmode=verify-ca
sslrootcert=$db_ca_path" -c "SELECT * FROM images"
```

You could also use GUI clients such as Postico or DBeaver to interact with the database.

Deployment details and configuration for Supply Chain Security Tools - Store

This topic describes how you can deploy and configure your Kubernetes cluster for Supply Chain Security Tools (SCST) - Store.

What is deployed

The installation creates the following in your Kubernetes cluster:

- Four components:
  - `metadata-store` API back end
  - Database
  - AMR API back end. If AMR is deployed, see Deploying AMR.
  - AMR CloudEvent Handler. If AMR is deployed, see Deploying AMR.
- Services for each of the four components, named:
  - `metadata-store-app`
  - `metadata-store-db`
  - `amr-cloudevent-handler`. If AMR is deployed, see Deploying AMR.
  - `amr-graphql-app`. If AMR is deployed, see Deploying AMR.
- A namespace called `metadata-store`.

- Persistent volume claim `postgres-db-pv-claim` in the `metadata-store` namespace.
- A Kubernetes secret in the namespace `tap` is installed to allow pulling SCST - Store images from a registry.
- Two ClusterRoles:
  - `metadata-store-read-write-client` is bound to a service account by default, giving the service account read and write privileges
  - `metadata-store-read-only` isn't bound to any service accounts, you can bind to it if needed. See Service Accounts.
- (Optional) An HTTPProxy object for ingress support.

Deployment configuration

All configurations are nested inside of `metadata_store` in your Tanzu Application Platform values deployment YAML. AMR specific configurations are nested under `amr` in the `metadata_store` section.

Supported Network Configurations

VMware recommends the following connection methods for Tanzu Application Platform:

- For a single or multicluster configuration with Contour, use `Ingress`.
- For a single cluster without Contour and with `LoadBalancer` support configuration, use `LoadBalancer`.
- For a single cluster without Contour and without `LoadBalancer` configuration, use `NodePort`.
- Multicluster without Contour configuration is not supported.

For a production environment, VMware recommends installing SCST - Store with ingress enabled.

App service type

The Metadata Store's app service type is configured inside the `metadata_store` property of the values file.

```
metadata_store:
  app_service_type: "ClusterIP"
```

Supported values include:

- `LoadBalancer`
- `ClusterIP`
- `NodePort`

The `app_service_type` is set to `ClusterIP` by default.

Ingress support

SCST - Store's values file allows you to enable ingress support and to configure a custom domain name to use Contour to provide external access to SCST - Store's API. These ingress configurations are shared for the metadata store and AMR. Enabling ingress for store enables it for both metadata store and AMR.

For example:

```
metadata_store:
  ingress_enabled: "true"
  ingress_domain: "example.com"
  app_service_type: "ClusterIP" # recommended setting when ingress is enabled
```

An HTTPProxy object is installed with `metadata-store.example.com` as the fully qualified domain name. See Ingress.

Note

The `ingress_enabled` property expects a string value of `"true"` or `"false"`, not a Boolean value.

Database configuration

The default database included with the deployment gets you started using the metadata store. The default database deployment does not support many enterprise production requirements, including scaling, redundancy, or fail over. However, it is a secure deployment.

Using AWS RDS PostgreSQL database

Users can also configure the deployment to use their own RDS database instead of the default. See AWS RDS Postgres Configuration.

Using external PostgreSQL database

Users can configure the deployment to use any other PostgreSQL database. See Use external postgres database.

Custom database password

By default, a database password is generated upon deployment. To configure a custom password, use the `metadata_store.db_password` property in the values file

Important

There is a known issue related to changing database passwords Persistent Volume Retains Data.

To configure a custom database password for AMR:

```
metadata_store:
  db_password: "PASSWORD"
```

Where `PASSWORD` is the same password used for both deployments.

Service accounts

By default, a service account with read-write privileges to the metadata store app is installed. This service account is a cluster-wide account that uses ClusterRole. If you don't want the service account and role, set the `add_default_rw_service_account` property to `"false"`. To create a custom service account, see Create Service Account.

The store creates a read-only cluster role, which is bound to a service account by using `ClusterRoleBinding`. To create service accounts to bind to this cluster role, see Create Service

Account.

Exporting certificates

SCST - Store creates a Secret Export for exporting certificates to `Supply Chain Security Tools - Scan` to securely post scan results. These certificates are exported to the namespace where `Supply Chain Security Tools - Scan` is installed.

Configure your AWS RDS PostgreSQL configuration

This topic describes how you can configure your AWS RDS PostgreSQL configuration for Supply Chain Security Tools (SCST) - Store.

Prerequisites

- AWS Account

Setup certificate and configuration

1. Create an Amazon RDS Postgres using the Amazon RDS Getting Started Guide
2. Once the database instance starts, retrieve the following information:
    1. DB Instance Endpoint
    2. Master Username
    3. Master Password
    4. Database Name

    

    Note

    If the database name is – in the AWS RDS UI, the value is likely `postgres`.
3. Create a security group to allow inbound connections from the cluster to the Postgres DB
4. Retrieve the corresponding CA Certificate that signed the Postgres TLS Certificate using the following link
5. In the `metadata-store-values.yaml` fill the following settings:

```
db_host: "<DB Instance Endpoint>"
db_user: "<Master Username>"
db_password: "<Master Password>"
db_name: "<Database Name>"
db_port: "5432"
db_sslmode: "verify-full"
db_max_open_conns: 10
db_max_idle_conns: 100
db_conn_max_lifetime: 60
db_ca_certificate: |
  <Corresponding CA Certification>
  ...
  ...
  ...
deploy_internal_db: "false"
```

Note

If `deploy_internal_db` is set to `false`, an instance of Postgres will not be deployed in the cluster.

Use external PostgreSQL database for Supply Chain Security Tools - Store

This topic describes how you configure Tanzu Application Platform to use an external database.

For production deployments, VMware recommends you use an external PostgreSQL database rather than the one packaged with Tanzu Application Platform. This allows you to manage the external database using the best practices and processes that your organization has established.

Prerequisites

Gather the following connection information for the external PostgreSQL database:

- Database Instance Connect Endpoint
- CA Certificate for the database instance TLS certificate (if applicable)
- Database credentials
- Name of the database

If migrating from the internal database to an external database, back up the data before proceeding.

Configure Artifact Metadata Repository (AMR) and Metadata Store (MDS) to use the external database

1. Update your `tap-values.yaml` file:

```
metadata_store:
 db_host: "<DB Instance Endpoint>"
 db_user: "<Master Username>"
 db_password: "<Master Password>"
 db_name: "<Database Name>"
 # SEE NOTE BELOW
 # Disable the internal database deployment
 deploy_internal_db: "false"
 db_port: "5432"
 db_max_open_conns: 10
 db_max_idle_conns: 100
 db_conn_max_lifetime: 60
 # If TLS is enabled on PostgreSQL Instance
 db_sslmode: "verify-full"
 # If TLS Certificate is self-signed
 db_ca_certificate: |
   <Corresponding CA Certification>
   ...
   ...
   ...
```

Note

If you initially deployed Tanzu Application Platform with an internal database and are migrating to an external database, be aware that setting `deploy_internal_db` to `false`, removes the internal instance of PostgreSQL. Back up and migrate your data to the database before setting this value to false or it might cause data loss.

2. Apply the new configuration:

```
tanzu package installed update tap -p tap.tanzu.vmware.com -v 1.9.1  --values-f
ile tap-values.yaml -n tap-install
```

3. (Optional) If you are migrating from the internal database to an external database, the reconciliation might fail. You must manually delete the secret the cert-manager created and cycle the AMR and MDS Services so that the new secret is picked up.

```
kubectl delete secret -n metadata_store postgres-db-tls-cert
kubectl rollout restart -n metadata_store deployment metadata_store-app
```

Validation

Use Bitnami PostgreSQL to verify. For more information, see the Bitnami documentation.

Database backup recommendations for Supply Chain Security Tools - Store

This topic describes database backup recommendations for Supply Chain Security Tools - Store.

By default, the metadata store uses a `PersistentVolume` mounted on a Postgres instance, making it a stateful component of Tanzu Application Platform. VMware recommends implementing a regular backup strategy as part of your disaster recovery plan when using the provided Postgres instance.

Backup

You can use Velero to create regular backups.

Note

Backup support for `PersistentVolume` depends on the used `StorageClass` and existing provider plug-ins. See the officially supported plug-ins here.

```
velero install --provider PROVIDER --bucket BUCKET-NAME --plugins PLUGIN-IMAGE-LOCATIO
N --secret-file SECRET-FILE
```

Where:

- `PROVIDER` is the name of the provider you want to use.
- `BUCKET-NAME` is the name of the bucket you want to use.
- `PLUGIN-IMAGE-LOCATION` is the location of the plug ins you want to use.
- `SECRET-FILE` is the file where the secret is located.

Velero CLI can then be used to create a backup of all the resources in the `metadata-store` namespace, including `PersistentVolumeClaim` and `PersistentVolume`.

```
velero backup create metadata-store-$(date '+%s') --include-namespaces=metadata-store
```

Restore

Velero CLI can restore the Store in the same or a different cluster. The same namespace can be used to restore, but may collide with other Supply Chain Security Tools – Store installations. Furthermore, restoring into the same namespace restores a fully functional instance of Supply Chain Security Tools – Store; however, this instance is not managed by Tanzu Application Platform and can cause conflicts with future installations.

```
velero restore create restore-metadata-store-$timestamp --from-backup metadata-store
-$timestamp --namespace-mappings metadata-store:metadata-store
```

Alternatively, a different namespace can be used to restore Supply Chain Security Tools – Store. In this case, Supply Chain Security Tools – Store API is not available due to conflicting definitions in the RBAC proxy configuration, causing all requests to fail with an `Unauthorized` error. In this scenario, the postgres instance is still accessible, and tools such as `pg_dump` can be used to retrieve table contents and restore in a new live installation of Supply Chain Security Tools – Store.

```
velero restore create restore-metadata-store-$timestamp --from-backup metadata-store
-$timestamp --namespace-mappings metadata-store:restored-metadata-store
```

Currently, mounting an existing `PersistentVolume` or `PersistentVolumeClaim` during installation is not supported.

The minimum suggested resources for backups are `PersistentVolume`, `PersistentVolumeClaim` and `Secret`. The database password `Secret` is needed to set up a Postgres instance with the correct password to properly read data from the restored volume.

Log configuration and usage for Supply Chain Security Tools - Store

This topic describes how you can configure Supply Chain Security Tools (SCST) - Store to output and interpret detailed log information.

Verbosity levels

There are six verbosity levels that Supply Chain Security Tools - Store supports.

Level	Description
Trace	Output extended debugging logs.
Debug	Output standard debugging logs.
More	Output more verbose informational logs.
Default	Output standard informational logs.
Less	Outputs less verbose informational logs.
Minimum	Outputs a minimal set of informational logs.

When SCST - Store is deployed at a specific verbosity level, all logs of that level and lower are output to the console. For example, setting the verbosity level to `More` outputs logs from `Minimal` to `More`, while `Debug` and `Trace` logs are muted.

Currently, the application logs output at these levels:

- **Minimum** does not output any logs.
- **Less** outputs a single log line indicating the current verbosity level is configured in Metadata Store when the application starts.
- **Default** outputs API endpoint access information.
- **Debug** outputs API endpoint payload information, both for requests and responses.
- **Trace** outputs verbose debug information about the actual SQL queries for the database.

Other log levels do not output any additional log information and are present for future extensibility.

If you don't specify a verbosity level when the Store is installed, the level is set to `default`.

Slow SQL

A slow SQL statement is logged only when verbosity level is set to `trace` and the SQL query takes more than 200 milliseconds to execute. You can change this default by setting the `db_slow_threshold_ms` value in values.yaml file and redeploying metadata store.

Error logs

Error logs are always output regardless of the verbosity level, even when set to `minimum`.

Obtaining logs

Kubernetes pods emit logs. The deployment has two pods, one for the database and one for the API back end.

Use `kubectl get pods` to obtain the names of the pods:

```
kubectl get pods -n metadata-store
```

For example:

```
$ kubectl get pods -n metadata-store
NAME                                  READY   STATUS    RESTARTS   AGE
metadata-store-app-67659bbc66-2rc6k   2/2     Running   0          4d3h
metadata-store-db-64d5b88587-8dns7    1/1     Running   0          4d3h
```

The database pod has the prefix `metadata-store-db-`. The API backend pod has the prefix `metadata-store-app-`. Use `kubectl logs` to get the logs from the pod you're interested in. For example, to get the logs of the database pod, run:

```
$ kubectl logs metadata-store-db-64d5b88587-8dns7 -n metadata-store
The files belonging to this database system will be owned by user "postgres".
This user must also own the server process.
...
```

The API backend pod has two containers, one for `kube-rbac-proxy`, and one for the API server. Use the `--all-containers` flag to see logs from both containers. For example:

```
$ kubectl logs metadata-store-app-67659bbc66-2rc6k --all-containers -n metadata-store
I1206 18:34:17.686135       1 main.go:150] Reading config file: /etc/kube-rbac-proxy/c
onfig-file.yaml
I1206 18:34:17.784900       1 main.go:180] Valid token audiences:
...
{"level":"info","ts":"2022-05-27T13:47:52.54099339Z","logger":"MetadataStore","msg":"L
```

```
og settings","hostname":"metadata-store-app-5c9d6bccdb-kcrt2","LOG_LEVEL":"default"}
{"level":"info","ts":"2022-05-27T13:47:52.541133699Z","logger":"MetadataStore","ms

{"level":"info","ts":"2022-05-27T13:47:52.541150096Z","logger":"MetadataStore","ms
g":"Database Settings","hostname":"metadata-store-app-5c9d6bccdb-kcrt2","maxopenconnec
tion":10,"maxidleconnection":100,"connectionmaxlifetime":60}
```

Note

The `kube-rbac-proxy` container uses a different log format than the Store. For information about the proxy's container log format, see Logging Formats in GithHub.

API endpoint log output

When an API endpoint handles a request, the Store generates two and five log entries:

- When the endpoint receives a request, it outputs a `Processing request` line. This logline is shown at the `default` verbosity level.
- If the endpoint includes query or path parameters, it outputs a `Request parameters` line. This line logs the parameters passed in the request. This line is shown at the `default` verbosity level.
- If the endpoint takes in a request body, it outputs a `Request body` line. This line outputs the entire request body as a string. This line is shown at the `debug` verbosity level.
- When the endpoint returns a response, it outputs a `Request response` line. This line is shown at the `default` verbosity level.
- If the endpoint returns a response body, it outputs a second `Request response` line with an extra key `payload`, and its value is set to the entire response body. This line is shown at the `debug` verbosity level.

Format

The logs use JSON output format.

When the Store handles a request, it outputs API endpoint access information in the following format:

```
{"level":"info","ts":"2022-05-27T15:41:36.051991749Z","logger":"MetadataStore","ms
g":"Processing request","hostname":"metadata-store-app-c7c8648f7-8dmdl","method":"GE
T","endpoint":"/api/images?digest=sha256%3A20521f76ff3d27f436e03dc666cc97a511bbe71e8e8
495f851d0f4bf57b0bab6"}
```

Key-value pairs

Because JSON output format uses key-value pairs, the tables in the following sections list each key and the meaning of their values.

Common to all logs

The following key-value pairs are common for all logs.

Key	Type	Verbosity Level	Description
level	string	all	The log level of the message. This is either `error` for error messages, or `info` for all other messages.
ts	string	all	The timestamp when the log entry was generated. It uses RFC 3339 format with nanosecond precision and 00:00 offset from UTC, meaning Zulu time.
logger	string	all	Used to identify what produced the log entry. For Store, the name always starts with `MetadataStore`. For log entries that display the raw SQL queries, the name is `MetadataStore.gorm`
msg	string	all	A short description of the logged event
hostname	string	all	The Kubernetes host name of the pod handling the request. This helps identify the specific instance of the Store when you deploy multiple instances on a cluster.
error	string	all	The error message which is only available in error log entries
endpoint	string	default	The API endpoint the Metadata Store attempts to handle the request. This also includes any query and path parameters passed in.
method	string	default	The HTTP verb to access the endpoint. For example, `GET` or `POST`.
code	integer	default	The HTTP response code
response	string	default	The HTTP response in human-readable format. For example, `OK`, `Bad Request`, or `Internal Server Error`.
function	string	debug	The function name that handles the request.

Logging query and path parameter values

Those endpoints that use query or path parameters are logged on the `Request parameters` log entry as key-value pairs. They are appended to all other log entries of the same request as key-value pairs.

The key names are the query or path parameter's name, while the value is set to the value of those parameters in string format.

For example, the following log entry contains the `digest` and `id` key, which represents the respective `digest` and `id` query parameters, and their values:

```
{"level":"info","ts":"2022-05-27T15:41:36.0520631762","logger":"MetadataStore","msg":"Request parameters","hostname":"metadata-store-app-c7c8648f7-8dmdl","method":"GET","endpoint":"/api/images?digest=sha256%3A20521f76ff3d27f436e03dc666cc97a511bbe71e8e8495f851d0f4bf57b0bab6","id":0,"digest":"sha256:20521f76ff3d27f436e03dc666cc97a511bbe71e8e8495f851d0f4bf57b0bab6","name":""}
```

These key-value pairs show up in all subsequent log entries of the same call. For example:

```
{"level":"info","ts":"2022-05-27T15:41:36.0573935192","logger":"MetadataStore","msg":"Request response","hostname":"metadata-store-app-c7c8648f7-8dmdl","method":"GET","endpoint":"/api/images?digest=sha256%3A20521f76ff3d27f436e03dc666cc97a511bbe71e8e8495f851d0f4bf57b0bab6","id":0,"digest":"sha256:20521f76ff3d27f436e03dc666cc97a511bbe71e8e8495f851d0f4bf57b0bab6","name":"","code":200,"response":"OK"}
```

This is done to:

- Ensure that the application interprets the values of the query or path parameters correctly.

- Figure out which log entries are associated with a particular API request. Because there might be several simultaneous endpoint calls, this is a first attempt at grouping logs by specific calls.

API payload log output

As mentioned at the start of this section, by setting the verbosity level to `debug`, the Store logs the body payload data for both the request and response of an API call.

The `debug` verbosity level, instead of the `default`, displays this information instead of `default` because:

- Body payloads can contain full CycloneDX and SBOM information. Moving the payload information at this level helps keep the production log output to a reasonable size.
- Some information in these payloads might be sensitive, and the user might not want them exposed in production environment logs.

GraphQL endpoint log output

Note

This section is only applicable to Artifactory Metadata Repository (AMR) logs.

When an GraphQL endpoint handles a request, the AMR generates following types of logs:

- Every request received produces a `Processing request` log, which includes the name of the operation called and the requested fields.
- Every response will produces a log containing the actual query and the return status
- If the endpoint returns a response body, it outputs a second `Request response` line with an extra key `payload`, and its value is set to the entire response body. This line is shown at the `debug` verbosity level

Format

The logs output are in JSON format.

When the AMR handles a request, it outputs some GraphQL endpoint access information in the following format:

```
{"level":"info","ts":"2023-03-23T13:11:31.161531-06:00","logger":"Artifact Metadata Re
pository","msg":"Processing request","hostname":"xyzp2DMD6R.vmware.com","getAllApp
s":"query getAllApps {\n  apps(latest:true) {\n    \n    timestamp\n    location {\n
alias\n    }\n  }\n}"}
{"level":"info","ts":"2023-03-23T13:11:31.172953-06:00","logger":"Artifact Metadata Re
pository","msg":"Request response","hostname":"xyzp2DMD6R.vmware.com","getAllApps":"qu
ery getAllApps {\n  apps(latest:true) {\n    \n    timestamp\n    location {\n      al
ias\n    }\n  }\n}","code":200,"response":"OK"}
```

Key-value pairs

The following tables list the meaning of each key found in the logs.

Common to all logs

The following key-value pairs are common for all logs.

Key	Type	Verbosity Level	Description
level	string	all	The log level of the message. This is either `error` for error messages, or `info` for all other messages.
ts	string	all	The timestamp when the log entry was generated. It uses RFC 3339 format with nanosecond precision and 00:00 offset from UTC, meaning Zulu time.
logger	string	all	Used to identify what produced the log entry. For Store, the name always starts with `MetadataStore`. For log entries that display the raw SQL queries, the name is `MetadataStore.gorm`.
msg	string	all	A short description of the logged event
hostname	string	all	The Kubernetes host name of the pod handling the request. This helps identify the specific instance of the Store when you deploy multiple instances on a cluster.
error	string	all	The error message which is only available in error log entries
code	integer	default	The HTTP response code
response	string	default	The HTTP response in human-readable format. For example, `OK`, `Bad Request`, or `Internal Server Error`.
query	string	debug	The operation name is the key and value fields that the fields requested.

API payload log output

By setting the verbosity level to `debug`, the AMR logs the body payload data for both the request and response of an API call.

The `debug` verbosity level, instead of the `default`, displays this information instead of `default` because body payloads can be large and some information in these payloads might be sensitive. You might not want the sensitive payloads exposed in production environment logs.

Logs containing payload information might be in the following format:

```
{"level":"info","ts":"2023-03-23T13:11:31.172966-06:00","logger":"Artifact Metadata Repository","msg":"Request response","hostname":"xyzp2DMD6R.vmware.com","getAllApps":"query getAllApps {\n  apps(latest:true) {\n    \n    timestamp\n    location {\n      alias\n    }\n  }\n}","payload":{"apps":[{"timestamp":"2023-03-22T15:09:38.867371-06:00","location":{"alias":"1-Alias"}}]}}
```

Slow SQL query log output

When the verbosity level is set to `trace`, you see log entries containing slow SQL queries.

Note

Some information in these SQL Query `trace` logs might be sensitive, and you might not want them exposed in production environment logs.

SQL Query log output

Slow SQL query logs are displayed in the following format when verbosity level is set to `trace`:

```
{"level":"info","ts":"2023-03-23T12:48:12.337749-06:00","logger":"Artifact Metadata Repository.gorm","msg":"slow sql >= 200ms","hostname":"xyzp2DMD6R.vmware.com","rows":50000,"sql":"SELECT \"artifact_apps\".\"id\",\"artifact_apps\".\"created_at\",\"artifact_
```

```
apps\".\"updated_at\",\"artifact_apps\".\"deleted_at\",\"artifact_apps\".\"location_id
\",\"artifact_apps\".\"correlation_id\",\"artifact_apps\".\"image_url\",\"artifact_app
s\".\"image_digest\",\"artifact_apps\".\"namespace\",\"artifact_apps\".\"name\",\"arti
fact_apps\".\"instances\",\"artifact_apps\".\"status\",\"artifact_apps\".\"timestamp\"
FROM \"artifact_apps\" INNER JOIN (select max(timestamp) as timestamp, name, namespac
e, location_id from artifact_apps group by location_id, name, namespace) as argo on ar
go.timestamp = artifact_apps.timestamp and argo.name = artifact_apps.name and argo.loc
ation_id = artifact_apps.location_id and argo.namespace = artifact_apps.namespace WHER
E \"artifact_apps\".\"deleted_at\" IS NULL"}
```

It is similar to the API endpoint log output format, but uses the following key-value pairs:

Key	Type	Log Level	Description
rows	integer	trace	Indicates the number of rows affected by the SQL query
sql	string	trace	Displays the raw SQL query for the database
data#	string	all	Used in error log entries. You can replace `#` with an integer because multiples of these keys can appear in the same log entry. These keys contain extra information related to the error.

SQL Query log output

Some Store logs display the executed SQL query commands when you set the verbosity level to `trace` or a SQL call fails.

Note

Some information in these SQL Query trace logs might be sensitive, and you might not want them exposed in production environment logs.

Format

When the Store display SQL query logs, it uses the following format:

```
{"level":"info","ts":"2022-05-27T15:37:26.1869603242","logger":"MetadataStore.gorm","m
sg":"sql call","hostname":"metadata-store-app-c7c8648f7-8dmdl","rows":1,"sql":"SELECT
count(*) FROM information_schema.tables WHERE table_schema = CURRENT_SCHEMA() AND tabl
e_name = 'images' AND table_type = 'BASE TABLE'"}
```

It is similar to the API endpoint log output format, but uses the following key-value pairs:

Key	Type	Log Level	Description
rows	integer	trace	Indicates the number of rows affected by the SQL query
sql	string	trace	Displays the raw SQL query for the database
data#	string	all	Used in error log entries. You can replace `#` with an integer because multiples of these keys can appear in the same log entry. These keys contain extra information related to the error.

Connecting to the Postgres Database

To connect to the Postgres Database, you will need the following values: * database name * username * password * database host * database port * database CA certificate

1. To obtain the database name, username, password, and CA cert, run the following commands:

```
db_name=$(kubectl get secret postgres-db-secret -n metadata-store -o json | jq
-r '.data.POSTGRES_DB' | base64 -d)
db_username=$(kubectl get secret postgres-db-secret -n metadata-store -o json |
jq -r '.data.POSTGRES_USER' | base64 -d)
db_password=$(kubectl get secret postgres-db-secret -n metadata-store -o json |
jq -r '.data.POSTGRES_PASSWORD' | base64 -d)

db_ca_dir=$(mktemp -d -t ca-cert-XXXX)
db_ca_path="$db_ca_dir/ca.crt"
kubectl get secrets postgres-db-tls-cert -n metadata-store -o json | jq -r '.da
ta."ca.crt"' | base64 -d > $db_ca_path
```

   If the password was auto-generated, the above `password` command will return an empty string. Instead, run the following command:

```
db_password=$(kubectl get secret postgres-db-password -n metadata-store -o json
| jq -r '.data.DB_PASSWORD' | base64 -d)
```

2. In a separate terminal, run the following command:

```
kubectl port-forward service/metadata-store-db 5432:5432 -n metadata-store
```

   Set the database host and port values on the first terminal with the following:

```
db_host="localhost"
db_port=5432
```

   To port forward to a different local port number, use the following command template:

```
kubectl port-forward service/metadata-store-db <LOCAL_PORT>:5432 -n metadata-st
ore
```

With this setup, you can now connect to the database and make queries like the following example:

```
psql "host=$db_host port=$db_port user=$db_username dbname=$db_name sslmode=verify-ca
sslrootcert=$db_ca_path" -c "SELECT * FROM images"
```

You could also use GUI clients such as Postico or DBeaver to interact with the database.

Troubleshooting Supply Chain Security Tools - Store

This topic contains ways you can troubleshoot known issues for Supply Chain Security Tools (SCST) - Store.

Querying by `insight source` returns zero CVEs even though there are CVEs in the source scan

Symptom

The `insight source get` and other `insight source` commands return zero results.

Solution

You might have to include different combinations of `--repo`, `--org`, `--commit` due to how the scan-controller populates the software bill of materials (SBOM). For more information see Query vulnerabilities, images, and packages.

Persistent volume retains data

Symptom

If SCST - Store is deployed, deleted, redeployed, and the database password is changed during the redeployment, the `metadata-store-db` pod fails to start. The persistent volume used by PostgreSQL retaining old data, even though the retention policy is set to `DELETE`, causes this issue.

Solution

Caution

Changing the database password deletes your SCST - Store data.

To redeploy the app, either use the same database password or follow these steps to erase the data on the volume:

1. Deploy metadata-store app by using `kapp`.
2. Verify that the `metadata-store-db-*` pod fails.
3. Run:

   ```
   kubectl exec -it metadata-store-db-<some-id> -n metadata-store /bin/bash
   ```

   Where `<some-id>` is the ID generated by Kubernetes and appended to the pod name.
4. Run `rm -rf /var/lib/postgresql/data/*` to delete all database data.

   Where `/var/lib/postgresql/data/*` is the path found in `postgres-db-deployment.yaml`.
5. Delete the `metadata-store` app by using `kapp`.
6. Deploy the `metadata-store` app by using `kapp`.

Missing persistent volume

Symptom

After SCST - Store is deployed, `metadata-store-db` pod might fail for missing volume while `postgres-db-pv-claim` pvc is in `PENDING` state.

This is because the cluster where SCST - Store is deployed does not have `storageclass` defined. `storageclass`'s provisioner is responsible for creating the persistent volume after `metadata-store-db` attaches `postgres-db-pv-claim`.

Solution

1. Verify that your cluster has `storageclass` by running `kubectl get storageclass`.
2. Create a `storageclass` in your cluster before deploying SCST - Store. For example:

   ```
   # This is the storageclass that Kind uses
   kubectl apply -f https://raw.githubusercontent.com/rancher/local-path-provision
   er/master/deploy/local-path-storage.yaml
   ```

```
# set the storage class as default
kubectl patch storageclass local-path -p '{"metadata": {"annotations":{"storage
class.kubernetes.io/is-default-class":"true"}}}'
```

Builds fail due to volume errors on EKS running Kubernetes v1.23

Symptom

When installing SCST - Store on or upgrading an existing EKS cluster to Kubernetes v1.23, the satabase pod shows:

```
running PreBind plugin "VolumeBinding": binding volumes: provisioning failed for PVC
"postgres-db-pv-claim"
```

Explanation

This is due to the CSIMigrationAWS in this Kubernetes version which requires users to install the Amazon Elastic Block Store (EBS) CSI Driver to use EBS volumes. For more information, see the AWS documentation.

SCST - Store uses the default storage class which uses EBS volumes by default on EKS.

Solution

Follow the AWS documentation to install the Amazon EBS CSI Driver before installing SCST - Store or before upgrading to Kubernetes v1.23. For more information, see the AWS documentation.

CA Cert expires

Symptom

The Insight CLI or Scan Controller fails to communicate with the SCST - Store and receives an error message containing the following text:

```
tls: failed to verify certificate: x509: certificate has expired or is not yet valid
```

Explanation

The CA certificate expired before the app certificate expires, which causes the error even though the app certificate is still valid. Certmanager will rotate the expired CA certificate, but it doesn't rotate the certificates that were previously created by the expired CA certificate. So this leads to contour being in a bad state and the certificates won't be refreshed properly.

Solution

1. Delete the existing expired cacert

```
kubectl delete secret cacert contourcert envoycert -n projectcontour
```

1. Delete the contour-certgen job

```
kubectl delete job contour-certgen -n projectcontour
```

1. Trigger reconciliation for contour

```
kctrl package installed kick --package-install contour -n tap-install
```

1. Restart envoy pods. First find the name of the envoy pod

```
kubectl get pods -n projectcontour
```

Find the pod that is named in the format `envoy-<some-random-id>`. Use that name and restart the pods by deleting them:

```
kubectl delete pod <envoy-pod-name> -n projectcontour
```

Certificate Expires

Symptom

The Insight CLI or the Scan Controller fails to connect to SCST - Store.

The logs of the metadata-store-app pod show the following error:

```
$ kubectl logs deployment/metadata-store-app -c metadata-store-app -n metadata-store
...
2022/09/12 21:22:07 http: TLS handshake error from 127.0.0.1:35678: write tcp 127.0.0.
1:9443->127.0.0.1:35678: write: broken pipe
...
```

or

The logs of metadata-store-db show the following error:

```
$ kubectl logs statefulset/metadata-store-db -n metadata-store
...
2022-07-20 20:02:51.206 UTC [1] LOG:  database system is ready to accept connections
2022-09-19 18:05:26.576 UTC [13097] LOG:  could not accept SSL connection: sslv3 alert
bad certificate
...
```

Explanation

cert-manager rotates the certificates, but the metadata-store and the PostgreSQL db are unaware of the change, and are using the old certificates.

Solution

If you see `TLS handshake error` in the metadata-store-app logs, delete the metadata-store-app pod and wait for it to come back up.

```
kubectl delete pod metadata-store-app-xxxx -n metadata-store
```

If you see `could not accept SSL connection` in the metadata-store-db logs, delete the metadata-store-db pod and wait for it to come back up.

```
kubectl delete pod metadata-store-db-0 -n metadata-store
```

Database index corruption issue in SCST - Store

Metadata Store unable to reconcile because the metadata store pod complains about potential database index corruption issue.

```
kubectl logs metadata-store-app-pod_name -n metadata-store
```

```
{"level":"error","ts":"2023-08-15T16:38:31.528115988Z","logger":"MetadataStore","ms
g":"unable to check index corruption since user is not a superuser to perform \"CREATE
EXTENSION amcheck\". Please create this extension and check for index corruption using
following sql command \"SELECT bt_index_check(oid) FROM pg_class WHERE relname in (SEL
ECT indexrelid::regclass::text FROM (SELECT indexrelid, indrelid, indcollation[i] coll
FROM pg_index, generate_subscripts(indcollation, 1) g(i)) s JOIN pg_collation c ON col
l=c.oid WHERE collprovider IN ('d', 'c') AND collname NOT IN ('C', 'POSIX'));\"","host
name":"metadata-store-app-77c9fb59c8-qplxt"}
{"level":"error","ts":"2023-08-15T16:38:31.528139637Z","logger":"MetadataStore","ms
g":"Found corrupted database indexes but unable to fix them","hostname":"metadata-stor
e-app-77c9fb59c8-qplxt","error":"unable to check index corruption since user is not a
superuser to perform \"CREATE EXTENSION amcheck\". Please create this extension and ch
eck for index corruption using following sql command \"SELECT bt_index_check(oid) FROM
pg_class WHERE relname in (SELECT indexrelid::regclass::text FROM (SELECT indexrelid,
indrelid, indcollation[i] coll FROM pg_index, generate_subscripts(indcollation, 1) g
(i)) s JOIN pg_collation c ON coll=c.oid WHERE collprovider IN ('d', 'c') AND collname
NOT IN ('C', 'POSIX'));\""}
```

For information about the solution, seePostgres Database Index Corruption.

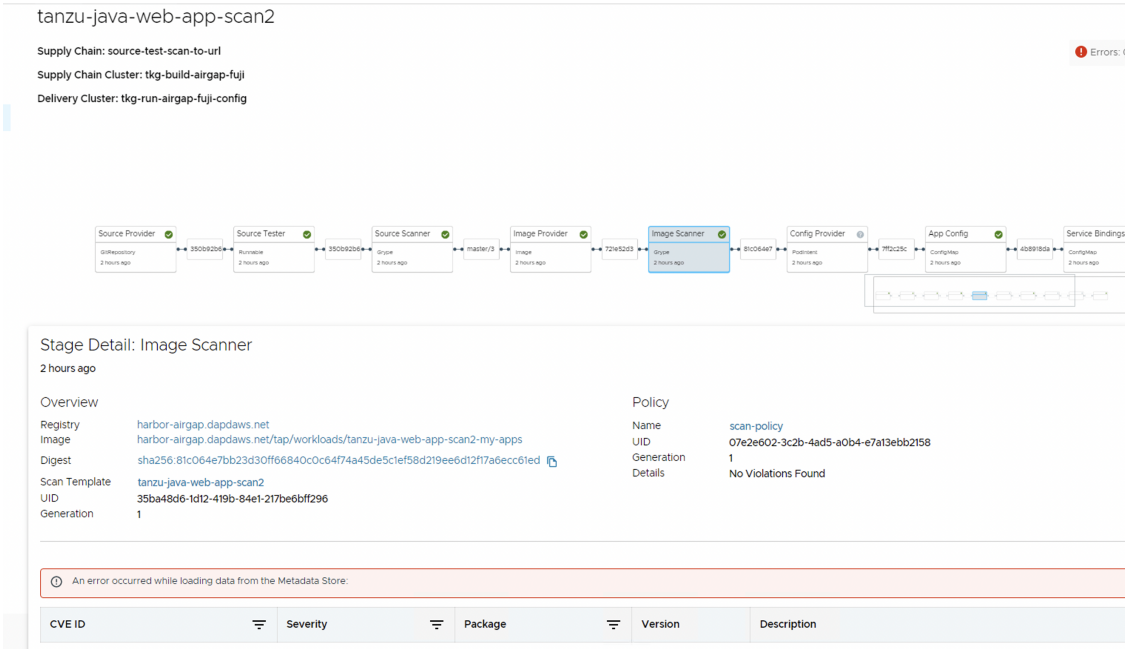
Errors from Tanzu Developer Portal related to SCST - Store

Different Tanzu Developer Portal plug-ins use SCST - Store to display information about vulnerabilities and packages. Some errors visible in Tanzu Developer Portal are related to this connection.

An error occurred while loading data from the Metadata Store

Symptom

In the Supply Chain Choreographer plug-in, you see the error message `An error occurred while loading data from the Metadata Store`.



Cause

There are multiple potential causes. The most common cause is `tap-values.yaml` missing the configuration that enables Tanzu Developer Portal to communicate with Supply Chain Security Tools - Store.

Solution

See Supply Chain Choreographer - Enable CVE scan results for the necessary configuration to add to `tap-values.yaml`. After adding the configuration, update your Tanzu Application Platform deployment or Tanzu Developer Portal deployment with the new values.

Upgrade Supply Chain Security Tools - Store

This topic tells you how to upgrade Supply Chain Security Tools (SCST) - Store and how to troubleshoot upgrade issues.

Upgrading to 1.7 and later

In Tanzu Application Platform v1.7 and later, VMware introduces Artifact Metadata Repository (AMR) to SCST - Store. Tanzu Application Platform installs AMR components by default after upgrading.

How you must configure AMR depends on if:

- Tanzu Application Platform is installed in a single cluster, Full profile, deployment. See Single cluster or Full profile upgrade.
- Tanzu Application Platform is installed in a multicluster deployment. See Multicluster upgrade.

Single cluster or Full profile upgrade

In a Full profile, AMR does not need any additional user configuration. See AMR architecture and deployment details.

Multicluster upgrade

In a multicluster deployment, AMR components are installed on the View, Build and Run clusters. The AMR Observer is installed on the Build and Run clusters, and must be configured to talk to the AMR CloudEvent Handler installed on the View cluster.

Read SCST - Store multicluster setup for the new configuration in detail. The documentation includes instructions for configuring both the new AMR and the existing Metadata Store. The new configurations for 1.7 and later are:

1. Copy AMR CloudEvent Handler CA certificate data from the View cluster
2. Copy AMR CloudEvent Handler edit token from the View cluster
3. Apply the CloudEvent Handler CA certificate data and edit token to the Build and Run clusters

Upgrading AMR Beta to 1.7 and later

This topic is about a special upgrade scenario for AMR: Upgrading from Tanzu Application Platform 1.6 with AMR beta enabled to Tanzu Application Platform v1.7 and later. Because AMR was not enabled by default in Tanzu Application Platform 1.6, most users will not encounter this scenario. See Upgrading from AMR Beta to AMR GA release.

Troubleshoot upgrading

The following sections tell you how to troubleshoot AMR upgrades.

AMR Observer cannot talk to AMR CloudEvent Handler

To see the AMR Observer pod:

```
kubectl get pods -n amr-observer-system
```

To view AMR Observer logs:

```
kubectl logs OBSERVER-POD-NAME -n amr-observer-system
```

Where:

- `OBSERVER-POD-NAME` is the name of the AMR observer pod.

If you encounter errors relating to the authentication token, verify that you configured the AMR Observer correctly. It might be missing the edit token for the AMR CloudEvent Handler. For information about how to configure the edit token, and the CA certificate and endpoint, see SCST - Store multicluster setup.

Database deployment does not exist

To prevent issues with the metadata store database, such as the ones described in this topic, the database deployment is `StatefulSet` in:

- Tanzu Application Platform v1.2 and later
- Metadata Store v1.1 and later

If you have scripts searching for a `metadata-store-db` deployment, edit the scripts to instead search for `StatefulSet`.

Invalid checkpoint record

When you use Tanzu to upgrade SCST - Store, there is occasionally data corruption. For example:

```
PostgreSQL Database directory appears to contain a database; Skipping initialization

2022-01-21 21:53:38.799 UTC [1] LOG:  starting PostgreSQL 13.5 (Ubuntu 13.5-1.pgdg18.0
4+1) on x86_64-pc-linux-gnu, compiled by gcc (Ubuntu 7.5.0-3ubuntu1~18.04) 7.5.0, 64-b
it
2022-01-21 21:53:38.799 UTC [1] LOG:  listening on IPv4 address "0.0.0.0", port 5432
2022-01-21 21:53:38.799 UTC [1] LOG:  listening on IPv6 address "::", port 5432
2022-01-21 21:53:38.802 UTC [1] LOG:  listening on Unix socket "/var/run/postgresql/.
s.PGSQL.5432"
2022-01-21 21:53:38.807 UTC [14] LOG:  database system was shut down at 2022-01-21 21:
21:12 UTC
2022-01-21 21:53:38.807 UTC [14] LOG:  invalid record length at 0/1898BE8: wanted 24,
got 0
2022-01-21 21:53:38.807 UTC [14] LOG:  invalid primary checkpoint record
2022-01-21 21:53:38.807 UTC [14] PANIC:  could not locate a valid checkpoint record
2022-01-21 21:53:39.496 UTC [1] LOG:  startup process (PID 14) was terminated by signa
l 6: Aborted
2022-01-21 21:53:39.496 UTC [1] LOG:  aborting startup due to startup process failure
2022-01-21 21:53:39.507 UTC [1] LOG:  database system is shut down
```

The log shows a database pod in a failure loop. For information about how to fix the issue, see the SysOpsPro documentation.

Upgraded pod stops responding

Because the default access mode in the PVC is `ReadWriteOnce`, if you are deploying in an environment with multiple nodes then each pod might be on a different node. This causes the upgraded pod to spin up but then get stuck initializing because the original pod does not stop. To resolve this issue, find, and delete the original pod so that the new pod can attach to the persistent volume:

1. Discover the name of the app pod that is not in a pending state by running:

   ```
   kubectl get pods -n metadata-store
   ```

2. Delete the pod by running:

   ```
   kubectl delete pod METADATA-STORE-APP-POD-NAME -n metadata-store
   ```

Upgrading from AMR Beta to AMR GA release

This topic tells you how to upgrade from Tanzu Application Platform 1.6 to Tanzu Application Platform 1.7 or later with Artifact Metadata Repository (AMR) beta enabled. Because AMR is not enabled by default in Tanzu Application Platform 1.6, most users will not encounter this scenario. To upgrade without AMR, see Supply Chain Security Tools - Store - Upgrading.

Known issues and workarounds

Because AMR was in beta in Tanzu Application Platform v1.6, there are breaking changes when upgrading to Tanzu Application Platform v1.9. This section lists all the known issues and workarounds.

Configuration Changes

In the AMR Beta release, most of the AMR configurations are in-line with `metadata_store` section inside `values.yaml` file. You must remove `metadata_store.amr` from the `values.yaml` file.

1. Remove `metadata_store.amr` from the values file.

   ```
   metadata_store:
     amr:
       deploy: true
       graphql:
       app_service_type: "ClusterIP"
   ```

2. Remove `amr.deploy_observer: true` from the values file
3. Remove Alias from the `amr.observer.location` configmap

   ```
   location: |
     alias: my-cluster
   ```

Database changes

In the AMR Beta release, the `Alias` field was introduced in the `Location` table. The `Alias` field is removed in Tanzu Application Platform v1.9. To drop this field from Tanzu Application Platform v1.9:

1. Connect to the Postgres database.
2. Run the following SQL command:

```
ALTER TABLE artifact_locations DROP COLUMN IF EXISTS alias;
```

Failover, redundancy, and backups for Supply Chain Security Tools - Store

This topic describes how you can configure and use failover, redundancy, and backups for Supply Chain Security Tools (SCST) - Store.

API Server

By default the API server has 1 replica. If the pod fails, the single instance restarts by normal Kubernetes behavior, but there is downtime. If you upgrade, some downtime is possible.

You can configure the number of replicas by using the `app_replicas` text box in the `scst-store-values.yaml` file.

Database

By default, the database has one replica, and restarts with some downtime if it fails.

Caution

Although you can configure `db_replicas` in `scst-store-values.yaml`, this is discouraged because `db_replicas` is still experimental. The default internal database is not for production use. For production deployments, use an external database.

- Use external postgres database
- AWS RDS postgres configuration

For the default PostgreSQL database deployment, with `deploy_internal_db` set to `true`, you can use `Velero` as the backup method. For information about using `Velero` as the backup method, see Backups.

Custom certificate configuration for Supply Chain Security Tools - Store

This topic describes how you can configure the following certificates for Supply Chain Security Tools (SCST) - Store:

1. Default configuration
2. Custom certificate

Default configuration

By default, SCST - Store creates a self-signed certificate and TLS communication is automatically enabled.

If ingress support is enabled, SCST - Store installation creates an HTTPProxy entry with host routing by using the qualified name `metadata-store.<ingress_domain>`. For example, `metadata-store.example.com`. The created route supports HTTPS communication using the self-signed certificate with the same subject `Alternative Name`.

(Optional) Setting up custom ingress TLS certificate

(Optional) Users can configure TLS to use a custom certificate. To do that:

1. Place the certificates in the secret.
2. Edit the `tap-values.yaml` to use this secret.

Place the certificates in secret

1. Create the certificate secret before deploying SCST - Store.
2. Create a Kubernetes object with kind `Secret` and type `kubernetes.io/tls`.

Update `tap-values.yaml`

1. In the `tap-values.yaml` file, you can configure the metadata store to use the `namespace` and `secretName` from the secret created in the last step.

```
metadata_store:
  tls:
    namespace: "namespace"
    secretName: "secretName"
```

Where:

- `namespace` is the targeted namespace for secret consumption by the HTTPProxy.
- `secretName` is the name of secret for consumption by the HTTPProxy.

Additional resources

- Ingress support
- TLS configuration

TLS configuration for Supply Chain Security Tools - Store

This topic describes how you can configure TLS for Supply Chain Security Tools (SCST) - Store.

Important

SCST - Store only supports TLS v1.2.

Setting up custom ingress TLS ciphers

In the `tap-values.yaml` file, `tls.server.rfcCiphers` are set as shown in the following YAML:

```
metadata_store:
  tls:
    server:
      rfcCiphers:
        - TLS_AES_128_GCM_SHA256
        - TLS_AES_256_GCM_SHA384
        - TLS_ECDHE_ECDSA_WITH_AES_128_GCM_SHA256
        - TLS_ECDHE_ECDSA_WITH_AES_256_GCM_SHA384
        - TLS_ECDHE_RSA_WITH_AES_128_GCM_SHA256
        - TLS_ECDHE_RSA_WITH_AES_256_GCM_SHA384
```

Where `tls.server.rfcCiphers` is a list of cipher suites for the server. Values are from the Go TLS package constants. If you omit values, the default Go cipher suites are used. These are the default values:

- `TLS_AES_128_GCM_SHA256`
- `TLS_AES_256_GCM_SHA384`
- `TLS_ECDHE_ECDSA_WITH_AES_128_GCM_SHA256`
- `TLS_ECDHE_ECDSA_WITH_AES_256_GCM_SHA384`
- `TLS_ECDHE_RSA_WITH_AES_128_GCM_SHA256`
- `TLS_ECDHE_RSA_WITH_AES_256_GCM_SHA384`

Example custom TLS settings

The following is a complete example of TLS configuration:

```
metadata_store:
  tls:
    namespace: NAMESPACE
    secretName: SECRET-NAME
    server:
      rfcCiphers:
        - TLS_AES_128_GCM_SHA256
        - TLS_AES_256_GCM_SHA384
        - TLS_ECDHE_ECDSA_WITH_AES_128_GCM_SHA256
        - TLS_ECDHE_ECDSA_WITH_AES_256_GCM_SHA384
        - TLS_ECDHE_RSA_WITH_AES_128_GCM_SHA256
        - TLS_ECDHE_RSA_WITH_AES_256_GCM_SHA384
```

Where:

- `NAMESPACE` is the name of the namespace you want to configure TLS with.
- `SECRET-NAME` is the name of the secret you want to configure TLS with.

Additional resources

- Custom certificate configuration
- Ingress support

Certificate rotation for Supply Chain Security Tools - Store

This topic describes how you can rotate TLS certificates for Supply Chain Security Tools (SCST) - Store.

Certificates

By default, the `use_cert_manager` setting is set to `"true"`. When the setting `use_cert_manager` is `"true"` the Store uses `cert-manager` to generate a CA certificate, an API certificate, and a database Certificate.

To see these certificates:

```
$ kubectl get certificate -n metadata-store
NAME                    READY   SECRET                  AGE
app-tls-ca-cert         True    app-tls-ca-cert         38d
```

```
app-tls-cert             True    app-tls-cert             38d
postgres-db-tls-cert     True    postgres-db-tls-cert     38d
```

The earlier certificates are automatically rotated by `cert-manager`.

The Store can run these certificates automatically once `cert-manager` rotates them.

If the environment is a multi-cluster setup, the operator must manually copy over the new CA certificate to the build cluster.

Certificate duration setting

In the `tap-values.yaml` file, `api_cert_duration`, `api_cert_renew_before`, `ca_cert_duration`, and `ca_cert_renew_before` are configurable as shown in the following YAML:

```
metadata_store:
  ca_cert_duration: CA-DURATION
  ca_cert_renew_before: CA-RENEW
  api_cert_duration: API-DURATION
  api_cert_renew_before: API-RENEW
```

Where:

- `CA-DURATION` is the duration that the ca certificate is valid for. Must be given in `h`, `m`, or `s`. Default value is 8760h.
- `CA-RENEW` is how long before the expiry of the ca certificate is renewed. Must be given in `h`, `m`, or `s`. Default value is 1h.
- `API-DURATION` is the duration that the API certificate is valid for. Must be given in `h`, `m`, or `s`. Default value is 2160h.
- `API-RENEW` is how long before the expiry of the API certificate is renewed. Must be given in h, m, or s. Default value is 24h.

Important

The `*_cert_duration` and the corresponding `*_renew_before` settings must not be close. For more information, see the cert-manager documentation. This can lead to a renewal loop. The `*_cert_duration` must be greater than the corresponding `*_renew_before`. The earlier settings only take effect when `use_cert_manager` is `"true"`. If the `use_cert_manager` is not set, it defaults to `"true"`.

Ingress support for Supply Chain Security Tools - Store

This topic describes how to configure ingress for Supply Chain Security Tools (SCST) - Store.

Ingress configuration

Supply Chain Security Tools (SCST) - Store has ingress support by using Contour's HTTPProxy resources. To enable ingress support, a Contour installation must be available in the cluster.

To change ingress configuration, edit your `tap-values.yaml` when you install a Tanzu Application Platform profile. When you configure the `shared.ingress_domain` property, SCST - Store automatically uses that setting.

Alternatively, you can customize SCST - Store's configuration under the `metadata_store` property. Under `metadata_store`, there are two values to configure the proxy:

- `ingress_enabled`
- `ingress_domain`

This is an example snippet in a `tap-values.yaml`:

```
...
metadata_store:
  ingress_enabled: "true"
  ingress_domain: "example.com"
  app_service_type: "ClusterIP"  # Defaults to `LoadBalancer`. If ingress is enabled t
hen this must be set to `ClusterIP`.
...
```

SCST - Store installation creates an HTTPProxy entry with host routing by using the qualified name `METADATA-STORE.INGRESS-DOMAIN`. For example, `metadata-store.example.com`. The route supports HTTPS communication using a certificate. By default, a self-signed certificate is used with the same subject `alternative name`. For more information, see Custom certificate configuration.

Contour and DNS setup are not part of SCST - Store installation. Access to SCST - Store using Contour depends on the correct configuration of these two components.

Make the proper DNS record available to clients to resolve `metadata-store` and set `ingress_domain` to Envoy service's external IP address.

DNS setup example:

```
$ kubectl describe svc envoy -n tanzu-system-ingress
> ...
  Type:                     LoadBalancer
  ...
  LoadBalancer Ingress:     100.2.3.4
  ...
  Port:                     https  443/TCP
  ...

$ nslookup metadata-store.example.com
> Server:    8.8.8.8
  Address:  8.8.8.8#53

  Non-authoritative answer:
  Name:  metadata-store.example.com
  Address: 100.2.3.4

$ curl https://metadata-store.example.com/api/health -k -v
> ...
  < HTTP/2 200
  ...
```

Note

The preceding `curl` example uses the not secure `-k` flag to skip TLS verification because the Store installs a self-signed certificate. The following section shows how to access the CA certificate to enable TLS verification for HTTP clients.

Get the TLS CA certificate

To get SCST - Store's TLS CA certificate, use `kubectl get secret`. In this example, you save the certificate for the environment variable to a file.

```
kubectl get secret CERT-NAME -n metadata-store -o json | jq -r '.data."ca.crt"' | base
64 -d > OUTPUT-FILE
```

Where:

- `CERT-NAME` is the name of the certificate. This must be `ingress-cert` if no custom certificate is used.
- `OUTPUT-FILE` is the file you want to create to store the certificate.

For example:

```
$ kubectl get secret tap-ingress-selfsigned-root-ca -n cert-manager -o json | jq -r '.
data."ca.crt"' | base64 -d > insight-ca.crt
$ cat insight-ca.crt
```

Additional Resources

- Custom certificate configuration
- TLS configuration
- Certificate rotation
- Configure target endpoint and certificate

Use your LoadBalancer with Supply Chain Security Tools - Store

This topic describes how to use your LoadBalancer with Supply Chain Security Tools (SCST) - Store.

Configure LoadBalancer

Note

`LoadBalancer` is not the recommended service type. Consider the recommended configuration of enabling Ingress.

To configure a `LoadBalancer`:

1. Edit `/etc/hosts/` to use the external IP address of the `metadata-store-app` service.

   ```
   METADATA_STORE_IP=$(kubectl get service/metadata-store-app --namespace metadata
   -store -o jsonpath="{.status.loadBalancer.ingress[0].ip}")
   METADATA_STORE_PORT=$(kubectl get service/metadata-store-app --namespace metada
   ta-store -o jsonpath="{.spec.ports[0].port}")
   METADATA_STORE_DOMAIN="metadata-store-app.metadata-store.svc.cluster.local"

   # Delete any previously added entry
   sudo sed -i '' "/$METADATA_STORE_DOMAIN/d" /etc/hosts

   echo "$METADATA_STORE_IP $METADATA_STORE_DOMAIN" | sudo tee -a /etc/hosts > /de
   v/null
   ```

   Note

   On EKS, you must get the IP address for the LoadBalancer. Find the IP address by running something similar to the following: `dig RANDOM-SHA.us-`

east-2.elb.amazonaws.com. Where RANDOM-SHA is the EXTERNAL-IP received for the LoadBalancer.

2. Select one of the IP addresses returned from the dig command and write it to the /etc/hosts file.

Port forwarding

If you want to use port forwarding instead of the external IP address from the LoadBalancer, follow these steps:

Configure port forwarding for the service so the insight plug-in can access SCST - Store. Run:

```
kubectl port-forward service/metadata-store-app 8443:8443 -n metadata-store
```

Note: You must run the port forwarding command in a separate terminal window, or run the command in the background: kubectl port-forward service/metadata-store-app 8443:8443 -n metadata-store &

Edit your /etc/hosts file for Port Forwarding

Use the following script to add a new local entry to /etc/hosts:

```
METADATA_STORE_PORT=$(kubectl get service/metadata-store-app --namespace metadata-stor
e -o jsonpath="{.spec.ports[0].port}")
METADATA_STORE_DOMAIN="metadata-store-app.metadata-store.svc.cluster.local"

# delete any previously added entry
sudo sed -i '' "/$METADATA_STORE_DOMAIN/d" /etc/hosts

echo "127.0.0.1 $METADATA_STORE_DOMAIN" | sudo tee -a /etc/hosts > /dev/null
```

Configure the Insight plug-in

Because you deployed Supply Chain Security Tools (SCST) - Store without using Ingress, you must use the Certificate resource app-tls-cert for HTTPS communication.

To get the CA Certificate:

```
kubectl get secret app-tls-cert -n metadata-store -o json | jq -r '.data."ca.crt"' | b
ase64 -d > insight-ca.crt
```

Set the target by running:

```
tanzu insight config set-target https://$METADATA_STORE_DOMAIN:$METADATA_STORE_PORT --
ca-cert insight-ca.crt
```

Important

The tanzu insight config set-target does not initiate a test connection. Use tanzu insight health to test connecting using the configured endpoint and CA certificate. Neither commands test whether the access token is correct. For that you must use the plug-in to add data and query data.

Use your NodePort with Supply Chain Security Tools - Store

This topic describes how you can use your NodePort with Supply Chain Security Tools (SCST) - Store.

Overview

Note

The recommended service type is Ingress. NodePort is only recommended when the cluster does not support Ingress or the cluster does not support the LoadBalancer service type. `NodePort` is not supported for a multicluster setup, as certificates cannot be modified.

You must use port forwarding when using the `NodePort` configuration.

Configure port forwarding for the service so the insight plug-in can access SCST - Store. Run:

```
kubectl port-forward service/metadata-store-app 8443:8443 -n metadata-store
```

Note: You must run the port forwarding command in a separate terminal window, or run the command in the background: `kubectl port-forward service/metadata-store-app 8443:8443 -n metadata-store &`

Edit your `/etc/hosts` file for Port Forwarding

Use the following script to add a new local entry to `/etc/hosts`:

```
METADATA_STORE_PORT=$(kubectl get service/metadata-store-app --namespace metadata-stor
e -o jsonpath="{.spec.ports[0].port}")
METADATA_STORE_DOMAIN="metadata-store-app.metadata-store.svc.cluster.local"

# delete any previously added entry
sudo sed -i '' "/$METADATA_STORE_DOMAIN/d" /etc/hosts

echo "127.0.0.1 $METADATA_STORE_DOMAIN" | sudo tee -a /etc/hosts > /dev/null
```

Configure the Insight plug-in

Because you deployed Supply Chain Security Tools (SCST) - Store without using Ingress, you must use the Certificate resource `app-tls-cert` for HTTPS communication.

To get the CA Certificate:

```
kubectl get secret app-tls-cert -n metadata-store -o json | jq -r '.data."ca.crt"' | b
ase64 -d > insight-ca.crt
```

Set the target by running:

```
tanzu insight config set-target https://$METADATA_STORE_DOMAIN:$METADATA_STORE_PORT --
ca-cert insight-ca.crt
```

Important

> The `tanzu insight config set-target` does not initiate a test connection. Use `tanzu insight health` to test connecting using the configured endpoint and CA certificate. Neither commands test whether the access token is correct. For that you must use the plug-in to add data and query data.

Developer namespace setup for Supply Chain Security Tools - Store

This topic describes how you can set up your developer namespace for Supply Chain Security Tools (SCST) - Store.

Overview

After you finish the entire Tanzu Application Platform installation process, you are ready to configure the developer namespace. When you configure a developer namespace, you must export the Supply Chain Security Tools (SCST) - Store CA certificate and authentication token to the namespace. This enables SCST - Scan to find the credentials to send scan results to SCST - Store.

There are two ways to deploy Tanzu Application Platform:

- Single cluster, which entails using the Tanzu Application Platform values file
- Multicluster, which entails using `SecretExport`

Single cluster - Using the Tanzu Application Platform values file

When deploy the Tanzu Application Platform Full or Build profile, edit the `tap-values.yaml` file you used to deploy Tanzu Application Platform.

```
metadata_store:
  ns_for_export_app_cert: "DEV-NAMESPACE"
```

Where `DEV-NAMESPACE` is the name of the developer namespace.

The `ns_for_export_app_cert` supports one namespace at a time. If you have multiple namespaces you can replace this value with a `"*"`, but this exports the CA to all namespaces. Consider whether this increased visibility presents a risk.

```
metadata_store:
  ns_for_export_app_cert: "*"
```

Update Tanzu Application Platform to apply the changes by running:

```
$ tanzu package installed update tap -f tap-values.yaml -n tap-install
```

Multicluster - Using `SecretExport`

In a multicluster deployment, follow the steps in Multicluster setup. It describes how to create secrets and export secrets to developer namespaces.

Next steps

If you arrived in this topic from Setting up the Out of the Box Supply Chain with testing and scanning, return to that topic and continue with the instructions.

Retrieve access tokens for Supply Chain Security Tools - Store

This topic describes how you can retrieve access tokens for Supply Chain Security Tools (SCST) - Store.

Overview

When you install Tanzu Application Platform, the Supply Chain Security Tools (SCST) - Store deployment automatically includes a read-write service account. This service account is bound to the `metadata-store-read-write` role.

There are two types of SCST - Store service accounts:

1. Read-write service account - full access to the `POST` and `GET` API requests
2. Read-only service account - can only use `GET` API requests

This topic shows how to retrieve the access token for these service accounts.

Retrieving the read-write access token

To retrieve the read-write access token, run:

```
kubectl get secrets metadata-store-read-write-client -n metadata-store -o jsonpath="{.data.token}" | base64 -d
```

Retrieving the read-only access token

In order retrieve the read-only access token, you must first have a read-only service account. See Create read-only service account.

To retrieve the read-only access token, run:

```
kubectl get secrets metadata-store-read-client -n metadata-store -o jsonpath="{.data.token}" | base64 -d
```

Using an access token

The access token is a Bearer token used in the http request header `Authorization`. For example, `Authorization: Bearer eyJhbGciOiJSUzI1NiIsImtpZCI6IjhMV0....`

Additional Resources

- Create service accounts
- Create a service account with a custom cluster role

Retrieve and create service accounts for Supply Chain Security Tools - Store

This topic explains how you can create service accounts for Supply Chain Security Tools (SCST) - Store.

Overview

When you install Tanzu Application Platform, the Supply Chain Security Tools (SCST) - Store deployment automatically includes a read-write service account. This service account is bound to the `metadata-store-read-write` role.

There are two types of SCST - Store service accounts:

1. Read-write service account - full access to the `POST` and `GET` API requests
2. Read-only service account - can only use `GET` API requests

Create read-write service account

When you install Tanzu Application Platform, the SCST - Store deployment automatically includes a read-write service account. This service account is already bound to the `metadata-store-read-write` role.

To create an additional read-write service account, run the following command. The command creates a service account called `metadata-store-read-write-client`:

```
kubectl apply -f - -o yaml << EOF
apiVersion: rbac.authorization.k8s.io/v1
kind: Role
metadata:
  name: metadata-store-read-write
  namespace: metadata-store
rules:
- resources: ["all"]
  verbs: ["get", "create", "update"]
  apiGroups: [ "metadata-store/v1" ]
---
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: metadata-store-read-write
  namespace: metadata-store
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: Role
  name: metadata-store-read-write
subjects:
- kind: ServiceAccount
  name: metadata-store-read-write-client
  namespace: metadata-store
---
apiVersion: v1
kind: ServiceAccount
metadata:
  name: metadata-store-read-write-client
  namespace: metadata-store
  annotations:
    kapp.k14s.io/change-group: "metadata-store.apps.tanzu.vmware.com/service-account"
automountServiceAccountToken: false
---
apiVersion: v1
kind: Secret
type: kubernetes.io/service-account-token
metadata:
  name: metadata-store-read-write-client
  namespace: metadata-store
  annotations:
    kapp.k14s.io/change-rule: "upsert after upserting metadata-store.apps.tanzu.vmwar
e.com/service-account"
```

```
    kubernetes.io/service-account.name: "metadata-store-read-write-client"
EOF
```

Create a read-only service account

You can create a read-only service account with a default cluster role or with a custom cluster role.

With a default cluster role

During Store installation, the `metadata-store-read-only` cluster role is created by default. This cluster role allows the bound user to have `get` access to all resources. To bind to this cluster role, run the following command:

```
kubectl apply -f - -o yaml << EOF
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: metadata-store-read-only
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: metadata-store-read-only
subjects:
- kind: ServiceAccount
  name: metadata-store-read-client
  namespace: metadata-store
---
apiVersion: v1
kind: ServiceAccount
metadata:
  name: metadata-store-read-client
  namespace: metadata-store
  annotations:
    kapp.k14s.io/change-group: "metadata-store.apps.tanzu.vmware.com/service-account"
automountServiceAccountToken: false
---
apiVersion: v1
kind: Secret
type: kubernetes.io/service-account-token
metadata:
  name: metadata-store-read-client
  namespace: metadata-store
  annotations:
    kapp.k14s.io/change-rule: "upsert after upserting metadata-store.apps.tanzu.vmwar
e.com/service-account"
    kubernetes.io/service-account.name: "metadata-store-read-client"
EOF
```

With a custom cluster role

If using the default role is not sufficient, see Create a service account with a custom cluster role.

Additional Resources

- Retrieve access tokens
- Create a service account with a custom cluster role

Create a service account with a custom cluster role for Supply Chain Security Tools - Store

This topic describes how you can create a service account with a custom cluster role for Supply Chain Security Tools (SCST)- Store.

Example service account

If you do not want to bind to the default cluster role, create a read-only role in the `metadata-store` namespace with a service account. The following example creates a service account named `metadata-store-read-client`:

```
kubectl apply -f - -o yaml << EOF
apiVersion: rbac.authorization.k8s.io/v1
kind: Role
metadata:
  name: metadata-store-ro
  namespace: metadata-store
rules:
- resources: ["all"]
  verbs: ["get"]
  apiGroups: [ "metadata-store/v1" ]
---
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: metadata-store-ro
  namespace: metadata-store
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: Role
  name: metadata-store-ro
subjects:
- kind: ServiceAccount
  name: metadata-store-read-client
  namespace: metadata-store
---
apiVersion: v1
kind: ServiceAccount
metadata:
  name: metadata-store-read-client
  namespace: metadata-store
  annotations:
    kapp.k14s.io/change-group: "metadata-store.apps.tanzu.vmware.com/service-account"
automountServiceAccountToken: false
---
apiVersion: v1
kind: Secret
type: kubernetes.io/service-account-token
metadata:
  name: metadata-store-read-client
  namespace: metadata-store
  annotations:
    kapp.k14s.io/change-rule: "upsert after upserting metadata-store.apps.tanzu.vmwar
e.com/service-account"
    kubernetes.io/service-account.name: "metadata-store-read-client"
EOF
```

Additional Resources

- Retrieve access tokens

- Create service accounts

Install Supply Chain Security Tools - Store

This topic describes how you can install Supply Chain Security Tools (SCST) - Store independently from Tanzu Application Platform (commonly known as TAP) profiles.

Note

Follow the steps in this topic if you do not want to use a profile to install Supply Chain Security Tools - Store. For more information about profiles, see Components and installation profiles.

Prerequisites

Before installing SCST - Store from the Tanzu Application Platform package repository:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- Install cert-manager on the cluster. See Install cert-manager.
- See Deployment Details and Configuration to review what resources are deployed. For more information, see the overview.
- Create ClusterIssuer

```
kubectl apply -f - <<EOF
apiVersion: cert-manager.io/v1
  kind: ClusterIssuer
  metadata:
    name: tap-ingress-selfsigned
  spec:
    selfSigned: {}
EOF
```

Install

To install SCST - Store:

1. To use this deployment, the user must have set up the Kubernetes cluster to provision persistent volumes on demand. Ensure that a default storage class is available in your cluster. Verify whether default storage class is set in your cluster using `kubectl get storageClass`.

   ```
   kubectl get storageClass
   ```

   For example:

   ```
   $ kubectl get storageClass
   NAME                 PROVISIONER             RECLAIMPOLICY   VOLUMEBINDINGMODE
   ALLOWVOLUMEEXPANSION   AGE
   standard (default)   rancher.io/local-path   Delete          WaitForFirstConsum
   er   false                  7s
   ```

2. List version information for the package using `tanzu package available list`.

```
tanzu package available list metadata-store.apps.tanzu.vmware.com --namespace t
ap-install
```

For example:

```
$ tanzu package available list metadata-store.apps.tanzu.vmware.com --namespace
tap-install
- Retrieving package versions for metadata-store.apps.tanzu.vmware.com...
  NAME                          VERSION       RELEASED-AT
  metadata-store.apps.tanzu.vmware.com  1.0.2
```

3. (Optional) List all the available deployment configuration options.

```
tanzu package available get metadata-store.apps.tanzu.vmware.com/VERSION --valu
es-schema -n tap-install
```

Where `VERSION` is the your package version number.

For example:

```
$ tanzu package available get metadata-store.apps.tanzu.vmware.com/1.0.2 --valu
es-schema -n tap-install
| Retrieving package details for metadata-store.apps.tanzu.vmware.com/1.0.2...
  KEY                             DEFAULT
TYPE     DESCRIPTION
  pg_limit_memory                 4Gi
string   Memory limit for postgres container in metadata-store-db deployment
  tls.namespace
string   The targeted namespace for secret consumption by the HTTPProxy.
  add_default_rw_service_account  true
string   Adds a read-write service account which can be used to obtain access t
oken to use metadata-store CLI
  api_host                        localhost
string   The internal hostname for the metadata api endpoint. This will be used
by the kube-rbac-proxy sidecar.
  app_replicas                    1
integer  The number of replicas for the metadata-store-app
  ingress_domain
string   Domain to be used by the HTTPProxy ingress object. The "metadata-stor
e" subdomain will be prepended to the value provided. For example: "example.co
m" would become "metadata-store.example.com". Required if ingress_enabled is tr
ue.
  kube_rbac_proxy_limit_cpu       250m
string   CPU limit for kube-rbac-proxy container in the metadata-store-app depl
oyment
  pg_limit_cpu                    2Gi
string   CPU limit for postgres container in metadata-store-db deployment
  tls.server.minTLSVersion        VersionTLS12
string   Minimum TLS version supported. Value must match version names from htt
ps://golang.org/pkg/crypto/tls/#pkg-constants. (default "VersionTLS12")
  db_host                         metadata-store-db
string   The address to the postgres database host that the metadata-store app
uses to connect. The default is set to metadata-store-db which is the postgres
service name. Changing this does not change the postgres service name
  db_replicas                     1
integer  The number of replicas for the metadata-store-db
  pg_req_cpu                      1Gi
string   CPU request for postgres container in metadata-store-db deployment
  priority_class_name
string   If specified, this value is the name of the desired PriorityClass for
the metadata-store-db deployment
  tls.secretName
string   The name of secret for consumption by the HTTPProxy.
  db_ca_certificate
```

```
string   This should only be set in the case when 'deploy_internal_db' is 'fals
e'. Set this to the trusted CA Certificate that signed the Postgres DB TLS Cert
ificate
  db_password
string   The database user password. If no value is provided, a 32 character va
lue will be generated.
  db_port                         5432
string   The database port to use. This is the port to use when connecting to t
he database pod.
  app_limit_cpu                   250m
string   CPU limit for metadata-store-app container
  auth_proxy_host                 0.0.0.0
string   The binding ip address of the kube-rbac-proxy sidecar
  db_max_open_conns               10
integer  Sets the maximum number of open database connections from the Metadata
Store to the database.
  db_name                         metadata-store
string   The name of the database to use.
  db_user                         metadata-store-user
string   The database user to create and use for updating and querying. The met
adata postgres section create this user. The metadata api server uses this user
name to connect to the database.
  kube_rbac_proxy_req_memory      128Mi
string   Memory request for kube-rbac-proxy container in the metadata-store-app
deployment
  auth_proxy_port                 8443
integer  The external port address of the of the kube-rbac-proxy sidecar
  db_conn_max_lifetime            60
integer  Sets the maximum amount of time a database connection may be reused in
seconds.
  ingress_enabled                 false
string   Contour is required to be installed to use this flag. When true, this
creates an HTTPProxy object for the metadata-store. If false, then no ingress i
s configured.
  storage_class_name
string   The storage class name of the persistent volume used by Postgres datab
ase for storing data. The default value will use the default class name defined
on the cluster.
  api_port                        9443
integer  The internal port for the metadata app api endpoint. This will be used
by the kube-rbac-proxy sidecar.
  app_service_type                LoadBalancer
string   The type of service to use for the metadata app service. This can be s
et to 'Nodeport', 'ClusterIP' or 'LoadBalancer'.
  db_sslmode                      verify-full
string   Determines the security connection between API server and Postgres dat
abase. This can be set to 'verify-ca' or 'verify-full'
  use_cert_manager                true
string   Cert manager is required to be installed to use this flag. When true,
this creates certificates object to be signed by cert manager for the API serve
r and Postgres database. If false, the certificate object have to be provided b
y the user.
  app_req_cpu                     100m
string   CPU request for metadata-store-app container
  database_request_storage        10Gi
string   The storage requested of the persistent volume used by Postgres databa
se for storing data.
  deploy_internal_db              true
string   If set to 'true', a postgres deployment will be created. If set to 'fa
lse', db_host and db_port should point to an accessible postgres instance. Post
gres connections require TLS, so the corresponding db_ca_certification must be
provided
  kube_rbac_proxy_req_cpu         100m
string   CPU request for kube-rbac-proxy container in the metadata-store-app de
ployment
  ns_for_export_app_cert          scan-link-system
```

```
string   The namespace where the "Supply Chain Security Tools for VMware Tanzu
- Scan" component is installed in. Certain certificates will be exported to tha
t namespace so that scan reports can be posted to the Metadata Store.
  pg_req_memory                  1Gi
string   Memory request for postgres container in metadata-store-db deployment
  app_limit_memory               512Mi
string   Memory limit for metadata-store-app container
  app_req_memory                 128Mi
string   Memory request for metadata-store-app container
  db_max_idle_conns              100
integer  Sets the maximum number of database connections from the Metadata Stor
e in the idle connection pool.
  kube_rbac_proxy_limit_memory   512Mi
string   Memory limit for kube-rbac-proxy container in the metadata-store-app d
eployment
  kubernetes_distribution
string   Kubernetes platform distribution where the metadata-store is being ins
talled on. Accepted values: ["", "openshift"]
  log_level                      default
string   Sets the log level. This can be set to "minimum", "less", "default",
"more", "debug" or "trace". "minimum" currently does not output logs. "less" ou
tputs log configuration options only. "default" and "more" outputs API endpoint
access information. "debug" and "trade" outputs extended API endpoint

access information(such as body payload) and other debug information.
  tls.server.rfcCiphers          [TLS_AES_128_GCM_SHA256 TLS_AES_256_GCM_SHA38
4 TLS_ECDHE_ECDSA_WITH_AES_128_GCM_SHA256 TLS_ECDHE_ECDSA_WITH_AES_256_GCM_SHA3
84 TLS_ECDHE_RSA_WITH_AES_128_GCM_SHA256 TLS_ECDHE_RSA_WITH_AES_256_GCM_SHA384]
array    List of cipher suites for the server. Values are from tls package cons
tants (https://golang.org/pkg/crypto/tls/#pkg-constants). If omitted, the defau
lt Go cipher suites will be used
  ingress_issuer                 tap-ingress-selfsigned
string   tap-ingress-selfsigned is the default value when installed via any TAP
profile. When installing only the metadata-store package, a ClusterIssuer needs
to be installed and its name needs to be specified as this value.
```

4. (Optional) Edit one of the deployment configurations by creating a configuration YAML with the custom configuration values you want. For example, if your environment does not support `LoadBalancer`, and you want to use `ClusterIP`, then create a `metadata-store-values.yaml` and configure the `app_service_type` property.

   ```
   ---
   app_service_type: "ClusterIP"
   ```

   See Deployment details and configuration for more information about configuration options.

   For information about ingress and custom domain name support, see Ingress support.

5. Install the package using `tanzu package install`.

   ```
   tanzu package install metadata-store \
     --package metadata-store.apps.tanzu.vmware.com \
     --version VERSION \
     --namespace tap-install \
     --values-file metadata-store-values.yaml
   ```

   Where:

   - `--values-file` is an optional flag. Only use it to customize the deployment configuration.
   - `VERSION` is the package version number.

   For example:

```
$ tanzu package install metadata-store \
  --package metadata-store.apps.tanzu.vmware.com \
  --version 1.0.2 \
  --namespace tap-install \
  --values-file metadata-store-values.yaml

- Installing package 'metadata-store.apps.tanzu.vmware.com'
/ Getting namespace 'tap-install'
- Getting package metadata for 'metadata-store.apps.tanzu.vmware.com'
/ Creating service account 'metadata-store-tap-install-sa'
/ Creating cluster admin role 'metadata-store-tap-install-cluster-role'
/ Creating cluster role binding 'metadata-store-tap-install-cluster-rolebindin
g'
/ Creating secret 'metadata-store-tap-install-values'
| Creating package resource
- Package install status: Reconciling

Added installed package 'metadata-store' in namespace 'tap-install'
```

Prerequisite for Standalone SCST - Store

The following prerequisites are required to install SCST - Store individually, instead of using a profile:

- Install the SelfSigned Cluster Issuer:

```
# Install `tap-ingress-selfsigned` ClusterIssuer
cat << EOF > /tmp/tap-ingress-selfsigned-cluster-issuer.yaml
apiVersion: cert-manager.io/v1
kind: ClusterIssuer
metadata:
name: tap-ingress-selfsigned
spec:
selfSigned: {}
EOF

kapp deploy -a issuer -f /tmp/tap-ingress-selfsigned-cluster-issuer.yaml -y
```

- Install `SCST - Store` and update the certificate:

```
cat << EOF > /tmp/ingress-issuer-cert.yaml
apiVersion: cert-manager.io/v1
kind: Certificate
metadata:
name: ingress-cert
namespace: metadata-store
spec:
isCA: true
dnsNames:
  - metadata-store.${INGRESS_DOMAIN}
issuerRef:
  kind: ClusterIssuer
  name: tap-ingress-selfsigned
  group: cert-manager.io
secretName: ingress-cert
commonName: metadata-store-ca
EOF
kubectl apply -f /tmp/ingress-issuer-cert.yaml
# `ingress-cert` is deleted. It will be automatically created again with newly
applied ClusterIssuer cert
kubectl delete secret ingress-cert -n metadata-store
```

These steps ensure that you have valid certificate after `SCST-Store` installation is complete.

Supply Chain Security Tools - Store Database Index Corruption

This topic tells you how to troubleshoot the Metadata Store Database index issue after upgrading from v1.5 to a higher version for Supply Chain Security Tools (SCST) - Store.

Overview

The index corruption happened due to a base OS upgrade in our PostgreSQL Database images to address some of the CVE which includes a breaking change in `glibc locale` library.

- Tanzu Application Platform v1.5 and before: `Postgres-bionic-13:1.22.0` uses `ubuntu:18.04` which includes `ubuntu/glibc 2.27-3ubuntu1.6`.
- Tanzu Application Platform v1.6 and later: `Postgres-bionic-13:1.23.0` uses `ubuntu:22.04`, `jammy, jammy-20221101`, which includes `ubuntu/glibc 2.35-0ubuntu3.1`.

`glibc v2.28` includes a major update to the locale data, which can potentially corrupt indexes after upgrade. For more information, see the postgreSQL wiki.

Database Index Corruption issue reported in Metadata Store App Container logs

Symptom

The Metadata Store can't reconcile because the Metadata Store pod complains about a potential database index corruption issue.

```
kubectl logs metadata-store-app-pod_name -n metadata-store
```

Output

```
{"level":"error","ts":"2023-08-15T16:38:31.528115988Z","logger":"MetadataStore","ms
g":"unable to check index corruption since user is not a superuser to perform \"CREATE
EXTENSION amcheck\". Please create this extension and check for index corruption using
following sql command \"SELECT bt_index_check(oid) FROM pg_class WHERE relname in (SEL
ECT indexrelid::regclass::text FROM (SELECT indexrelid, indrelid, indcollation[i] coll
FROM pg_index, generate_subscripts(indcollation, 1) g(i)) s JOIN pg_collation c ON col
l=c.oid WHERE collprovider IN ('d', 'c') AND collname NOT IN ('C', 'POSIX'));\"","host
name":"metadata-store-app-77c9fb59c8-qplxt"}
{"level":"error","ts":"2023-08-15T16:38:31.528139637Z","logger":"MetadataStore","ms
g":"Found corrupted database indexes but unable to fix them","hostname":"metadata-stor
e-app-77c9fb59c8-qplxt","error":"unable to check index corruption since user is not a
superuser to perform \"CREATE EXTENSION amcheck\". Please create this extension and ch
eck for index corruption using following sql command \"SELECT bt_index_check(oid) FROM
pg_class WHERE relname in (SELECT indexrelid::regclass::text FROM (SELECT indexrelid,
indrelid, indcollation[i] coll FROM pg_index, generate_subscripts(indcollation, 1) g
(i)) s JOIN pg_collation c ON coll=c.oid WHERE collprovider IN ('d', 'c') AND collname
NOT IN ('C', 'POSIX'));\""}
```

Solutions

There are several ways to address this issue, including upgrading Tanzu Application Platform with updated schema values to connect to the PostgreSQL database directly and fixing the index manually. The following alternative approaches are below:

- Edit `auto_correct_db_indexes` property to true in `tap-values.yaml`

- Connect to the Metadata Store database with the same account used by the Metadata Store API
- Connect to the Metadata Store database with a superuser account and manually fix the index

Edit `auto_correct_db_indexes` property to true in `tap-values.yaml`

1. To change `auto_correct_db_indexes`, edit your `tap-values.yaml` and upgrade the Tanzu Application Platform profile. Change the property `auto_correct_db_indexes` value to `true`.
2. Upgrade Tanzu Application Platform.

   ```
   tanzu package installed update tap -p tap.tanzu.vmware.com -v {{ vars.tap_versi
   on }}  --values-file tap-values.yaml -n tap-install
   ```

3. Examine the Metadata Store API logs. You should not see any errors.

Connect to the Metadata Store database with same account used by Metadata Store API

1. Connect to the Postgres Database.
2. Run this SQL to re-index individual tables.

   ```
   REINDEX TABLE  "artifact_groups";
   REINDEX TABLE  "artifact_group_images";
   REINDEX TABLE  "images";
   REINDEX TABLE  "sources";
   REINDEX TABLE  "source_images";
   REINDEX TABLE  "packages";
   REINDEX TABLE  "image_packages";
   REINDEX TABLE  "vulnerabilities";
   REINDEX TABLE  "package_vulnerabilities";
   REINDEX TABLE  "source_packages";
   REINDEX TABLE  "artifact_group_sources";
   REINDEX TABLE  "method_types";
   REINDEX TABLE  "ratings";
   REINDEX TABLE  "package_managers";
   REINDEX TABLE  "artifact_group_labels";
   REINDEX TABLE  "analysis_instances";
   REINDEX TABLE  "vulnerability_analyses";
   REINDEX TABLE  "reports";
   REINDEX TABLE  "report_ratings";
   REINDEX TABLE  "report_packages_vulnerabilities";
   REINDEX TABLE  "index_migration_statuses";
   ```

3. Run the following SQL:

   ```
   INSERT INTO index_migration_statuses (created_at, updated_at, "version", statu
   s) VALUES(now(), now(), version(), true)
   ```

4. Examine the Metadata Store API logs. You should not see any errors.

Connect to the Metadata Store database with a superuser account and manually fix the index

1. Connect to the Postgres Database.
2. Install the extension on your PostgreSQL Database.

   ```
   CREATE EXTENSION amcheck
   ```

3. Run the following SQL:

```
SELECT indexrelid::regclass::text FROM (SELECT indexrelid, indrelid, indcollati
on[i] coll FROM pg_index, generate_subscripts(indcollation, 1) g(i)) s JOIN pg_
collation c ON coll=c.oid
WHERE collprovider IN ('d', 'c') AND collname NOT IN ('C', 'POSIX');
```

4. Run the following SQL when you see an error:

```
SELECT indexrelid::regclass::text FROM (SELECT indexrelid, indrelid, indcollati
on[i] coll FROM pg_index, generate_subscripts(indcollation, 1) g(i)) s JOIN pg_
collation c ON coll=c.oid
WHERE collprovider IN ('d', 'c') AND collname NOT IN ('C', 'POSIX');
```

5. Run the following SQL if the previous step causes an error:

```
REINDEX database "metadata-store"
```

6. Run the following SQL:

```
INSERT INTO index_migration_statuses (created_at, updated_at, "version", statu
s) VALUES(now(), now(), version(), true)
```

7. Examine the Metadata Store API logs. You should not see any errors.

Overview of Tanzu Application Platform Telemetry

Tanzu Application Platform Telemetry (commonly known as TAP Telemetry) is a set of objects that collect data about the usage of Tanzu Application Platform (commonly known as TAP) and send it back to VMware for product improvements.

A benefit of remaining enrolled in telemetry and identifying your company during Tanzu Application Platform installation is that VMware can provide your organization with usage reports about Tanzu Application Platform.

For more information about enrolling in telemetry reports, see Tanzu Application Platform usage reports.

For more information about how to install the telemetry component, see Install Tanzu Application Platform Telemetry.

Tanzu Application Platform usage reports

VMware offers the option to enroll in a usage reporting program that offers a summary of usage of your Tanzu Application Platform. These reports provide an overview of various deployments of Tanzu Application Platform and their utilization. They encompass details such as the quantity of workloads and supply chains, and their health status. Additionally, the reports include information about the virtual CPU (vCPU) usage for each Tanzu Application Platform deployment. You can enroll in the program by providing the Entitlement Account Number (EAN). An EAN is a unique ID assigned to all VMware customers. VMware uses EAN to identify data about Tanzu Application Platform.

After locating the EAN, pass the number under the telemetry header in the `tap-values.yaml` file as a value for the `customer_entitlement_account_number` key.

```
tap_telemetry:
  customer_entitlement_account_number: "CUSTOMER-ENTITLEMENT-ACCOUNT-NUMBER"
```

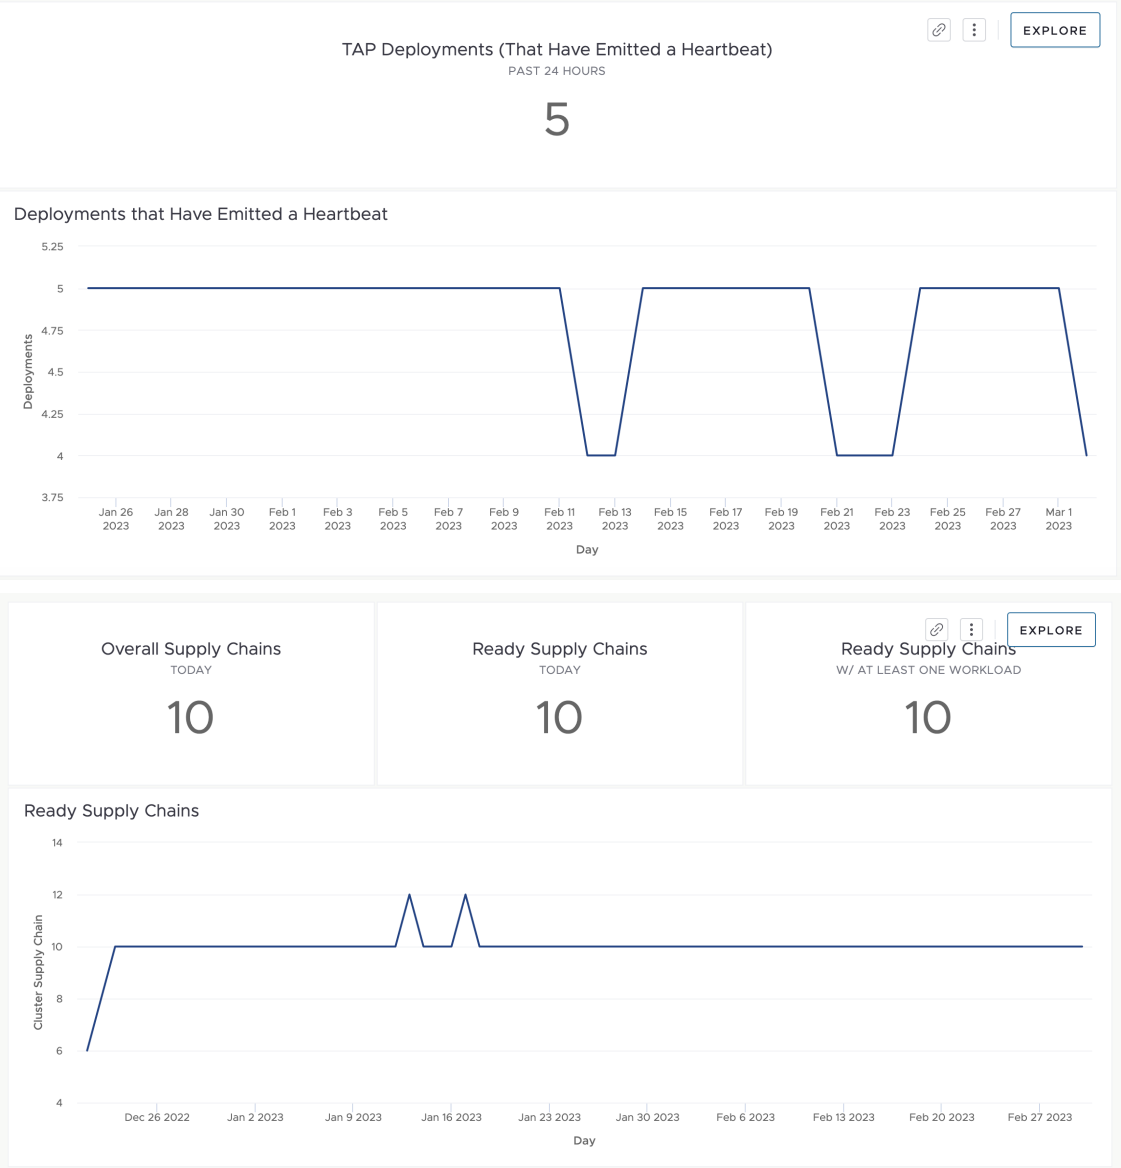
You must repeat the process for each Tanzu Application Platform Cluster included in the telemetry report. For more information, see Full profile.

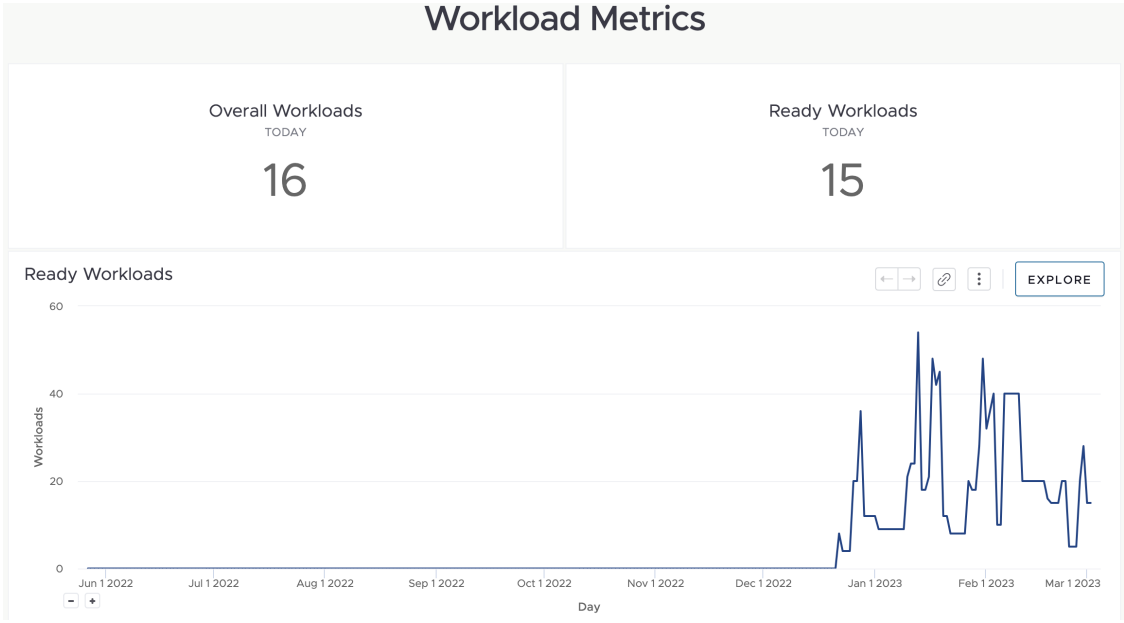
After enrollment, alert your VMware account team that you have configured the EAN field and want telemetry reports. This allows VMware to identify who the newly added EAN belongs to.

Note

Usage report is only supported for non-airgapped deployments of Tanzu Application Platform and the Cluster must participate in Tanzu Application Platform telemetry. You are enrolled in telemetry by default. You can opt out of telemetry collection by following the instructions in Opt out of telemetry collection.

The following screenshots show the sample telemetry reports.





Overview of Tanzu Application Platform Telemetry

Tanzu Application Platform Telemetry (commonly known as TAP Telemetry) is a set of objects that collect data about the usage of Tanzu Application Platform (commonly known as TAP) and send it back to VMware for product improvements.

A benefit of remaining enrolled in telemetry and identifying your company during Tanzu Application Platform installation is that VMware can provide your organization with usage reports about Tanzu Application Platform.

For more information about enrolling in telemetry reports, see Tanzu Application Platform usage reports.

For more information about how to install the telemetry component, see Install Tanzu Application Platform Telemetry.

Tanzu Application Platform usage reports

VMware offers the option to enroll in a usage reporting program that offers a summary of usage of your Tanzu Application Platform. These reports provide an overview of various deployments of Tanzu Application Platform and their utilization. They encompass details such as the quantity of workloads and supply chains, and their health status. Additionally, the reports include information about the virtual CPU (vCPU) usage for each Tanzu Application Platform deployment. You can enroll in the program by providing the Entitlement Account Number (EAN). An EAN is a unique ID assigned to all VMware customers. VMware uses EAN to identify data about Tanzu Application Platform.

After locating the EAN, pass the number under the telemetry header in the `tap-values.yaml` file as a value for the `customer_entitlement_account_number` key.

```
tap_telemetry:
  customer_entitlement_account_number: "CUSTOMER-ENTITLEMENT-ACCOUNT-NUMBER"
```

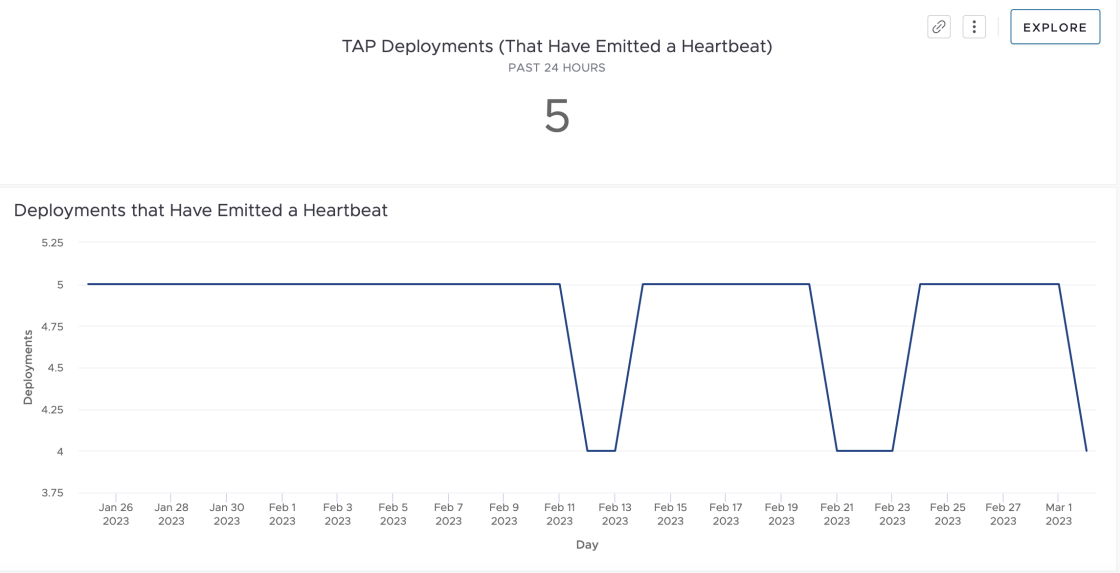
You must repeat the process for each Tanzu Application Platform Cluster included in the telemetry report. For more information, see Full profile.

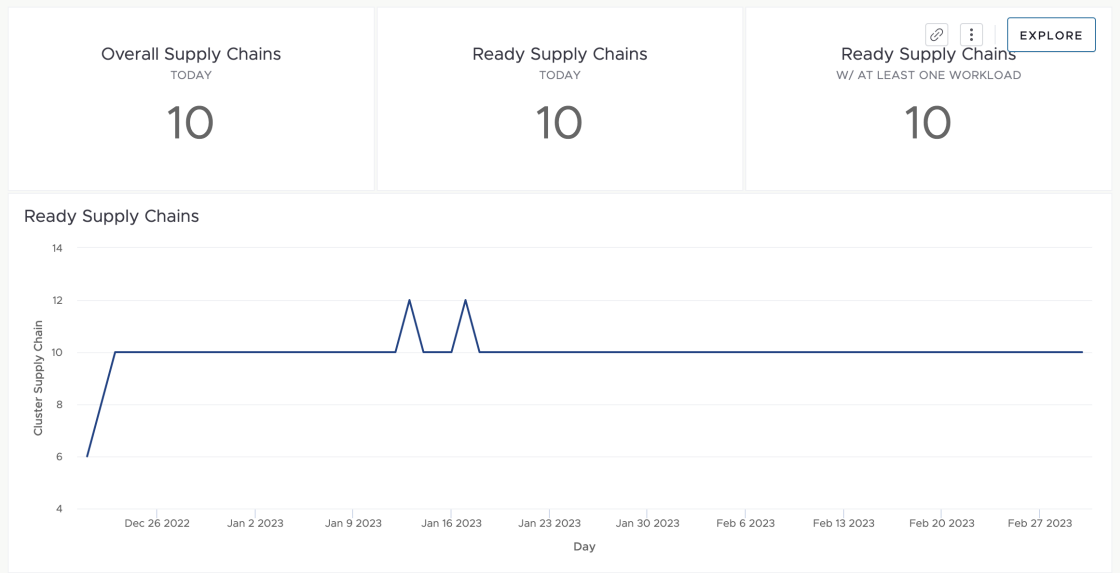
After enrollment, alert your VMware account team that you have configured the EAN field and want telemetry reports. This allows VMware to identify who the newly added EAN belongs to.

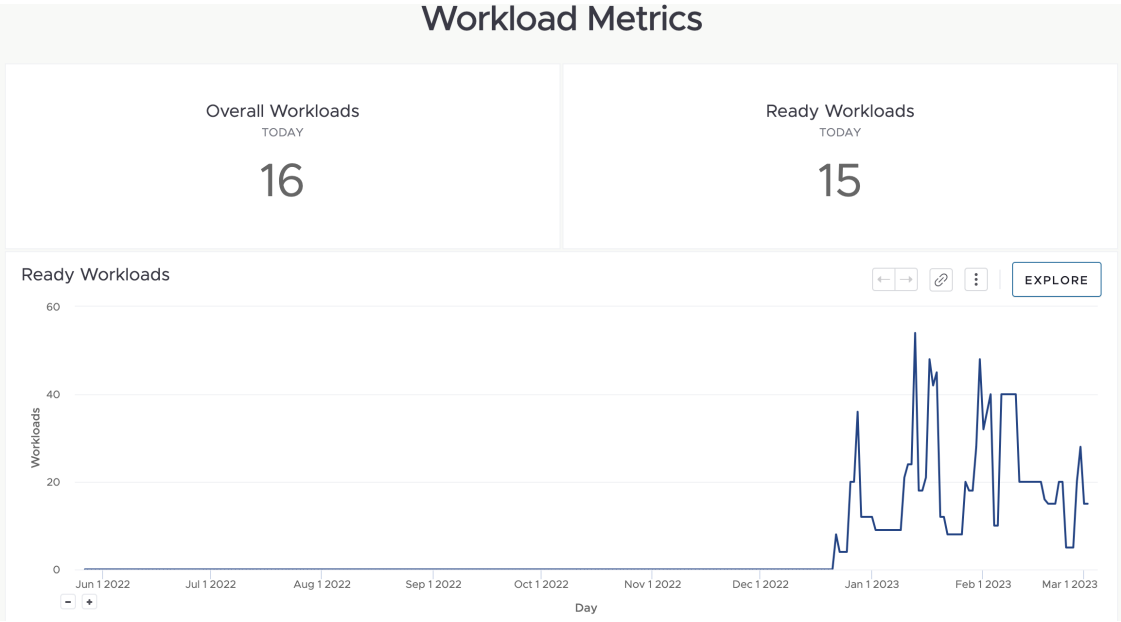
Note

Usage report is only supported for non-airgapped deployments of Tanzu Application Platform and the Cluster must participate in Tanzu Application Platform telemetry. You are enrolled in telemetry by default. You can opt out of telemetry collection by following the instructions in Opt out of telemetry collection.

The following screenshots show the sample telemetry reports.







Install Tanzu Application Platform Telemetry

This topic tells you how to install Tanzu Application Platform Telemetry from the Tanzu Application Platform (commonly known as TAP) package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install Telemetry. For more information about profiles, see Components and installation profiles.

Prerequisites

Before installing Tap Telemetry:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- Install cert-manager on the cluster. For more information, see the cert-manager documentation.
- See Deployment Details and Configuration to review what resources will be deployed.

Install

To install Tanzu Application Platform Telemetry:

1. List version information for the package by running:

   ```
   tanzu package available list tap-telemetry.tanzu.vmware.com --namespace tap-ins
   tall
   ```

   For example:

   ```
   $ tanzu package available list tap-telemetry.tanzu.vmware.com --namespace tap-i
   nstall
   - Retrieving package versions for tap-telemetry.tanzu.vmware.com...
   ```

```
  NAME                           VERSION       RELEASED-AT
  tap-telemetry.tanzu.vmware.com  0.3.1
```

2. (Optional) List all the available deployment configuration options:

   ```
   tanzu package available get tap-telemetry.tanzu.vmware.com/VERSION --values-sch
   ema -n tap-install
   ```

   Where `VERSION` is the your package version number. For example, `0.3.1`.

   For example:

   ```
   $ tanzu package available get tap-telemetry.tanzu.vmware.com/0.3.1 --values-sch
   ema -n tap-install
   | Retrieving package details for tap-telemetry.tanzu.vmware.com/0.3.1...
   KEY                                  DEFAULT  TYPE    DESCRIPTION
   kubernetes_distribution                       string  Kubernetes platform flavo
   r where the tap-telemetry is being installed on. Accepted values are ['', 'open
   shift']
   customer_entitlement_account_number           string  Account number used to di
   stinguish data by customer.
   installed_for_vmware_internal_use             string  Indication of if the depl
   oyment is for vmware internal user. Accepted values are ['true', 'false']
   ```

3. (Optional) Modify the deployment configurations by creating a configuration YAML with the desired custom configuration values. For example, if you want to provide your Customer Entitlement Number, create a `tap-telemetry-values.yaml` and configure the `customer_entitlement_account_number` property:

   ```
   ---
   customer_entitlement_account_number: "12345"
   ```

   See Deployment details and configuration for more information about the configuration options.

4. Install the package by running:

   ```
   tanzu package install tap-telmetry \
     --package tap-telemetry.tanzu.vmware.com \
     --version VERSION \
     --namespace tap-install \
     --values-file tap-telemetry-values.yaml
   ```

   Where:

   - `--values-file` is an optional flag. Only use it to customize the deployment configuration.
   - `VERSION` is the package version number. For example, `0.3.1`.

   For example:

   ```
   $ tanzu package install tap-telmetry \
     --package tap-telemetry.tanzu.vmware.com \
     --version 0.3.1 \
     --namespace tap-install \
     --values-file tap-telemetry-values.yaml

     Installing package 'tap-telemetry.tanzu.vmware.com'
     Getting package metadata for 'tap-telemetry.tanzu.vmware.com'
     Creating service account 'tap-telemetry-tap-install-sa'
     Creating cluster admin role 'tap-telemetry-tap-install-cluster-role'
     Creating cluster role binding 'tap-telemetry-tap-install-cluster-rolebinding'
   ```

```
  Creating secret 'tap-telemetry-tap-install-values'
  Creating package resource
  Waiting for 'PackageInstall' reconciliation for 'tap-telemetry'
  'PackageInstall' resource install status: Reconciling
  'PackageInstall' resource install status: ReconcileSucceeded
  'PackageInstall' resource successfully reconciled

Added installed package 'tap-telemetry'
```

Deployment details and configurations of Tanzu Application Platform Telemetry

Use this topic to learn the deployment details and configurations of your Tanzu Application Platform Telemetry (commonly known as TAP Telemetry).

What is deployed

The installation creates the following in your Kubernetes cluster:

- A deployment.
- A pod.
- A namespace `tap-telemetry`.
- A service account with read-write privileges named `informer`, and a corresponding secret for the service account. This secret is bound to a ClusterRole named `tap-telemetry-admin`.
- A Role `tap-telemetry-informer` to retrieve the deployment ID, which is sent as sender ID in heartbeat metrics.
- A RoleBinding `tap-telemetry-informer-admin` that binds the `informer` service account to the `tap-telemetry-informer` role.
- A ClusterRole `tap-telemetry-admin` that has access to each Tanzu Application Platform component to gather information from.
- A ClusterRoleBinding `tap-telemetry-informer-admin` that binds the `informer` service account to the `tap-telemetry-informer` cluster role.

Deployment configuration

`customer_entitlement_account_number` is the unique identifier to differentiate between the data from your cluster and the data from other clusters. You can configure this property in your `tap-telemetry-values.yaml`:

```
customer_entitlement_account_number: "12345"
```

It creates a config map named `vmware-telemetry-identifiers` in the `vmware-system-telemetry` namespace, which is used internally to log your information.

Repeat these steps for the Build, Run, and View Cluster. For more information, see Install multicluster Tanzu Application Platform profiles.

Overview of Tanzu Build Service

This topic provides you with an overview of VMware Tanzu Build Service in Tanzu Application Platform (commonly known as TAP).

Overview

Tanzu Build Service automates container creation, management, and governance at enterprise scale. Tanzu Build Service uses the open-source Cloud Native Buildpacks project to turn application source code into container images. It executes reproducible builds aligned with modern container standards and keeps images up to date.

Use the Tanzu Build Service CLI plug-in to view all the Tanzu Build Service resources on any Kubernetes cluster that has Tanzu Application Platform or Tanzu Build Service installed. For information about how to install the Tanzu CLI and plug-ins, see Install Tanzu CLI and Overview of Tanzu CLI.

For more information about Tanzu Build Service, see the Tanzu Build Service documentation. For more information about Tanzu Buildpacks and their configuration, see the Tanzu Buildpack documentation.

Tanzu Application Platform v1.7 includes Tanzu Build Service v1.12.

Overview of Tanzu Build Service

This topic provides you with an overview of VMware Tanzu Build Service in Tanzu Application Platform (commonly known as TAP).

Overview

Tanzu Build Service automates container creation, management, and governance at enterprise scale. Tanzu Build Service uses the open-source Cloud Native Buildpacks project to turn application source code into container images. It executes reproducible builds aligned with modern container standards and keeps images up to date.

Use the Tanzu Build Service CLI plug-in to view all the Tanzu Build Service resources on any Kubernetes cluster that has Tanzu Application Platform or Tanzu Build Service installed. For information about how to install the Tanzu CLI and plug-ins, see Install Tanzu CLI and Overview of Tanzu CLI.

For more information about Tanzu Build Service, see the Tanzu Build Service documentation. For more information about Tanzu Buildpacks and their configuration, see the Tanzu Buildpack documentation.

Tanzu Application Platform v1.7 includes Tanzu Build Service v1.12.

Install Tanzu Build Service

This topic describes how to install Tanzu Build Service from the Tanzu Application Platform (commonly known as TAP) package repository by using the Tanzu CLI.

Before you begin

Use this topic if you do not want to use a Tanzu Application Platform profile that includes Tanzu Build Service. The Full, Iterate, and Build profiles include Tanzu Build Service. For more information about profiles, see Components and installation profiles.

The following procedure might not include some configurations required for your environment. For advanced information about installing Tanzu Build Service, see the Tanzu Build Service documentation.

Prerequisites

Before installing Tanzu Build Service:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- You must have access to a Docker registry that Tanzu Build Service can use to create builder images. Approximately 10 GB of registry space is required when using the `full` dependencies.
- Your Docker registry must be accessible with user name and password credentials.

Deprecated Features

The Cloud Native Buildpack Bill of Materials (CNB BOM) format has been removed.

Install the Tanzu Build Service package

To install Tanzu Build Service by using the Tanzu CLI:

1. Get the latest version of the Tanzu Build Service package by running:

   ```
   tanzu package available list buildservice.tanzu.vmware.com --namespace tap-inst
   all
   ```

2. Gather the values schema by running:

   ```
   tanzu package available get buildservice.tanzu.vmware.com/VERSION --values-sche
   ma --namespace tap-install
   ```

   Where `VERSION` is the version of the Tanzu Build Service package you retrieved earlier in this procedure.

3. Create the secret for the `kp-default-repository` credentials using the `tanzu` cli:

   ```
   tanzu secret registry add kp-default-repository-creds \
     --server "${REGISTRY-HOSTNAME}" \
     --username "${REGISTRY-USERNAME}" \
     --password "${REGISTRY-PASSWORD}" \
     --namespace tap-install
   ```

   Where: - `REGISTRY-HOST` is the host name for the registry that contains your `kp_default_repository`. For example: - Harbor has the form `server: "my-harbor.io"`. - Docker Hub has the form `server: "index.docker.io"`. - Google Cloud Registry has the form `server: "gcr.io"`. - `REGISTRY-USERNAME` and `REGISTRY-PASSWORD` are the user name and password for the user that can write to the repository used in the following step. For Google Cloud Registry, use `_json_key` as the user name and the contents of the service account JSON file for the password.

4. Create a `tbs-values.yaml` file using the following template. If `shared.image_registry.project_path` and `shared.image_registry.secret` are configured in the `tap-values.yaml` file, Tanzu Build Service inherits all three values in that section. This can be disabled by setting any of the following three values.

   ```
   ---
   kp_default_repository: "REPO-NAME"
   kp_default_repository_secret:
     name: kp-default-repository-creds
     namespace: tap-install
   ```

Where: - `REPO-NAME` is a writable repository in your registry. Tanzu Build Service dependencies are written to this location. Examples: - Harbor has the form `"my-harbor.io/my-project/build-service"`. - Docker Hub has the form `"my-dockerhub-user/build-service"` or `"index.docker.io/my-user/build-service"`. - Google Cloud Registry has the form `"gcr.io/my-project/build-service"`.

5. If you are running on OpenShift, add `kubernetes_distribution: openshift` to your `tbs-values.yaml` file.

6. (Optional) Under the `ca_cert_data` key in the `tbs-values.yaml` file, provide a PEM-encoded CA certificate for Tanzu Build Service. This certificate is used for accessing the container image registry and is also provided to the build process.

   
   Note

   If `shared.ca_cert_data` is configured in the `tap-values.yaml` file, Tanzu Build Service inherits that value.

   Configuring `ca_cert_data` key in the `tbs-values.yaml` file adds the CA certificates at build time. To add CA certificates to the built image, see Configure custom CA certificates for a single workload using service bindings.

   For example:

   ```
   ---
   kp_default_repository: "REPO-NAME"
   kp_default_repository_secret:
     name: kp-default-repository-creds
     namespace: tap-install
   ca_cert_data: |
     -----BEGIN CERTIFICATE-----
     ...
     -----END CERTIFICATE-----
   ```

7. (Optional) Tanzu Build Service is bootstrapped with the `lite` set of dependencies. To configure `full` dependencies, add the key-value pair `exclude_dependencies: true` to your `tbs-values.yaml` file. This is to exclude the default `lite` dependencies from the installation. For example:

   ```
   ---
   kp_default_repository: "REPO-NAME"
   kp_default_repository_secret:
     name: kp-default-repository-creds
     namespace: tap-install
   exclude_dependencies: true
   ```

   For more information about the differences between `full` and `lite` dependencies, see About lite and full dependencies.

8. Install the Tanzu Build Service package by running:

   ```
   tanzu package install tbs \
     --package buildservice.tanzu.vmware.com \
     --version VERSION \
     --namespace tap-install \
     --values-file tbs-values.yaml
   ```

   Where `VERSION` is the version of the Tanzu Build Service package you retrieved earlier.

For example:

```
$ tanzu package install tbs \
    --package buildservice.tanzu.vmware.com \
    --version 1.12.4 \
    --namespace tap-install \
    --values-file tbs-values.yaml

| Installing package 'buildservice.tanzu.vmware.com'
| Getting namespace 'tap-install'
| Getting package metadata for 'buildservice.tanzu.vmware.com'
| Creating service account 'tbs-tap-install-sa'
| Creating cluster admin role 'tbs-tap-install-cluster-role'
| Creating cluster role binding 'tbs-tap-install-cluster-rolebinding'
| Creating secret 'tbs-tap-install-values'
- Creating package resource
- Package install status: Reconciling

 Added installed package 'tbs' in namespace 'tap-install'
```

9. (Optional) Verify the cluster builders that the Tanzu Build Service installation created by running:

   ```
   tanzu package installed get tbs -n tap-install
   ```

10. If you configured `full` dependencies in your `tbs-values.yaml` file, install the `full` dependencies by following the procedure in Install full dependencies.

Use AWS IAM authentication for registry credentials

Tanzu Build Service supports using AWS IAM roles to authenticate with Amazon Elastic Container Registry (ECR) on Amazon Elastic Kubernetes Service (EKS) clusters.

To use AWS IAM authentication:

1. Configure an AWS IAM role that has read and write access to the repository in the container image registry used when installing Tanzu Application Platform.
2. Use the following alternative configuration for `tbs-values.yaml`:

   > **Note**
   >
   > if you are installing Tanzu Build Service as part of a Tanzu Application Platform profile, you configure this in your `tap-values.yaml` file under the `buildservice` section.

   ```
   ---
     kp_default_repository: "REPO-NAME"
     kp_default_repository_aws_iam_role_arn: "IAM-ROLE-ARN"
   ```

   Where:

   - `REPO-NAME` is a writable repository in your registry. Tanzu Build Service dependencies are written to this location.
   - `IAM-ROLE-ARN` is the AWS IAM role Amazon Resource Name (ARN) for the role configured earlier in this procedure. For example, `arn:aws:iam::xyz:role/my-install-role`.

3. The developer namespace requires configuration for Tanzu Application Platform to use AWS IAM authentication for ECR. Configure an AWS IAM role that has read and write

access to the registry for storing workload images.

4. Using the supply chain service account, add an annotation including the role ARN configured earlier by running:

   ```
   kubectl annotate serviceaccount -n DEVELOPER-NAMESPACE SERVICE-ACCOUNT-NAME \
     eks.amazonaws.com/role-arn=IAM-ROLE-ARN
   ```

   Where:

   - `DEVELOPER-NAMESPACE` is the namespace where workloads are created.
   - `SERVICE-ACCOUNT-NAME` is the supply chain service account. This is `default` if unset.
   - `IAM-ROLE-ARN` is the AWS IAM role ARN for the role configured earlier. For example, `arn:aws:iam::xyz:role/my-developer-role`.

5. Apply this configuration by continuing the steps in Install the Tanzu Build Service package.

Install full dependencies

If you configured `full` dependencies in your `tbs-values.yaml` file, you must install the `full` dependencies package. For a more information about `lite` and `full` dependencies, see About lite and full dependencies.

To install `full` Tanzu Build Service dependencies:

1. Get the latest version of the Tanzu Application Platform package by running:

   ```
   tanzu package available list tap.tanzu.vmware.com --namespace tap-install
   ```

2. If you have not done so already, you must exclude the default dependencies by adding the key-value pair `exclude_dependencies: true` to your `tap-values.yaml` file under the `buildservice` section. For example:

   ```
   buildservice:
     exclude_dependencies: true
   ```

3. If you have not updated your Tanzu Application Platform package installation after adding the key-value pair `exclude_dependencies: true` to your values file, perform the update by running:

   ```
   tanzu package installed update tap --namespace tap-install --values-file VALUES
   -FILE
   ```

   Where `VALUES-FILE` is the path to the `tap-values.yaml` file you edited earlier.

4. Relocate the Tanzu Build Service `full` dependencies package repository by doing one of the following:

   - Relocate the images directly for online installation:

     ```
     imgpkg copy \
       -b registry.tanzu.vmware.com/tanzu-application-platform/full-deps-packa
     ge-repo:VERSION \
       --to-repo ${INSTALL_REGISTRY_HOSTNAME}/full-deps-package-repo
     ```

     Where `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.

   - Relocate the images to an external storage device and then to the registry in the air-gapped environment:

```
imgpkg copy \
  -b registry.tanzu.vmware.com/tanzu-application-platform/full-deps-packa
ge-repo:VERSION \
  --to-tar=full-deps-package-repo.tar

# move full-deps-package-repo.tar to environment with registry access
imgpkg copy \
  --tar full-deps-package-repo.tar \
  --to-repo=INSTALL-REGISTRY-HOSTNAME/TARGET-REPOSITORY/full-deps-package
-repo
```

Where:

- `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.
- `INSTALL-REGISTRY-HOSTNAME` is your container registry.
- `TARGET-REPOSITORY` is your target repository.

5. Add the Tanzu Build Service `full` dependencies package repository by running:

```
tanzu package repository add full-deps-package-repo \
  --url INSTALL-REGISTRY-HOSTNAME/TARGET-REPOSITORY/full-deps-package-repo:VERS
ION \
  --namespace tap-install
```

Where:

- `INSTALL-REGISTRY-HOSTNAME` is your container registry.
- `TARGET-REPOSITORY` is your target repository.
- `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.

6. Create a new `tbs-full-deps-values.yaml` and copy the `kp_default_repository` key-value pair from your `tap-values.yaml` or `tbs-values.yaml`:

```
---
 kp_default_repository: "REPO-NAME"
 kp_default_repository_secret:
   name: kp-default-repository-creds
   namespace: tap-install
```

Where `REPO-NAME` is copied from the `buildservice.kp_default_repository` field in your `tap-values.yaml` or `tbs-values.yaml`.

1. (Optional) Install the UBI builder.

   The UBI builder uses Red Hat Universal Base Image (UBI) v8 for both build and run images. This builder only supports Java and Node.js. To install the UBI builder, add the key-value pair `enable_ubi_builder: true` to your `tbs-full-deps-values.yaml`.

   ```
   ---
   enable_ubi_builder: true
   ```

2. (Optional) Install the Static builder.

   The Static builder uses Ubuntu Jammy for both build images and a minimal static run image. This builder only supports Golang. To install the Static builder, add the key-value pair `enable_static_builder: true` to your `tbs-full-deps-values.yaml`.

```
---
enable_static_builder: true
```

7. Install the `full` dependencies package by running:

```
tanzu package install full-deps \
  --package full-deps.buildservice.tanzu.vmware.com \
  --version "> 0.0.0" \
  --namespace tap-install \
  --values-file VALUES-FILE
```

   Where `VALUES-FILE` is the path to the `tbs-full-deps-values.yaml` you created earlier.

Install Tanzu Build Service on an air-gapped environment

This topic tells you how to install Tanzu Build Service on a Kubernetes cluster and registry that are air-gapped from external traffic.

Before you begin

Use this topic if you do not want to use a Tanzu Application Platform profile that includes Tanzu Build Service.

The Full, Iterate, and Build profiles include Tanzu Build Service. For more information about profiles, see Components and installation profiles.

Prerequisites

Before installing Tanzu Build Service:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- You must have access to a Docker registry that Tanzu Build Service can use to create builder images. Approximately 10 GB of registry space is required when using the `full` dependencies.
- Your Docker registry must be accessible with user name and password credentials.

Deprecated Features

The Cloud Native Buildpack Bill of Materials (CNB BOM) format has been removed.

Install the Tanzu Build Service package

These steps assume that you have installed the Tanzu Application Platform packages in your air-gapped environment.

To install the Tanzu Build Service package on an air-gapped environment:

1. Get the latest version of the Tanzu Build Service package by running:

```
tanzu package available list buildservice.tanzu.vmware.com --namespace tap-inst
all
```

2. Gather the values schema by running:

```
tanzu package available get buildservice.tanzu.vmware.com/VERSION --values-sche
```

```
ma --namespace tap-install
```

Where `VERSION` is the version of the Tanzu Build Service package you retrieved in the previous step.

3. Create a `tbs-values.yaml` file. The required fields for an air-gapped installation are as follows:

```
---
kp_default_repository: REPO-NAME
kp_default_repository_secret:
  name: "SECRET_NAME"
  namespace: "SECRET_NAMESPACE"
ca_cert_data: CA-CERT-CONTENTS
exclude_dependencies: true
```

Where:

- `REPO-NAME` is the fully qualified path to a writeable repository in your internal registry. Tanzu Build Service dependencies are written to this location. For example:
  - For Harbor: `harbor.io/my-project/build-service`
  - For Artifactory: `artifactory.com/my-project/build-service`
- `SECRET_NAME` is the name of the secret containing credentials that can write to `REPO-NAME`.
- `SECRET_NAMESPACE` is the namespace of the secret containing credentials that can write to `REPO-NAME`.
- `CA-CERT-CONTENTS` are the contents of the PEM-encoded CA certificate for the internal registry.

4. Install the package by running:

```
tanzu package install tbs \
  --package buildservice.tanzu.vmware.com \
  --version VERSION \
  --namespace tap-install \
  --values-file tbs-values.yaml
```

Where `VERSION` is the version of the Tanzu Build Service package you retrieved earlier.

For example:

```
$ tanzu package install tbs \
    --package buildservice.tanzu.vmware.com \
    --version 1.12.4 \
    --namespace tap-install \
    --values-file tbs-values.yaml

| Installing package 'buildservice.tanzu.vmware.com'
| Getting namespace 'tap-install'
| Getting package metadata for 'buildservice.tanzu.vmware.com'
| Creating service account 'tbs-tap-install-sa'
| Creating cluster admin role 'tbs-tap-install-cluster-role'
| Creating cluster role binding 'tbs-tap-install-cluster-rolebinding'
| Creating secret 'tbs-tap-install-values'
- Creating package resource
- Package install status: Reconciling
 Added installed package 'tbs' in namespace 'tap-install'
```

Install the Tanzu Build Service dependencies

Important

By default, Tanzu Build Service is installed with the `lite` dependencies.

When installing Tanzu Build Service in an air-gapped environment, the `lite` dependencies are not available because they require Internet access. You must install the `full` dependencies.

To install `full` dependencies:

1. Get the latest version of the Tanzu Application Platform package by running:

   ```
   tanzu package available list tap.tanzu.vmware.com --namespace tap-install
   ```

2. If you have not done so already, you must exclude the default dependencies by adding the key-value pair `exclude_dependencies: true` to your `tap-values.yaml` file under the `buildservice` section. For example:

   ```
   buildservice:
     exclude_dependencies: true
   ```

3. If you have not updated your Tanzu Application Platform package installation after adding the key-value pair `exclude_dependencies: true` to your values file, perform the update by running:

   ```
   tanzu package installed update tap --namespace tap-install --values-file VALUES
   -FILE
   ```

   Where `VALUES-FILE` is the path to the `tap-values.yaml` file you edited earlier.

4. Relocate the Tanzu Build Service `full` dependencies package repository by doing one of the following:

   - Relocate the images directly for online installation:

     ```
     imgpkg copy \
       -b registry.tanzu.vmware.com/tanzu-application-platform/full-deps-packa
     ge-repo:VERSION \
       --to-repo ${INSTALL_REGISTRY_HOSTNAME}/full-deps-package-repo
     ```

     Where `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.

   - Relocate the images to an external storage device and then to the registry in the air-gapped environment:

     ```
     imgpkg copy \
       -b registry.tanzu.vmware.com/tanzu-application-platform/full-deps-packa
     ge-repo:VERSION \
       --to-tar=full-deps-package-repo.tar

     # move full-deps-package-repo.tar to environment with registry access
     imgpkg copy \
       --tar full-deps-package-repo.tar \
       --to-repo=INSTALL-REGISTRY-HOSTNAME/TARGET-REPOSITORY/full-deps-package
     -repo
     ```

     Where:

     - `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.

- `INSTALL-REGISTRY-HOSTNAME` is your container registry.
- `TARGET-REPOSITORY` is your target repository.

5. Add the Tanzu Build Service `full` dependencies package repository by running:

```
tanzu package repository add full-deps-package-repo \
  --url INSTALL-REGISTRY-HOSTNAME/TARGET-REPOSITORY/full-deps-package-repo:VERS
ION \
  --namespace tap-install
```

Where:

- `INSTALL-REGISTRY-HOSTNAME` is your container registry.
- `TARGET-REPOSITORY` is your target repository.
- `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.

6. Create a new `tbs-full-deps-values.yaml` and copy the `kp_default_repository` key-value pair from your `tap-values.yaml` or `tbs-values.yaml`:

```
---
 kp_default_repository: "REPO-NAME"
 kp_default_repository_secret:
   name: kp-default-repository-creds
   namespace: tap-install
```

Where `REPO-NAME` is copied from the `buildservice.kp_default_repository` field in your `tap-values.yaml` or `tbs-values.yaml`.

1. (Optional) Install the UBI builder.

   The UBI builder uses Red Hat Universal Base Image (UBI) v8 for both build and run images. This builder only supports Java and Node.js. To install the UBI builder, add the key-value pair `enable_ubi_builder: true` to your `tbs-full-deps-values.yaml`.

   ```
   ---
   enable_ubi_builder: true
   ```

2. (Optional) Install the Static builder.

   The Static builder uses Ubuntu Jammy for both build images and a minimal static run image. This builder only supports Golang. To install the Static builder, add the key-value pair `enable_static_builder: true` to your `tbs-full-deps-values.yaml`.

   ```
   ---
   enable_static_builder: true
   ```

7. Install the `full` dependencies package by running:

```
tanzu package install full-deps \
  --package full-deps.buildservice.tanzu.vmware.com \
  --version "> 0.0.0" \
  --namespace tap-install \
  --values-file VALUES-FILE
```

Where `VALUES-FILE` is the path to the `tbs-full-deps-values.yaml` you created earlier.

Configure Tanzu Build Service properties on a workload

This topic tells you how to configure your workload with Tanzu Build Service properties.

Overview

Tanzu Build Service builds registry images from source code for Tanzu Application Platform. You can configure these build configurations by using a workload.

Tanzu Build Service is only applicable to the build process. Configurations, such as environment variables and service bindings, might require a different process for runtime.

Configure build-time service bindings

You can configure build-time service bindings for Tanzu Build Service.

Tanzu Build Service supports using the Service Binding Specification for Kubernetes for application builds. For more information, see the service binding specification for Kubernetes in GitHub.

Service binding configuration is specific to the buildpack that is used to build the app. For more information about configuring buildpack service bindings for the buildpack you are using, see the VMware Tanzu Buildpacks documentation.

To configure a service binding for a Tanzu Application Platform workload, follow these steps:

1. Create a YAML file named `service-binding-secret.yaml`
    - A Maven secret for example:

      ```
      apiVersion: v1
      kind: Secret
      metadata:
        name: settings-xml
        namespace: DEVELOPER-NAMESPACE
      type: service.binding/maven
      stringData:
        type: maven
        provider: sample
        settings.xml: |
        MY-SETTINGS
      ```

      Where: - `DEVELOPER-NAMESPACE` is the namespace where workloads are created. - `MY-SETTINGS` is the contents of your service bindings file.

    - A NuGet secret for example:

      ```
      apiVersion: v1
      kind: Secret
      metadata:
        name: nuget-config
        namespace: DEVELOPER-NAMESPACE
      type: service.binding/nugetconfig
      stringData:
        type: nugetconfig
        nuget.config: |
        MY-SETTINGS
      ```

      Where: - `DEVELOPER-NAMESPACE` is the namespace where workloads are created. - `MY-SETTINGS` is the contents of your service bindings file.

    - A Git secret for example:

      ```
      apiVersion: v1
      kind: Secret
      metadata:
        name: git-credentials
        namespace: DEVELOPER-NAMESPACE
      ```

```
type: service.binding/git-credentials
stringData:
  type: git-credentials
  context: CREDENTIAL-CONTEXT
  credentials: |
  MY-CREDENTIALS
```

Where:

- `DEVELOPER-NAMESPACE` is the namespace where workloads are created.
- `CREDENTIAL-CONTEXT` is the URL context of the credential. If the workload only has one git-credential service binding, this field can be omitted.
- `MY-CREDENTIALS` is the credential defined in the git credential format.

2. Apply the YAML file by running:

```
kubectl apply -f service-binding-secret.yaml
```

3. Create the workload with `buildServiceBindings` configured by running:

```
tanzu apps workload create WORKLOAD-NAME \
  --param-yaml buildServiceBindings='[{"name": "settings-xml", "kind": "Secre
t"}]' \
  ...
```

Where `WORKLOAD-NAME` is the name of the workload you want to configure.

Configure environment variables

If you have build-time environment variable dependencies, you can set environment variables that are available at build-time.

You can also configure buildpacks with environment variables. Buildpack configuration depends on the specific buildpack being used. For more information about configuring environment variables for the buildpack you are using, see the VMware Tanzu Buildpacks documentation.

For example:

```
tanzu apps workload create WORKLOAD-NAME \
  --build-env "ENV_NAME=ENV_VALUE" \
  --build-env "BP_MAVEN_BUILD_ARGUMENTS=-Dmaven.test.skip=true"
```

Where `WORKLOAD-NAME` is the name of the workload you want to configure.

Configure the service account

Using the Tanzu CLI, you can configure the service account used during builds. This service account is the one configured for the developer namespace. If unset, `default` is used.

To configure the service account used during builds, run:

```
tanzu apps workload create WORKLOAD-NAME \
  --param serviceAccount=SERVICE-ACCOUNT-NAME \
```

Where:

- `WORKLOAD-NAME` is the name of the workload you want to configure.
- `SERVICE-ACCOUNT-NAME` is the name of the service account you want to use during builds.

Configure the cluster builder

To configure the ClusterBuilder used during builds:

1. View the available ClusterBuilds by running:

   ```
   kubectl get clusterbuilder
   ```

2. Set the ClusterBuilder used during builds by running:

   ```
   tanzu apps workload create WORKLOAD-NAME \
     --param clusterBuilder=CLUSTER-BUILDER-NAME \
   ```

   Where:

   - `WORKLOAD-NAME` is the name of the workload you want to configure.
   - `CLUSTER-BUILDER-NAME` is the ClusterBuilder you want to use.

Configure the workload container image registry

Using the Tanzu CLI, you can configure the registry where workload images are saved. The service account used for this workload must have read and write access to this registry location.

To configure the registry where workload images are saved, run:

```
tanzu apps workload create WORKLOAD-NAME \
  --param-yaml registry={"server": SERVER-NAME, "repository": REPO-NAME}
```

Where:

- `SERVER-NAME` is the host name of the registry server. Examples:
  - Harbor has the form `"my-harbor.io"`.
  - Docker Hub has the form `"index.docker.io"`.
  - Google Cloud Registry has the form `"gcr.io"`.
- `REPO-NAME` is where workload images are stored in the registry. Images are written to `SERVER-NAME/REPO-NAME/workload-name`. Examples:
  - Harbor has the form `"my-project/supply-chain"`.
  - Docker Hub has the form `"my-dockerhub-user"`.
  - Google Cloud Registry has the form `"my-project/supply-chain"`.

Configure custom CA certificates for a single workload using service bindings

If the language family buildpack you are using includes the Paketo CA certificates buildpack, you can use a service binding to provide custom certificates during the build and run process. For more information about language family buildpacks, see the Tanzu Buildpacks documentation.

To create a service binding to provide custom CA certificates for a workload:

1. Create a YAML file named `service-binding-ca-cert.yaml` for a secret as follows:

   ```
   apiVersion: v1
   kind: Secret
   metadata:
     name: my-ca-certs
   data:
   ```

```
  type: ca-certificates
  provider: sample
  CA-CERT-FILENAME: |
    -----BEGIN CERTIFICATE-----
    ...
    -----END CERTIFICATE-----
```

Where `CA-CERT-FILENAME` is the name of your PEM encoded CA certificate file. For example, `arbitrary-file-name.pem`.

2. Apply the YAML file by running:

```
kubectl apply -f service-binding-ca-cert.yaml
```

3. To build with the custom certificate, create the workload with `--param-yaml buildServiceBindings` flag:

```
tanzu apps workload create WORKLOAD-NAME \
  --param-yaml buildServiceBindings='[{"apiVersion": "v1", "kind": "Secret", "n
ame": "my-ca-certs"}]' \
  ...
```

Where `WORKLOAD-NAME` is the name of the workload you want to create.

4. To deploy with the custom certificate, create the workload with the `--service-ref` flag:

```
tanzu apps workload create WORKLOAD-NAME \
  --service-ref my-ca-certs=v1:Secret:my-ca-certs \
  ...
```

Where `WORKLOAD-NAME` is the name of the workload you want to create.

Using custom CA certificates for all workloads

To provide custom CA certificates to the build process for all workloads, see the optional step to add the `ca_cert_data` key Install the Tanzu Build Service package.

Create a signed container image with Tanzu Build Service

This topic tells you how to create a Tanzu Build Service image resource that builds a container image from source code signed with Cosign.

Prerequisites

Before you can configure Tanzu Build Service to sign your image builds, you must:

- Install Tanzu Build Service. The Full, Iterate, and Build profiles include Tanzu Build Service by default. If you have not installed Tanzu Application Platform with one of these profiles, see Installing Tanzu Build Service.
- Install Cosign. For instructions, see the Cosign documentation.
- Have a Builder or ClusterBuilder resource configured.
- Have an image resource configured.
- Review the kpack tutorial. This topic builds upon the steps in this tutorial.

Configure Tanzu Build Service to sign your image builds

To configure Tanzu Build Service to sign your image builds:

1. Ensure that you are in a Kubernetes context where you are authenticated and authorized to create and edit secret and service account resources.
2. Generate a Cosign keypair and store it as a Kubernetes secret by running:

   ```
   cosign generate-key-pair k8s://NAMESPACE/COSIGN-KEYPAIR-NAME
   ```

   Where:

   - `NAMESPACE` is the namespace to store the Kubernetes secret in.
   - `COSIGN-KEYPAIR-NAME` is the name of the Kubernetes secret.

   For example:

   ```
   cosign generate-key-pair k8s://default/tutorial-cosign-key-pair
   ```

3. Enter a password for the private key. Enter any password you want. After the command has completed, you will see the following output:

   ```
   Successfully created secret tutorial-cosign-key-pair in namespace default
   Public key written to cosign.pub
   ```

   You will also see a `cosign.pub` file in your current directory. Keep this file as you will need it to verify the signature of the images that are built.

4. If you are using Docker Hub or a registry that does not support OCI media types, add the annotation `kpack.io/cosign.docker-media-types: "1"` to the Cosign secret as follows:

   ```
   apiVersion: v1
   kind: Secret
   type: Opaque
   metadata:
     name: tutorial-cosign-key-pair
     namespace: default
     annotations:
       kpack.io/cosign.docker-media-types: "1"
   data:
     cosign.key: PRIVATE-KEY-DATA
     cosign.password: COSIGN-PASSWORD
     cosign.pub: PUBLIC-KEY-DATA
   ```

   For more information about configuring Cosign key pairs, see Image signing with cosign in the Tanzu Build Service documentation.

5. To enable Cosign signing, create or edit the service account resource that is referenced in the image resource so that it includes the Cosign keypair secret created earlier. The service account is in the same namespace as the image resource and is directly referenced by the image or default if there isn't one.

   ```
   apiVersion: v1
   kind: ServiceAccount
   metadata:
     name: SERVICE-ACCOUNT-NAME
     namespace: default
   secrets:
   - name: REGISTRY-CREDENTIALS
   - name: COSIGN-KEYPAIR-NAME
   imagePullSecrets:
   - name: REGISTRY-CREDENTIALS
   ```

Where:

- `SERVICE-ACCOUNT-NAME` is the name of your service account resource. For example, `tutorial-cosign-service-account`.
- `COSIGN-KEYPAIR-NAME` is the name of the Cosign keypair secret generated earlier. For example, `tutorial-cosign-key-pair`.
- `REGISTRY-CREDENTIALS` is the secret that provides credentials for the container registry where application container images are pushed to.

6. Apply the service account resource to the cluster by running:

```
kubectl apply -f cosign-service-account.yaml
```

7. Create an image resource file named `image-cosign.yaml`. For example:

```
apiVersion: kpack.io/v1alpha2
kind: Image
metadata:
  name: tutorial-cosign-image
  namespace: default
spec:
  tag: IMAGE-REGISTRY
  serviceAccountName: tutorial-cosign-service-account
  builder:
    name: my-builder
    kind: Builder
  source:
    git:
      url: https://github.com/spring-projects/spring-petclinic
      revision: 82cb521d636b282340378d80a6307a08e3d4a4c4
```

Where:

- `IMAGE-REGISTRY` with a writable repository in your registry. The secret referenced in the service account is a secret providing credentials for the registry where application container images are pushed to. For example:
  - Harbor has the form `"my-harbor.io/my-project/my-repo"`
  - Docker Hub has the form `"my-dockerhub-user/my-repo"` or `"index.docker.io/my-user/my-repo"`
  - Google Cloud Registry has the form `"gcr.io/my-project/my-repo"`

8. If you are using Out of the Box Supply Chains, edit the respective `ClusterImageTemplate` to enable signing in your supply chain. For more information, see Authoring supply chains.

Important

VMware discourages referencing the service account using the `service_account` value when installing the Out of the Box Supply Chain. This is because it gives your run cluster access to the private signing key.

9. Apply the image resource to the cluster by running:

```
kubectl apply -f image-cosign.yaml
```

10. After the image resource finishes building, you can get the fully resolved and built OCI image by running:

```
kubectl -n default get image tutorial-cosign-image
```

Example output:

```
NAME                  LATESTIMAGE                                          READY
tutorial-cosign-image index.docker.io/your-project/app@sha256:6744b...    True
```

11. Verify image signature by running:

```
cosign verify --insecure-ignore-tlog --key cosign.pub LATEST-IMAGE-WITH-DIGEST
```

Where `LATEST-IMAGE-WITH-DIGEST` is the value of `LATESTIMAGE` you retrieved in the previous step. For example, `index.docker.io/your-project/app@sha256:6744b...`.

Expected output:

```
Verification for index.docker.io/your-project/app@sha256:6744b... --
The following checks were performed on each of these signatures:
- The cosign claims were validated
- The signatures were verified against the specified public key
- Any certificates were verified against the Fulcio roots.
```

Note

You must use the `--insecure-ignore-tlog` flag because the supply chain does not write the signature attestation to a transparency log.

12. Configure Supply Chain Security Tools for VMware Tanzu - Policy Controller to ensure that only signed images are allowed in your cluster. For more information, see the Supply Chain Security Tools for VMware Tanzu - Policy Controller documentation.

Generate Supply-chain Levels for Software Artifacts attestations with Tanzu Build Service

This topic tells you how to configure Tanzu Build Service to generate Supply-chain Levels for Software Artifacts (SLSA) attestations for image resources. It also describes how you can view the attestation and verify the signature.

About SLSA security levels in Tanzu Build Service

Tanzu Build Service supports generating SLSA v1 attestations. Tanzu Build Service can achieve SLSA security levels up to `L3` depending on how the installation and workload is configured. This section documents how Tanzu Build Service adheres to each SLSA security level.

For more technical details about how kpack handles SLSA, see the kpack documentation in GitHub.

Build L0

Specification: Build L0: No guarantees

This is the default level in Tanzu Build Service and Tanzu Application Platform because attestations are not generated unless configured for your installation.

Build L1

Specification: Build L1: Provenance exists

This is the level Tanzu Build Service and Tanzu Application Platform achieve if SLSA generation is enabled.

- The build process is consistent. You can see an example app with expected output in Deploy an app on Tanzu Application Platform.
- The provenance generated is complete, but it is unsigned.
- To view the generated provenance, see View the attestation later in this topic.

Build L2

Specification: Build L2: Hosted build platform

This is the level Tanzu Build Service and Tanzu Application Platform achieve if SLSA generation is enabled and a signing key is attached to the service account of the workload.

- All builds executed by Tanzu Build Service occur on a dedicated Kubernetes cluster, not the user's workstation.
- To verify the attestation signature, see Verify the attestation signature.

Build L3

Specification: Build L3: Hardened builds

This is the level Tanzu Build Service and Tanzu Application Platform achieve if SLSA generation is enabled and a signing key is attached to the service account of the workload.

- Builds are isolated from each other by using a different Kubernetes pod per build process.
- Signing keys are only readable by Tanzu Build Service system resources. No user defined build steps, such as custom Buildpacks, custom Stacks, and custom Builders, can access the signing keys.
- You can use Kubernetes Role-Based Access Control (RBAC) to secure the signing keys at the cluster level.

Prerequisites

Before you can configure Tanzu Build Service to sign your image builds, you must:

- Install Tanzu Application Platform.
- If you did not install Tanzu Application Platform by using the Full, Iterate, or Build profile, install the Tanzu Build Service package. See Installing Tanzu Build Service.
- Install jq. For instructions, see the jq documentation.
- To view and verify signed attestations, install Cosign. For instructions, see the Cosign documentation.
- To view unsigned attestations, install Crane. For instructions, see the Crane documentation.
- Ensure that you have access to the `base64` and `awk` commands. These commands are pre-installed on every macOS and Linux machine.
- Have a Builder or ClusterBuilder resource configured. For instructions, see Manage builders for Tanzu Build Service.

Enable SLSA attestation

Tanzu Build Service does not generate SLSA attestation by default. To enable this behavior:

1. Set the `generate_slsa_attestation` key to `true` in your `tap-values.yaml`:

```
buildservice:
    generate_slsa_attestation: true
```

2. Apply the updated configuration by running:

```
tanzu package installed update tap \
  --package tap.tanzu.vmware.com \
  --version TAP-VERSION \
  --namespace tap-install \
  --values-file tap-values.yaml
```

Where `TAP-VERSION` is the version of Tanzu Application Platform installed.

Create unsigned attestations (SLSA L0)

If Tanzu Build Service has SLSA attestation enabled, every app image built by Tanzu Build Service generates a second image where the attestation is stored.

Build the image

No action is required to configure the Image or Workload resources. To learn how to create an app, see Configure Tanzu Build Service properties on a workload.

View the attestation

To view the attestation, run:

```
crane export ATTESTATION-TAG | jq --raw-output '.payload' | base64 --decode | jq
```

Where `ATTESTATION-TAG` is the tag derived from the app image's digest. For more information, see Location of the attestation later in this topic.

For more information about the attestation, see the kpack documentation.

For an example of expected output, see the kpack documentation.

Create signed attestations (SLSA L3)

If the service account of the workload has a secret with a signing key attached, Tanzu Build Service automatically signs the generated attestation.

Generate and save the signing key

To generate and save the signing key:

1. Use the cosign CLI to generate the Kubernetes secret:

```
cosign generate-key-pair k8s://NAMESPACE/COSIGN-KEYPAIR-NAME
```

Where:

- `NAMESPACE` is the namespace to store the Kubernetes secret in.
- `COSIGN-KEYPAIR-NAME` is the name of the Kubernetes secret.

You will see a `cosign.pub` file in your current directory. Keep this file as you need it to verify the signature of the images that are built.

2. Annotate the secret to use it for signing SLSA attestations by running:

```
kubectl annotate secret COSIGN-KEYPAIR-NAME 'kpack.io/slsa='
```

Tanzu Build Service only considers secrets with the annotation `kpack.io/slsa: ""` for signing.

3. Attach the secret to the service account by running:

```
kubectl patch serviceaccount SERVICE-ACCOUNT-NAME -p '{"secrets":[{"name":"COSI
GN-KEYPAIR-NAME"}]}'
```

Where `SERVICE-ACCOUNT-NAME` is the name of the service account that the workload will use.

Build the image

No action is required to configure the Image or Workload resources. To learn how to create an app, see Configure Tanzu Build Service properties on a workload.

Verify the attestation signature

Because Cosign operates on the tag-based discovery, you can only view the latest attestation for a reproducible build. For more information, see Reproducible builds later in this topic.

1. To verify the signature of the attestation, run:

```
cosign verify-attestation \
  --insecure-ignore-tlog=true \
  --key PUBLIC-KEY \
  --type=slsaprovenance1 APP-IMAGE-DIGEST > /dev/null
```

Where:

- `PUBLIC-KEY` is either `k8s://NAMESPACE/COSIGN-KEYPAIR-NAME` from Generate and save the signing key earlier or the path to the `cosign.pub` that was generated.
- `APP-IMAGE-DIGEST` is digest of the image that the workload built.

Example output:

```
Verification for index.docker.io/your-project/app@sha256:1234... --
The following checks were performed on each of these signatures:
  - The cosign claims were validated
  - The signatures were verified against the specified public key
```

2. (Optional) To view the generated attestation, run:

```
cosign verify-attestation \
  --insecure-ignore-tlog=true \
  --key PUBLIC-KEY \
  --type=slsaprovenance1 APP-IMAGE-DIGEST | jq \
  --raw-output '.payload' | base64 --decode | jq
```

Where:

- `PUBLIC-KEY` is either `k8s://NAMESPACE/COSIGN-KEYPAIR-NAME` from Generate and save the signing key earlier or the path to the `cosign.pub` that was generated.
- `APP-IMAGE-DIGEST` is the digest of the image that the workload built.

For more information about the attestation, see the kpack documentation.

For an example of expected output, see the kpack documentation.

Location of the attestation

The tag of the attestation image is predictable from the digest of the app image.

If the digest of your app image is `index.docker.io/your-project/app@sha256:1234`, the tag of your attestation image is `index.docker.io/your-project/app:sha256-1234.att`.

Reproducible builds

Tanzu Build Service supports reproducible builds. This means that it's possible for a build to generate the exact same bit-for-bit image as a previous run. This is most likely to occur if a build is manually re-triggered, but might also automatically occur as part of a dependency upgrade.

In these cases, because the image is bit-for-bit identical and has the same digest as the previous image, the tag of the attestation image overlaps. In this scenario, the newer attestation overwrites the older attestation.

To view the older attestation, the digest of the attestation image is exposed in the status of the Build resource under the key `.status.latestAttestationImage`. You can retrieve this by running:

```
kubectl get builds.kpack.io BUILD-NAME -o yaml
```

Where `BUILD-NAME` is the name of the Build resource. It is usually in the format `IMAGE-NAME-build-N`.

Expected output:

```
apiVersion: kpack.io/v1alpha2
kind: Build
...
status:
  ...
  latestAttestationImage: index.docker.io/your-project/app@sha256:1234
```

Tanzu Build Service Dependencies

This topic tells you about Tanzu Build Service dependencies.

Important

Ubuntu Bionic stack is deprecated and will be removed in a future release. VMware recommends that you migrate builds to Jammy stacks. For Tanzu Application Platform v1.5 and later, the default stack for Tanzu Build Service is Jammy.

To build OCI images, Tanzu Build Service has the following dependencies: Cloud Native Buildpacks, Stacks, and Lifecycles.

How dependencies are installed

When Tanzu Application Platform is installed with Tanzu Build Service, it is bootstrapped with a set of dependencies. No extra configuration is required. Each version of Tanzu Application Platform and Tanzu Build Service contains new dependencies.

When Tanzu Application Platform is upgraded, new dependencies are installed which might cause workload images to rebuild. To ensure dependency compatibility, Tanzu Build Service only releases patches for dependencies in patch versions of Tanzu Application Platform. For upgrade instructions, see Upgrade the full dependencies package.

By default, Tanzu Build Service is installed with the `lite` set of dependencies, which have a smaller-footprint and contain a subset of the buildpacks and stacks in the `full` set of dependencies. For a comparison of `lite` and `full` dependencies, see Dependency comparison.

View installed dependencies

To view the set of dependencies installed with Tanzu Build Service, inspect the status of the cluster builders by running:

```
kubectl get clusterbuilder -o yaml
```

Cluster builders contain stack and buildpack metadata.

Bionic and Jammy stacks

Tanzu Application Platform v1.3 and later supports Ubuntu v22.04 (Jammy) based builds and will default to it from Tanzu Application Platform v1.5 and later.

Ubuntu Bionic will stop receiving support in April 2023. VMware recommends that you migrate builds to Jammy.

For more information about support for Jammy stacks, see About lite and full dependencies later in this topic.

Note

While upgrading apps to a later stack, you might encounter the build platform erroneously reusing the old build cache. If you encounter this issue, delete and recreate the workload in Tanzu Application Platform, or delete and recreate the image in Tanzu Build Service.

About lite and full dependencies

Each version of Tanzu Application Platform is released with two types of Tanzu Build Service dependencies: `lite` and `full`. These dependencies consist of the buildpacks and stacks required for application builds. Each type serves different use cases. Both types are suitable for production workloads.

By default, Tanzu Build Service is installed with `lite` dependencies, which do not contain all buildpacks and stacks. To use all buildpacks and stacks, you must install the `full` dependencies. For instructions about installing `full` dependencies, see Install full dependencies.

For a table comparing the differences between `full` and `lite` dependencies, see Dependency comparison.

Lite dependencies

The `lite` dependencies are the default set installed with Tanzu Build Service.

`lite` dependencies contain a smaller footprint to speed up installation time, but do not support all workload types. For example, `lite` dependencies do not contain the PHP buildpack and cannot be used to build PHP workloads.

Lite dependencies: stacks

The `lite` dependencies contain the following stacks:

- `base-jammy` (Ubuntu Jammy)
- `default` (identical to `base-jammy`)

For more information, see Stacks in the VMware Tanzu Buildpacks documentation

Lite dependencies: buildpacks

The `lite` dependencies contain the following buildpacks in Tanzu Application Platform v1.9:

Buildpack	Version	Supported Stacks
Java Buildpack for VMware Tanzu (Lite)	9.16.0	Bionic, Jammy, UBI
Java Native Image Buildpack for Tanzu (Lite)	7.14.0	Bionic, Jammy
.NET Core Buildpack for VMware Tanzu (Lite)	2.13.0	Bionic, Jammy, UBI
Node.js Buildpack for VMware Tanzu (Lite)	2.7.1	Bionic, Jammy, UBI
Python Buildpack for VMware Tanzu (Lite)	2.9.1	Bionic, Jammy
Go Buildpack for VMware Tanzu (Lite)	3.3.1	Bionic, Jammy, Jammy Static
Web Servers Buildpack for VMware Tanzu (Lite)	0.19.0	Bionic, Jammy, UBI
Ruby Buildpack for VMware Tanzu (Lite)	2.12.1	Bionic, Jammy

And the following components:

Component	Version	Supported Stacks
CNB Lifecycle	0.16.0	Bionic, Jammy
Base Stack of Ubuntu Jammy for VMware Tanzu	0.1.88	Jammy

Full dependencies

The Tanzu Build Service `full` set of dependencies contain more buildpacks and stacks, which allows for more workload types.

The dependencies are pre-packaged, so builds do not have to download them from the Internet. This can speed up build times and allows builds to occur in air-gapped environments. Due to the larger footprint of `full`, installations might take longer.

The `full` dependencies are not installed with Tanzu Build Service by default, you must install them. For instructions for installing `full` dependencies, see Install Tanzu Build Service with full dependencies.

Full dependencies: stacks

The `full` dependencies contain the following stacks, which support different use cases:

- `base-jammy` (Ubuntu Jammy)
- `full-jammy` (Ubuntu Jammy)
- `tiny-jammy` (Ubuntu Jammy)
- `default` (identical to `base-jammy`)

For more information, see Stacks in the VMware Tanzu Buildpacks documentation.

Full dependencies: buildpacks

The `full` dependencies contain the following buildpacks in Tanzu Application Platform v1.7:

Buildpack	Version	Supported Stacks
Java Buildpack for VMware Tanzu	9.16.0	Bionic, Jammy, UBI
Java Native Image Buildpack for Tanzu	7.14.0	Bionic, Jammy
.NET Core Buildpack for VMware Tanzu	2.13.0	Bionic, Jammy, UBI
Node.js Buildpack for VMware Tanzu	2.7.1	Bionic, Jammy, UBI
Python Buildpack for VMware Tanzu	2.9.1	Bionic, Jammy
Ruby Buildpack for VMware Tanzu	2.12.1	Bionic, Jammy
Go Buildpack for VMware Tanzu	3.3.1	Bionic, Jammy, Jammy Static
PHP Buildpack for VMware Tanzu	2.12.0	Bionic, Jammy
Web Servers Buildpack for VMware Tanzu	0.19.0	Bionic, Jammy, UBI
Procfile Buildpack for VMware Tanzu	5.7.0	Bionic, Jammy

And the following components:

Component	Version	Supported Stacks
CNB Lifecycle	0.16.0	Bionic, Jammy
Tiny Stack of Ubuntu Jammy for VMware Tanzu	0.1.92	Jammy
Base Stack of Ubuntu Jammy for VMware Tanzu	0.1.88	Jammy
Full Stack of Ubuntu Jammy for VMware Tanzu	0.1.148	Jammy
Standard Stack of UBI 8 for VMware Tanzu	0.0.13	UBI 8
Static Stack of Ubuntu Jammy for VMware Tanzu	0.1.28	Jammy

Dependency comparison

The following table compares the contents of the `lite` and `full` dependencies.

Feature	lite	full
Faster installation time	Yes	No
Dependencies pre-packaged (faster builds)	No	Yes
Supports air-gapped installation	No	Yes
Contains base stack	Yes	Yes
Contains full stack	No	Yes
Contains tiny stack	No	Yes
Contains Jammy stack	Yes	Yes
Supports Java workloads	Yes	Yes
Supports Node.js workloads	Yes	Yes
Supports Go workloads	Yes	Yes
Supports Python workloads	Yes	Yes
Supports Ruby workloads	Yes	Yes
Supports .NET Core workloads	Yes	Yes

Feature	lite	full
Supports PHP workloads	No	Yes
Supports static workloads	Yes	Yes
Supports binary workloads	Yes	Yes
Supports web servers buildpack	Yes	Yes

Update dependencies in band with Tanzu Application Platform releases

New versions of dependencies such as buildpacks, and stacks are available in new versions of Tanzu Application Platform. To update dependencies, VMware recommends that you update to the latest patch version of Tanzu Application Platform.

- If you are using `lite` or `full` dependencies, upgrade to the latest patch version of Tanzu Application Platform to update your dependencies.
- If you are using `full` dependencies, you must complete some extra steps after you upgrade to the latest patch. For more information, see Upgrading the full dependencies package.

Note

When Tanzu Application Platform is upgraded, new dependencies are installed which might cause workload images to rebuild.

Update dependencies out of band with Tanzu Application Platform releases

To update dependencies between Tanzu Application Platform releases, you can either use automatic dependency updates or you can update dependencies manually.

Automatic dependency updates

Tanzu Build Service dependencies might be upgraded between Tanzu Application Platform releases, for example, if a CVE is discovered in the OS (stack update) or language (buildpack update).

Automatic dependency updates enable your cluster to consume the stack and buildpack updates immediately instead of waiting for the next Tanzu Application Platform patch release to pull in the updated dependencies.

- Updates are provided through a separate package repository with available version lines for all supported Tanzu Application Platform minor versions.
- Within a version line, only patch versions are incremented to avoid breaking changes.
- You can customize the packages that you want the automatic dependency updater to update through your `tap-values.yaml` file or your full dependencies values.

Prerequisites: These steps assume a registry secret already exists in the cluster for accessing `registry.tanzu.vmware.com` and your registry.

To enable automatic dependency updates:

1. Add the following to your `tap-values.yaml` file:

```
buildservice:
  dependency_updates:
    allow: true
    scope: SCOPE
    include_packages: [""]
    exclude_packages: [""]
```

Where:

- `SCOPE` is the list of dependencies you want updated. The options are:
  - `stacks-only` (default): Only stacks and builders are updated. This addresses CVEs in the base image or operating system.
  - `all`: Stacks, builders, and buildpacks are updated. This addresses CVEs in the base image or operating system and CVEs in the language toolchain such as compilers, interpreters, and standard libraries.
  - `custom`: This list is empty by default. Use the `include_packages` key to add packages to be updated.

Note

You must update the Tanzu Application Platform package install and the Full Dependencies package install after changing the `tap-values.yaml`.

2. Add the Tanzu Build Service Dependency Updates package repository by running:

```
kubectl apply -f - <<EOF
  apiVersion: packaging.carvel.dev/v1alpha1
  kind: PackageRepository
  metadata:
    name: tbs-dependencies-package-repository
    namespace: tap-install
  spec:
    fetch:
      imgpkgBundle:
        image: DEPENDENCY-UPDATER-PACKAGE-REPO
        tagSelection:
          semver:
            constraints: VERSION-CONSTRAINT
EOF
```

Where:

- `DEPENDENCY-UPDATER-PACKAGE-REPO` is the location of the package repository. This is `registry.tanzu.vmware.com/build-service-dependency-updater/package-repo` for online installs and the internal container image registry for air-gapped installs.
- `VERSION-CONSTRAINT` is the Tanzu Application Platform version in the form of `MAJOR.MINOR.x`. For example, `1.8.x`.

After completing this configuration, the repository you set with `DEPENDENCY-UPDATER-PACKAGE-REPO` will be polled for updates and any new releases will automatically be made available to the cluster.

Manual dependency updates

You can update buildpack dependencies outside of upgrading Tanzu Application Platform, but VMware recommends that you upgrade Tanzu Application Platform when possible instead. Each Tanzu Application Platform release version includes a tested set of buildpacks. If you consume a

buildpack from VMware Tanzu Network that is not packaged and tested in a Tanzu Application Platform release, it might introduce errors.

1. Sign into VMware Tanzu Network so that the image can be retrieved from the registry.
2. Select the required buildpack in the Tanzu Buildpacks documentation. Select `full` or `lite` dependencies. Scroll to the Docker command, and copy the buildpack image URL for use in the next step.
3. Run:

   ```
   imgpkg copy -b BUILDPACK-IMAGE-URL --to-repo ${INSTALL_REGISTRY_HOSTNAME}/${INS
   TALL_REPO}/tbs-deps/BUILDPACK-LANGUAGE
   ```

   Where `BUILDPACK-IMAGE-URL` is the buildpack image URL copied from the Docker command in the previous step
4. Create a `ClusterBuildpack` resource referencing the copied buildpack image:

   ```
   apiVersion: kpack.io/v1alpha2
   kind: ClusterBuildpack
   metadata:
     name: out-of-band-LANGUAGE-NAME-BUILDPACK-VERSION
   spec:
     image: RELOCATED-BUILDPACKIMAGE
     serviceAccountRef:
       name: dependencies-pull-serviceaccount
       namespace: build-service
   ```

   Where `RELOCATED-BUILDPACKIMAGE` is the URL of the relocated buildpack image from previous step.

   To avoid naming collisions, follow the name conventions specified in `metadata.name`. The name can follow any convention that allows the Cluster Operator to distinguish this `ClusterBuildpack` from others installed by Tanzu Application Platform.
5. Apply the YAML from the previous step to the Tanzu Application Platform cluster:

   ```
   kubectl apply -f FILE-FROM-PREVIOUS-STEP
   ```

The `ClusterBuildpack` is now deployed. Tanzu Build Service uses the latest available version to run builds. All images that were built with older versions of the buildpack will now be rebuilt.

When you upgrade Tanzu Application Platform, new buildpacks with later versions are installed. After an upgrade, the `ClusterBuildpack` created in this procedure is not needed and can be removed.

Security context constraint for OpenShift

This topic tells you about running Tanzu Build Service on OpenShift clusters.

On OpenShift clusters Tanzu Build Service must run with a custom Security Context Constraint (SCC) to enable compliance. Tanzu Application Platform configures the following SCC for Tanzu Build Service when you configure the `kubernetes_distribution: openshift` key in the `tap-values.yaml` file.

```
---
kind: SecurityContextConstraints
apiVersion: security.openshift.io/v1
metadata:
  name: tbs-restricted-scc-with-seccomp
allowHostDirVolumePlugin: false
```

```
allowHostIPC: false
allowHostNetwork: false
allowHostPID: false
allowHostPorts: false
allowPrivilegeEscalation: false
allowPrivilegedContainer: false
allowedCapabilities:
  - NET_BIND_SERVICE
defaultAddCapabilities: null
fsGroup:
  type: RunAsAny
groups: []
priority: null
readOnlyRootFilesystem: false
requiredDropCapabilities:
  - ALL
runAsUser:
  type: MustRunAsNonRoot
seLinuxContext:
  type: MustRunAs
seccompProfiles:
  - runtime/default
supplementalGroups:
  type: RunAsAny
users: []
volumes:
  - configMap
  - downwardAPI
  - emptyDir
  - persistentVolumeClaim
  - projected
  - secret
```

It also applies the following RBAC to allow Tanzu Build Service services to use the SCC:

```
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  labels:
    apps.tanzu.vmware.com/aggregate-to-workload: "true"
  annotations:
    rbac.authorization.kubernetes.io/autoupdate: "true"
  name: system:tbs:scc:restricted-with-seccomp
rules:
  - apiGroups:
      - security.openshift.io
    resourceNames:
      - tbs-restricted-scc-with-seccomp
    resources:
      - securitycontextconstraints
    verbs:
      - use
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: system:tbs:scc:restricted-with-seccomp
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: system:tbs:scc:restricted-with-seccomp
subjects:
  - kind: ServiceAccount
    namespace: build-service
    name: dependency-updater-serviceaccount
```

```
  - kind: ServiceAccount
    namespace: build-service
    name: dependency-updater-controller-serviceaccount
  - kind: ServiceAccount
    namespace: build-service
    name: secret-syncer-service-account
  - kind: ServiceAccount
    namespace: build-service
    name: warmer-service-account
  - kind: ServiceAccount
    namespace: build-service
    name: build-service-daemonset-serviceaccount
  - kind: ServiceAccount
    namespace: cert-injection-webhook
    name: cert-injection-webhook-sa
  - kind: ServiceAccount
    namespace: kpack
    name: kp-default-repository-serviceaccount
  - kind: ServiceAccount
    namespace: kpack
    name: kpack-pull-lifecycle-serviceaccount
  - kind: ServiceAccount
    namespace: kpack
    name: controller
  - kind: ServiceAccount
    namespace: kpack
    name: webhook
  - kind: ServiceAccount
    namespace: stacks-operator-system
    name: controller-manager
```

Troubleshoot Tanzu Build Service

This topic tells you how to troubleshoot Tanzu Build Service when used with Tanzu Application Platform (commonly known as TAP).

Builds fail due to volume errors on EKS running Kubernetes v1.23

Symptom

After installing Tanzu Application Platform on or upgrading an existing Amazon Elastic Kubernetes Service (EKS) cluster to Kubernetes v1.23, build pods show:

```
'running PreBind plugin "VolumeBinding": binding volumes: timed out waiting
 for the condition'
```

Cause

This is due to the CSIMigrationAWS in this Kubernetes version, which requires users to install the Amazon EBS CSI driver to use AWS Elastic Block Store (EBS) volumes. See the Amazon documentation. For more information about EKS support for Kubernetes v1.23, see the Amazon blog post.

Tanzu Application Platform uses the default storage class which uses EBS volumes by default on EKS.

Solution

Follow the AWS documentation to install the Amazon EBS CSI driver before installing Tanzu Application Platform, or before upgrading to Kubernetes v1.23. See

---

Smart-warmer-image-fetcher reports ErrImagePull due to dockerd's layer depth limitation

Symptom

When using dockerd as the cluster's container runtime, you might see the `smart-warmer-image-fetcher` pods report a status of `ErrImagePull`.

Cause

This error might be due to dockerd's layer depth limitation, in which the maximum supported image layer depth is 125.

To verify that the `ErrImagePull` status is due to dockerd's maximum supported image layer depth, check for event messages containing the words `max depth exceeded`. For example:

```
$ kubectl get events -A | grep "max depth exceeded"
  build-service        73s         Warning     Failed         pod/smart-warmer-image-f
etcher-wxtr8     Failed to pull image
  "harbor.somewhere.com/aws-repo/build-service:clusterbuilder-full@sha256:065bb361fd91
4a3970ad3dd93c603241e69cca214707feaa6
  d8617019e20b65e":  rpc error: code = Unknown desc = failed to register layer: max de
pth exceeded
```

Solution

To work around this issue, configure your cluster to use containerd or CRI-O as its default container runtime. For instructions, see the following documentation for your Kubernetes cluster provider.

For AWS, see:

- The Amazon blog
- The eksctl CLI documentation

For AKS, see:

- The Microsoft Azure documentation
- The Microsoft Azure blog

For GKE, see:

- The GKE documentation

For OpenShift, see:

- The Red Hat Hybrid Cloud blog
- The Red Hat OpenShift documentation

Nodes fail due to "trying to send message larger than max" error

Symptom

You see the following error, or similar, in a node status:

```
Warning ContainerGCFailed 119s (x2523 over 42h) kubelet rpc error: code = ResourceExha
usted desc = grpc: trying to send message larger than max (16779959 vs. 16777216)
```

Cause

This is due to the way that the container runtime interface (CRI) handles garbage collection for unused images and containers.

Solution

Do not use Docker as the CRI because it is not supported. Some versions of EKS default to Docker as the runtime.

Build platform uses the old build cache after upgrade to new stack

Symptom

While upgrading apps to a later stack, you might encounter the build platform erroneously reusing the old build cache.

Solution

If you encounter this issue, delete, and recreate the workload in Tanzu Application Platform, or delete and recreate the image in Tanzu Build Service.

Switching from `buildservice.kp_default_repository` to `shared.image_registry`

Symptom

After switching to using the `shared.image_registry` fields in `tap-values.yaml`, your workloads might start failing with a `TemplateRejectedByAPIServer` error, with the error message: `admission webhook "validation.webhook.kpack.io" denied the request: validation failed: Immutable field changed: spec.tag`.

Cause

Tanzu Application Platform automatically appends `/buildservice` to the end of the repository specified in `shared.image_registry.project_path`. This updates the existing workload image tags, which is not allowed by Tanzu Build Service.

Solution

Delete the `images.kpack.io`, it has the same name as the workload. The workload then recreates it with valid values.

Alternatively, re-add the `buildservice.kp_default_repository_*` fields in the `tap-values.yaml`. You must set both the repository and the authentication fields to override the shared values. Set `kp_default_repository`, `kp_default_repository_secret.name`, and `kp_default_repository_secret.namespace`.

Failing builds during an upgrade

Symptom

During upgrades a large number of builds might be created due to buildpack and stack updates. Some of these builds might fail causing the workload to be in an unhealthy state.

Cause

Builds fail due to transient network issues.

Solution

This resolves itself on subsequent builds after a code change and does not affect the running application.

If you do not want to wait for subsequent builds to run, you can use either the Tanzu Build Service plug-in for the Tanzu CLI or the open source kpack CLI to trigger a build manually.

If using the Tanzu CLI, manually trigger a build as follows:

1. List the image resources in the developer namespace by running:

   ```
   tanzu build-service image list -n DEVELOPER-NAMESPACE
   ```

2. Manually trigger the image resources to re-run builds for each failing image by running:

   ```
   tanzu build-service image trigger IMAGE-NAME -n DEVELOPER-NAMESPACE
   ```

If using the kpack CLI, manually trigger a build as follows:

1. List the image resources in the developer namespace by running:

   ```
   kp image list -n DEVELOPER-NAMESPACE
   ```

2. Manually trigger the image resources to re-run builds for each failing image by running:

   ```
   kp image trigger IMAGE-NAME -n DEVELOPER-NAMESPACE
   ```

Create a GitHub build action (Alpha)

This topic tells you how to use a GitHub action to create a Tanzu Build Service build on a cluster.

Important

Alpha features are experimental and are not ready for production use. Configuration and behavior is likely to change, and functionality might be removed in a future release.

Prerequisites

- Ensure that Tanzu Application Platform is installed.

Procedure

Developer namespace

1. Create a developer namespace where the build resource will be created.

```
kubectl create namespace DEVELOPER-NAMESPACE
```

2. Create a service account in the `DEVELOPER-NAMESPACE` that has access to the registry credentials. This service account name will be used in the action.

Access to Kubernetes API server

The GitHub action talks directly to the Kubernetes API server, if you are running this on github.com with the default action runners, ensure that your API server is accessible from GitHub's IP ranges. Alternatively, it might be possible to run the action on a custom runner within your firewall (with access to the Tanzu Application Platform cluster).

Permissions Required

These are the minimum permissions required on the Tanzu Build Service cluster:

```
```bash
ClusterRole
 └ kpack.io
   └ clusterbuilders verbs=[get]
Role (DEVELOPER NAMESPACE)
 ├ ''
 │ ├ pods verbs=[get watch list] ✔
 │ └ pods/log verbs=[get] ✔
 └ kpack.io
   └ builds verbs=[get watch list create delete] ✔
```
```

This example contains the minimum required permissions:

```
```yaml
apiVersion: v1
kind: Namespace
metadata:
   name: DEVELOPER_NAMESPACE
---
apiVersion: v1
kind: ServiceAccount
metadata:
   namespace: DEVELOPER_NAMESPACE
   name: github-actions
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
   name: github-actions
subjects:
   - kind: ServiceAccount
     namespace: DEVELOPER_NAMESPACE
     name: github-actions
roleRef:
   kind: ClusterRole
   name: github-actions
   apiGroup: rbac.authorization.k8s.io
---
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
   name: github-actions
   namespace: DEVELOPER_NAMESPACE
subjects:
   - kind: ServiceAccount
```
```

```
     namespace: DEVELOPER_NAMESPACE
     name: github-actions
roleRef:
   kind: Role
   name: github-actions
   apiGroup: rbac.authorization.k8s.io
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
   name: github-actions
rules:
   - apiGroups: ['kpack.io']
     resources:
        - clusterbuilders
     verbs: ['get']
---
apiVersion: rbac.authorization.k8s.io/v1
kind: Role
metadata:
   name: github-actions
   namespace: DEVELOPER_NAMESPACE
rules:
   - apiGroups: ['']
     resources: ['pods']
     verbs: ['get', 'watch', 'list']
   - apiGroups: ['']
     resources: ['pods/log']
     verbs: ['get']
   - apiGroups: ['kpack.io']
     resources:
        - builds
     verbs: ['get', 'watch', 'list', 'create', 'delete']
```

To access the values on Google Kubernetes Engine (steps might vary on other IaaS providers):

```
  ```console
  DEV_NAMESPACE=DEVELOPER_NAMESPACE
  SECRET=$(kubectl get sa github-actions -oyaml -n $DEV_NAMESPACE | yq '.secrets[0].na
me')

  CA_CERT=$(kubectl get secret $SECRET -oyaml -n $DEV_NAMESPACE | yq '.data."ca.crt"')
  NAMESPACE=$(kubectl get secret $SECRET -oyaml -n $DEV_NAMESPACE | yq .data.namespace
| base64 -d)
  TOKEN=$(kubectl get secret $SECRET -oyaml -n $DEV_NAMESPACE | yq .data.token | base6
4 -d)
  SERVER=$(kubectl config view --minify | yq '.clusters[0].cluster.server')
  ```
```

Create the required secrets on the repository through GitHub.com or through the `gh` CLI:

```
```bash
gh secret set CA_CERT --app actions --body "$CA_CERT"
gh secret set NAMESPACE --app actions --body "$NAMESPACE"
gh secret set TOKEN --app actions --body "$TOKEN"
gh secret set SERVER --app actions --body "$SERVER"
```
```

Use the action

1. To use the action in a workflow, run the following YAML:

```
- uses: vmware-tanzu/build-image-action@v1-alpha
  with:
    ## Authorization
    # Host of the API server
    server: `${{ secrets.SERVER }}`
    # CA Certificate of the API Server
    ca_cert: `${{ secrets.CA_CERT }}`
    # Service Account token to access Kubernetes
    token: `${{ secrets.TOKEN }}`
    # _(required)_ The namespace to create the build resource in
    namespace: `${{ secrets.NAMESPACE }}`

    ## Image configuration
    # _(required)_ Destination for the built image
    # Example: gcr.io/<my-project>/<my-image>
    destination: ''
    # Optional list of build time environment variables
    env: ''
    # Name of the service account in the namespace, defaults to `default`
    serviceAccountName: ''
    # Name of the cluster builder to use, defaults to `default`
    clusterBuilder: ''
    # Max active time that the pod can run for in seconds, defaults to 3600
    timeout:
```

For example:

```
- name: Build Image
  id: build
  uses: vmware-tanzu/build-image-action@v1-alpha
  with:
    # Authorization
    server: ${{ secrets.SERVER }}
    token: ${{ secrets.TOKEN }}
    ca_cert: ${{ secrets.CA_CERT }}
    namespace: ${{ secrets.NAMESPACE }}
    # Image configuration
    destination: gcr.io/project-id/name-for-image
    serviceAccountName: my-sa-that-has-access-to-reg-credentials
    env: |
      BP_JAVA_VERSION=17
```

2. The previous step should output the full name, including the SHA of the built image. To use the output in a subsequent step:

```
- name: Do something with image
  run:
    echo "${{ steps.build.outputs.name }}"
```

Debugging

To run this action in “debug” mode, add a secret called `ACTIONS_STEP_DEBUG` with the value set to `true` as documented in the GitHub Action Docs.

Overview of Tanzu Buildpacks

This topic describes how to use Tanzu Buildpacks in Tanzu Application Platform (commonly known as TAP).

Tanzu Buildpacks provide framework and runtime support for applications. Buildpacks examine your applications to determine what dependencies to download, install, and how to configure the

applications to communicate with bound services.

Tanzu Buildpacks use open-source Paketo Buildpacks to allow Tanzu Application Platform users to turn their application source code into container images.

In Tanzu Application Platform v1.6 and later, builders, stacks, and buildpacks are packaged separately from Tanzu Build Service. They are included in the Full, Iterate, and Build installation profiles. All buildpacks follow the package name format `*.buildpacks.tanzu.vmware.com`.

For information about how to install buildpacks and stacks and the versions available in the `lite` and `full` profiles, see About lite and full dependencies.

For information about how to configure Tanzu Buildpacks features and components, see Tanzu Buildpack Documentation.

Overview of Tanzu Developer Portal

Tanzu Developer Portal is a tool for your developers to view your applications and services running for your organization. This portal provides a central location in which you can view dependencies, relationships, technical documentation, and the service status.

Tanzu Developer Portal is built from the Cloud Native Computing Foundation's project Backstage.

Tanzu Developer Portal consists of the following components:

- **Your organization catalog:**

  The catalog serves as the primary visual representation of your running services (components) and applications (systems).

- **Tanzu Developer Portal plug-ins:**

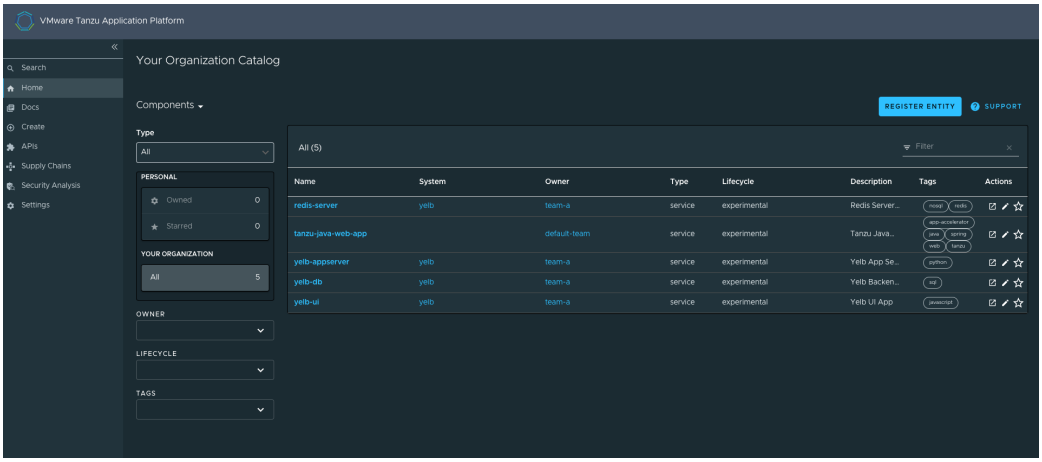
  These plug-ins expose capabilities regarding specific Tanzu Application Platform tools. Initially the included plug-ins are:

  - Runtime Resources Visibility
  - Application Live View
  - Application Accelerator
  - API Documentation

    - Supply Chain Choreographer

- **TechDocs:**

  This plug-in enables you to store your technical documentation in Markdown format in a source-code repository and display it alongside the relevant catalog entries.



- **Search:**

  This plug-in enables you to search your organization's catalog, including domains, systems, components, APIs, accelerators, and TechDocs.

- **A Git repository:**

  Tanzu Developer Portal stores the following in a Git repository:

    - The structure for your application catalog.
    - Your technical documentation about the catalog items, if you enable Tanzu Developer Portal TechDocs capabilities.

You can host the structure for your application catalog and your technical documentation in the same repository as your source code.

    - Your technical documentation about the catalog items, if you enable Tanzu Developer Portal TechDocs capabilities.

You can host the structure for your application catalog and your technical documentation in the same repository as your source code.

Install Tanzu Developer Portal

This topic tells you how to install Tanzu Developer Portal from the Tanzu Application Platform package repository.

> **Note**
>
> Follow the steps in this topic if you do not want to use a profile to install Tanzu Developer Portal. For more information about profiles, see Components and installation profiles.

Prerequisites

Before installing Tanzu Developer Portal:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see the Tanzu Application Platform Prerequisites.
- Create a Git repository for Tanzu Developer Portal software catalogs, with a token allowing read access. Supported Git infrastructure includes:
    - GitHub

    - GitLab
    - Azure DevOps
- Install Tanzu Developer Portal Blank Catalog
    1. Go to the Tanzu Application Platform section of VMware Tanzu Network.
    2. Under the list of available files to download, open the **tanzu-developer-portal-catalogs-latest** folder.
    3. Extract Tanzu Developer Portal Blank Catalog to your Git repository. This serves as the configuration location for your organization's Catalog inside Tanzu Developer Portal.

Procedure

To install Tanzu Developer Portal on a compliant Kubernetes cluster:

1. List version information for the package by running:

    ```
    tanzu package available list tap-gui.tanzu.vmware.com --namespace tap-install
    ```

    For example:

    ```
    $ tanzu package available list tap-gui.tanzu.vmware.com --namespace tap-install
    - Retrieving package versions for tap-gui.tanzu.vmware.com...
      NAME                      VERSION     RELEASED-AT
      tap-gui.tanzu.vmware.com  1.0.1       2022-01-10T13:14:23Z
    ```

2. (Optional) Make changes to the default installation settings by running:

    ```
    tanzu package available get tap-gui.tanzu.vmware.com/VERSION-NUMBER --values-sc
    hema --namespace \
    tap-install
    ```

    Where `VERSION-NUMBER` is the number you discovered previously. For example, `1.0.1`.

    For more information about values schema options, see the individual product documentation.

3. Create `tap-gui-values.yaml` and paste in the following YAML:

    ```
    ingressEnabled: true
    ingressDomain: "INGRESS-DOMAIN"
    app_config:
      catalog:
        locations:
          - type: url
            target: https://GIT-CATALOG-URL/catalog-info.yaml
    ```

    Where:

    - `INGRESS-DOMAIN` is the subdomain for the host name that you point at the `tanzu-shared-ingress` service's External IP address.
    - `GIT-CATALOG-URL` is the path to the `catalog-info.yaml` catalog definition file. It is from either the included Blank catalog (provided as an additional download named **Blank Tanzu Developer Portal Catalog**) or a Backstage-compliant catalog that you've already built and posted on the Git infrastructure specified in Adding Tanzu Developer Portal integrations.

4. Install the package by running:

```
tanzu package install tap-gui \
 --package tap-gui.tanzu.vmware.com \
 --version VERSION -n tap-install \
 --values-file tap-gui-values.yaml
```

Where `VERSION` is the version that you want. For example, `1.0.1`.

For example:

```
$ tanzu package install tap-gui --package tap-gui.tanzu.vmware.com --version 1.
0.1 -n \
tap-install --values-file tap-gui-values.yaml
- Installing package 'tap-gui.tanzu.vmware.com'
| Getting package metadata for 'tap-gui.tanzu.vmware.com'
| Creating service account 'tap-gui-default-sa'
| Creating cluster admin role 'tap-gui-default-cluster-role'
| Creating cluster role binding 'tap-gui-default-cluster-rolebinding'
| Creating secret 'tap-gui-default-values'
- Creating package resource
- Package install status: Reconciling

 Added installed package 'tap-gui' in namespace 'tap-install'
```

5. Verify that the package installed by running:

```
tanzu package installed get tap-gui -n tap-install
```

For example:

```
$ tanzu package installed get tap-gui -n tap-install
| Retrieving installation details for cc...
NAME:                    tap-gui
PACKAGE-NAME:            tap-gui.tanzu.vmware.com
PACKAGE-VERSION:         1.0.1
STATUS:                  Reconcile succeeded
CONDITIONS:              [{ReconcileSucceeded True  }]
USEFUL-ERROR-MESSAGE:
```

Verify that `STATUS` is `Reconcile succeeded`.

6. To access Tanzu Developer Portal, use the service you exposed in the `service_type` field in the values file.

Runtime configuration options for Tanzu Developer Portal

You can provide a series of options to the Tanzu Developer Portal package to configure it and do some basic runtime customization.

Identify the Tanzu Developer Portal version you have available

From the Tanzu CLI, discover the Tanzu Developer Portal package version that is available to configure by running:

```
tanzu package available get tap-gui.tanzu.vmware.com -n INSTALL-NAMESPACE
```

Where `INSTALL-NAMESPACE` is the namespace in which you configured the Tanzu Application Platform installation. In most cases the namespace is `tap-install`.

For example:

```
$ tanzu package available get tap-gui.tanzu.vmware.com -n tap-install

NAME:                    tap-gui.tanzu.vmware.com
DISPLAY-NAME:            Tanzu Application Platform GUI
CATEGORIES:
SHORT-DESCRIPTION:       web app graphical user interface for Tanzu Application Platfor
m
LONG-DESCRIPTION:        web app graphical user interface for Tanzu Application Platfor
m
PROVIDER:                VMware
MAINTAINERS:             - name: VMware
SUPPORT-DESCRIPTION:     https://tanzu.vmware.com/support

  VERSION  RELEASED-AT
  1.7.6    2023-10-17 00:25:21 +0000 UTC
```

Display the possible values options for Tanzu Developer Portal

From the Tanzu CLI, identify possible values options for Tanzu Developer Portal by running:

```
tanzu package available get tap-gui.tanzu.vmware.com/VERSION --values-schema -n INSTAL
L-NAMESPACE
```

Where:

- `VERSION` is the Tanzu Developer Portal package version you learned earlier
- `INSTALL-NAMESPACE` is the namespace in which you configured the Tanzu Application Platform installation. In most cases the namespace is `tap-install`.

For example:

```
$ tanzu package available get tap-gui.tanzu.vmware.com/1.7.6 --values-schema -n tap-in
stall

  KEY                                                              DEFAULT   TYPE
DESCRIPTION
  #Details of all the possible configuration values
  ...
```

Runtime customization of Tanzu Developer Portal

This topic tells you how to use runtime configuration parameters to customize the existing functions of your currently running portal.

This configuration entails changing the values file that you built while installing the portal, and then re-applying those changes to the running configuration. The actual steps can vary depending on how you performed the installation. The basic steps of updating your values file are described in Customize your package installation.

To learn how to add additional plug-ins and features to your portal by using build-time customization, see Overview of Configurator.

Customize branding

To customize the branding in your portal, you can choose the name of the portal and the logo for it. To make these customizations:

1. Provide additional configuration parameters to the `app_config` section of `tap-values.yaml`:

```
tap_gui:
  app_config:
    customize:
      custom_logo: 'BASE-64-IMAGE'
      custom_name: 'PORTAL-NAME'
```

Where:

- `BASE-64-IMAGE` is the image encoded in base64. A 512-pixel by 512-pixel PNG image with a transparent background is optimal.
- `PORTAL-NAME` is the name of your portal, such as `Our Custom Developer Experience Portal`.

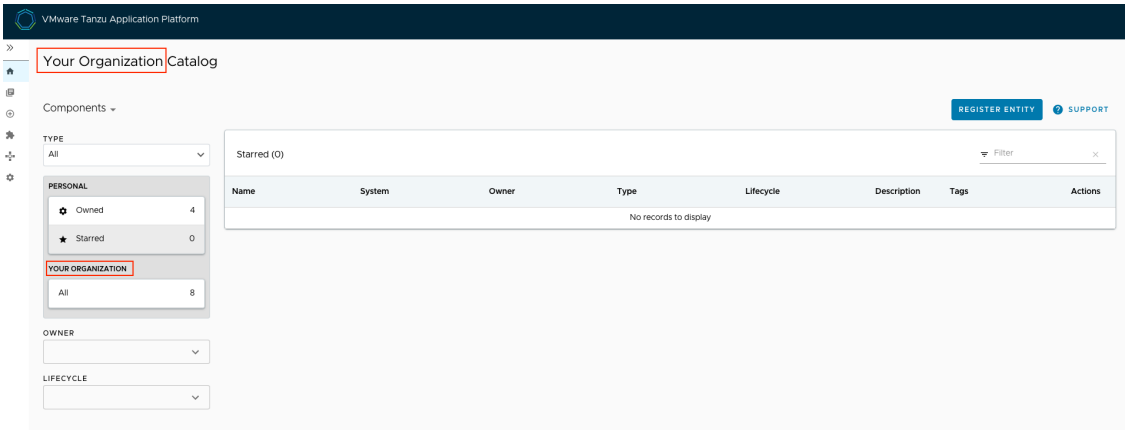
2. Reinstall your Tanzu Developer Portal package by following steps in Upgrading Tanzu Application Platform.

After the updated values configuration file is applied in Tanzu Developer Portal, you see the customized version of your portal.

If there is an error in any of the supplied images encoded in base64 or in your choice of portal name, Tanzu Developer Portal reverts to the original branding template.

Customize the Software Catalog page

You can customize the name of your organization on the Software Catalog page of Tanzu Developer Portal. By default, the portal displays **Your Organization** next to **Catalog** and in the selection box.



Customize the name of the organization

To customize the name of the organization for the software catalog in your portal:

1. Provide additional configuration parameters to the `app_config` section of your `tap-values.yaml` file:

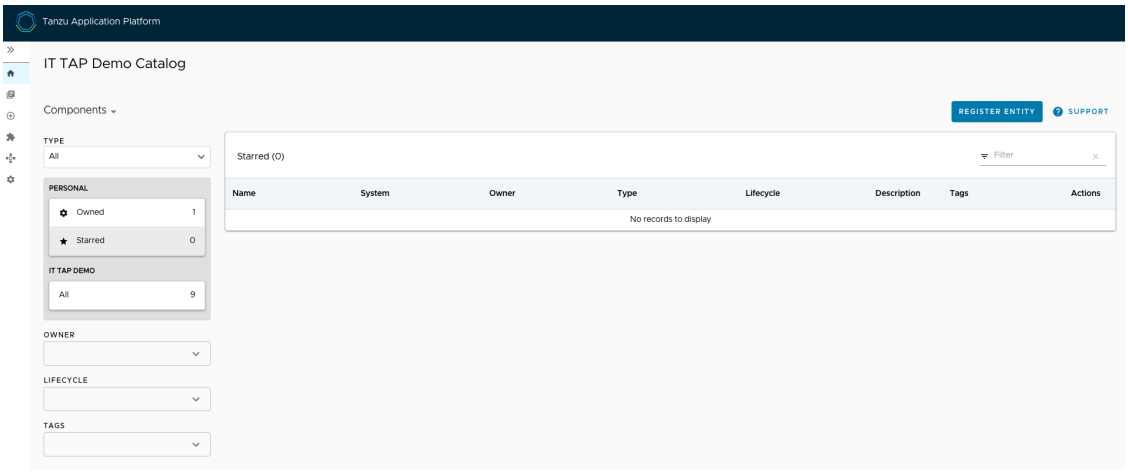
```
tap_gui:
  app_config:
    organization:
      name: 'ORG-NAME'
```

Where `ORG-NAME` is the name of your organization for the software catalog, such as `Our Organization Name`. You don't need to add `Catalog` to the `ORG-NAME`.

2. Reinstall your Tanzu Developer Portal package by following the steps in Upgrading Tanzu Application Platform.

After the updated values configuration file is applied in Tanzu Developer Portal, you see the customized version of your portal.

If there is an error in the provided configuration parameters, Tanzu Developer Portal reverts to the original organization name.



Prevent changes to the software catalog

You can deactivate the **Register Entity** button to prevent a user from making changes to the software catalog, including registering and deregistering locations. To do so, add `readonly: true` to the `catalog` section in `tap-values.yaml`, as in this example:

```
tap_gui:
  app_config:
    catalog:
      readonly: true
```

Customize the Authentication page

To customize the portal name on the **Authentication** page and the name of the browser tab for Tanzu Developer Portal:

1. Provide additional configuration parameters to the `app_config` section of your `tap-values.yaml` file:

   ```
   tap_gui:
     app_config:
       app:
         title: 'CUSTOM-TAB-NAME'
   ```

   Where `CUSTOM-TAB-NAME` is the name on the Authentication page and the browser tab of your portal, such as `Our Organization Full Name`.

2. Reinstall your Tanzu Developer Portal package by following the steps in Upgrading Tanzu Application Platform.

After the updated values configuration file is applied in Tanzu Developer Portal, you see the customized version of your portal.

Customize the default view

You can set your default route when the user is accessing your portal. Without this customization, when the user accesses the Tanzu Developer Portal URL, it displays the list of owned components of the software catalog.

To change the default view:

1. Provide additional configuration parameters to the `app_config` section of your `tap-values.yaml` file:

   ```
   tap_gui:
     app_config:
       customize:
         default_route: 'YOUR-PREFERRED-ROUTE'
   ```

   Where `YOUR-PREFERRED-ROUTE` is the path to the route that the portal uses by default. For example, you can type `/catalog?filters%5Bkind%5D=component&filters%5Buser%5D=all` to show all components of the software catalog instead of defaulting to owned components. As another example, you can type `/create` to show Application Accelerator when the portal starts.

   Caution

   Tanzu Developer Portal redirects you to `tap-gui.INGRESS-DOMAIN/YOUR-PREFERRED-ROUTE` even if there is an error in `YOUR-PREFERRED-ROUTE`.

2. Reinstall your Tanzu Developer Portal package by following the steps in Upgrading Tanzu Application Platform.

After the updated values configuration file is applied in Tanzu Developer Portal, you see the customized version of your portal.

Customize security banners

You can instruct Tanzu Developer Portal to create security banners on the top and bottom of the page. To add security banners to Tanzu Developer Portal:

1. Provide additional configuration parameters to the `app_config` section of your `tap-values.yaml` file, as in the following example:

   ```
   tap_gui:
     app_config:
       customize:
         banners:
           text: 'CUSTOM-TEXT'
           color: 'OPTIONAL-CUSTOM-TEXT-COLOR'
           bg: 'CUSTOM-BACKGROUND-COLOR'
           link: 'OPTIONAL-LINK'
   ```

   Where:

   - `CUSTOM-TEXT` is the text that is displayed in the banner. Keep this text short to accommodate various screen sizes.
   - `OPTIONAL-CUSTOM-TEXT-COLOR` is the color of the text displayed in the banner. Setting this is optional. It accepts CSS colors, such as `#ffffff`. The default color is `#FFFFFF`.
   - `CUSTOM-BACKGROUND-COLOR` is the color of the banner itself. Setting this is optional. It accepts CSS colors, such as `#ffffff`. The default color is `#C23B2E`
   - `OPTIONAL-LINK` is the link to which your text redirects. Setting this is optional.

2. Reinstall your Tanzu Developer Portal package by following the steps in Upgrading Tanzu Application Platform.

After the updated values configuration file is applied in Tanzu Developer Portal, the customized version of your portal is displayed.

Runtime customization of Tanzu Developer Portal

This topic tells you how to use runtime configuration parameters to customize the existing functions of your currently running portal.

This configuration entails changing the values file that you built while installing the portal, and then re-applying those changes to the running configuration. The actual steps can vary depending on how you performed the installation. The basic steps of updating your values file are described in Customize your package installation.

To learn how to add additional plug-ins and features to your portal by using build-time customization, see Overview of Configurator.

Customize branding

To customize the branding in your portal, you can choose the name of the portal and the logo for it. To make these customizations:

1. Provide additional configuration parameters to the `app_config` section of `tap-values.yaml`:

   ```
   tap_gui:
     app_config:
       customize:
         custom_logo: 'BASE-64-IMAGE'
         custom_name: 'PORTAL-NAME'
   ```

   Where:

   - `BASE-64-IMAGE` is the image encoded in base64. A 512-pixel by 512-pixel PNG image with a transparent background is optimal.
   - `PORTAL-NAME` is the name of your portal, such as `Our Custom Developer Experience Portal`.

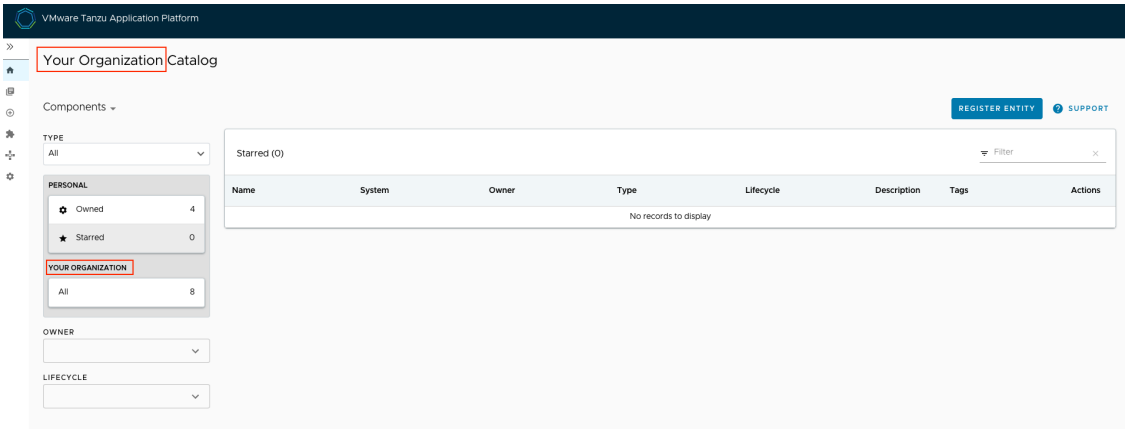
2. Reinstall your Tanzu Developer Portal package by following steps in Upgrading Tanzu Application Platform.

After the updated values configuration file is applied in Tanzu Developer Portal, you see the customized version of your portal.

If there is an error in any of the supplied images encoded in base64 or in your choice of portal name, Tanzu Developer Portal reverts to the original branding template.

Customize the Software Catalog page

You can customize the name of your organization on the Software Catalog page of Tanzu Developer Portal. By default, the portal displays **Your Organization** next to **Catalog** and in the selection box.



Customize the name of the organization

To customize the name of the organization for the software catalog in your portal:

1. Provide additional configuration parameters to the `app_config` section of your `tap-values.yaml` file:

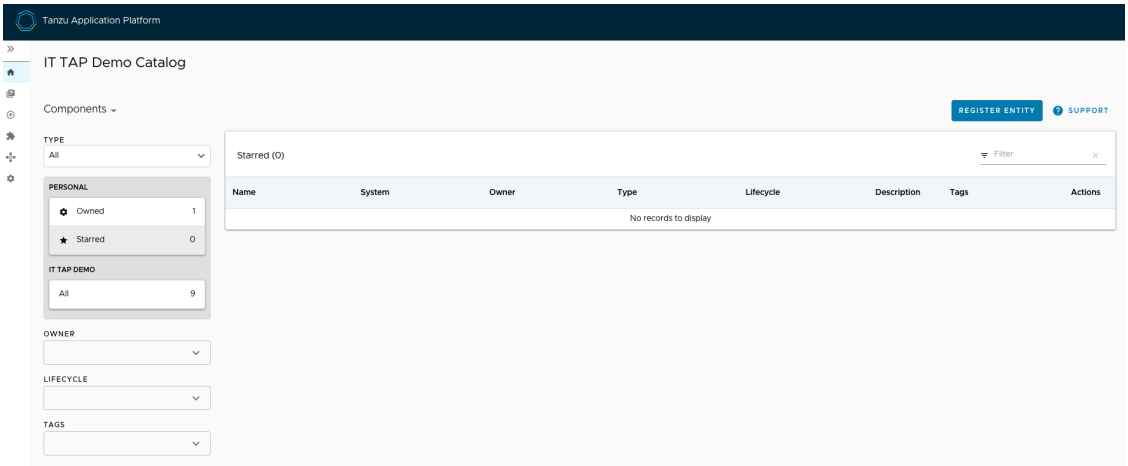
   ```
   tap_gui:
     app_config:
       organization:
         name: 'ORG-NAME'
   ```

   Where `ORG-NAME` is the name of your organization for the software catalog, such as `Our Organization Name`. You don't need to add `Catalog` to the `ORG-NAME`.

2. Reinstall your Tanzu Developer Portal package by following the steps in Upgrading Tanzu Application Platform.

After the updated values configuration file is applied in Tanzu Developer Portal, you see the customized version of your portal.

If there is an error in the provided configuration parameters, Tanzu Developer Portal reverts to the original organization name.



Prevent changes to the software catalog

You can deactivate the **Register Entity** button to prevent a user from making changes to the software catalog, including registering and deregistering locations. To do so, add `readonly: true` to the `catalog` section in `tap-values.yaml`, as in this example:

```
tap_gui:
  app_config:
    catalog:
      readonly: true
```

Customize the Authentication page

To customize the portal name on the **Authentication** page and the name of the browser tab for Tanzu Developer Portal:

1. Provide additional configuration parameters to the `app_config` section of your `tap-values.yaml` file:

   ```
   tap_gui:
     app_config:
       app:
         title: 'CUSTOM-TAB-NAME'
   ```

   Where `CUSTOM-TAB-NAME` is the name on the Authentication page and the browser tab of your portal, such as `Our Organization Full Name`.

2. Reinstall your Tanzu Developer Portal package by following the steps in Upgrading Tanzu Application Platform.

After the updated values configuration file is applied in Tanzu Developer Portal, you see the customized version of your portal.

Customize the default view

You can set your default route when the user is accessing your portal. Without this customization, when the user accesses the Tanzu Developer Portal URL, it displays the list of owned components of the software catalog.

To change the default view:

1. Provide additional configuration parameters to the `app_config` section of your `tap-values.yaml` file:

   ```
   tap_gui:
     app_config:
       customize:
         default_route: 'YOUR-PREFERRED-ROUTE'
   ```

   Where `YOUR-PREFERRED-ROUTE` is the path to the route that the portal uses by default. For example, you can type `/catalog?filters%5Bkind%5D=component&filters%5Buser%5D=all` to show all components of the software catalog instead of defaulting to owned components. As another example, you can type `/create` to show Application Accelerator when the portal starts.

   Caution

   Tanzu Developer Portal redirects you to `tap-gui.INGRESS-DOMAIN/YOUR-PREFERRED-ROUTE` even if there is an error in `YOUR-PREFERRED-ROUTE`.

2. Reinstall your Tanzu Developer Portal package by following the steps in Upgrading Tanzu Application Platform.

After the updated values configuration file is applied in Tanzu Developer Portal, you see the customized version of your portal.

Customize security banners

You can instruct Tanzu Developer Portal to create security banners on the top and bottom of the page. To add security banners to Tanzu Developer Portal:

1. Provide additional configuration parameters to the `app_config` section of your `tap-values.yaml` file, as in the following example:

   ```
   tap_gui:
     app_config:
       customize:
         banners:
           text: 'CUSTOM-TEXT'
           color: 'OPTIONAL-CUSTOM-TEXT-COLOR'
           bg: 'CUSTOM-BACKGROUND-COLOR'
           link: 'OPTIONAL-LINK'
   ```

   Where:

   - `CUSTOM-TEXT` is the text that is displayed in the banner. Keep this text short to accommodate various screen sizes.
   - `OPTIONAL-CUSTOM-TEXT-COLOR` is the color of the text displayed in the banner. Setting this is optional. It accepts CSS colors, such as `#ffffff`. The default color is `#FFFFFF`.
   - `CUSTOM-BACKGROUND-COLOR` is the color of the banner itself. Setting this is optional. It accepts CSS colors, such as `#ffffff`. The default color is `#C23B2E`
   - `OPTIONAL-LINK` is the link to which your text redirects. Setting this is optional.

2. Reinstall your Tanzu Developer Portal package by following the steps in Upgrading Tanzu Application Platform.

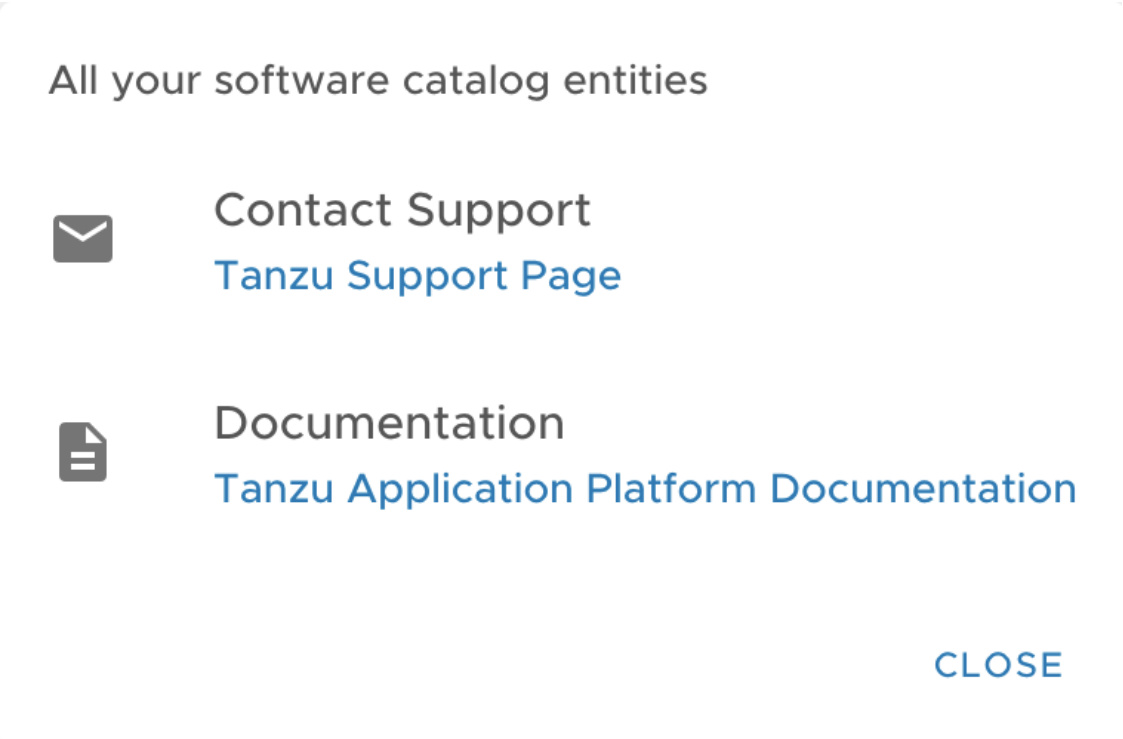
After the updated values configuration file is applied in Tanzu Developer Portal, the customized version of your portal is displayed.

Customize the Support menu

This topic describes how to customize the support menu.

Overview

Many important pages of Tanzu Developer Portal have a **Support** button that displays a pop-out menu. This menu contains a one-line description of the page the user is looking at, and a list of support item groupings.



As standard, there are two support item groupings:

- Contact Support, which is marked with an **email** icon and contains a link to VMware Tanzu's support portal.
- Documentation, which is marked with a **docs** icon and contains a link to the Tanzu Application Platform documentation that you are currently reading.

Customizing

The set of support item groupings is completely customizable. However, you might want to offer custom in-house links for your Tanzu Application Platform users rather than simply sending them to VMware support and documentation. You can provide this configuration by using your `tap-values.yaml`. Here is a configuration snippet, which produces the default support menu:

```
tap_gui:
  app_config:
    app:
      support:
        url: https://tanzu.vmware.com/support
        items:
          - title: Contact Support
            icon: email
            links:
              - url: https://tanzu.vmware.com/support
                title: Tanzu Support Page
          - title: Documentation
            icon: docs
            links:
              - url: https://docs.vmware.com/en/VMware-Tanzu-Application-Platform/inde
x.html
                title: Tanzu Application Platform Documentation
```

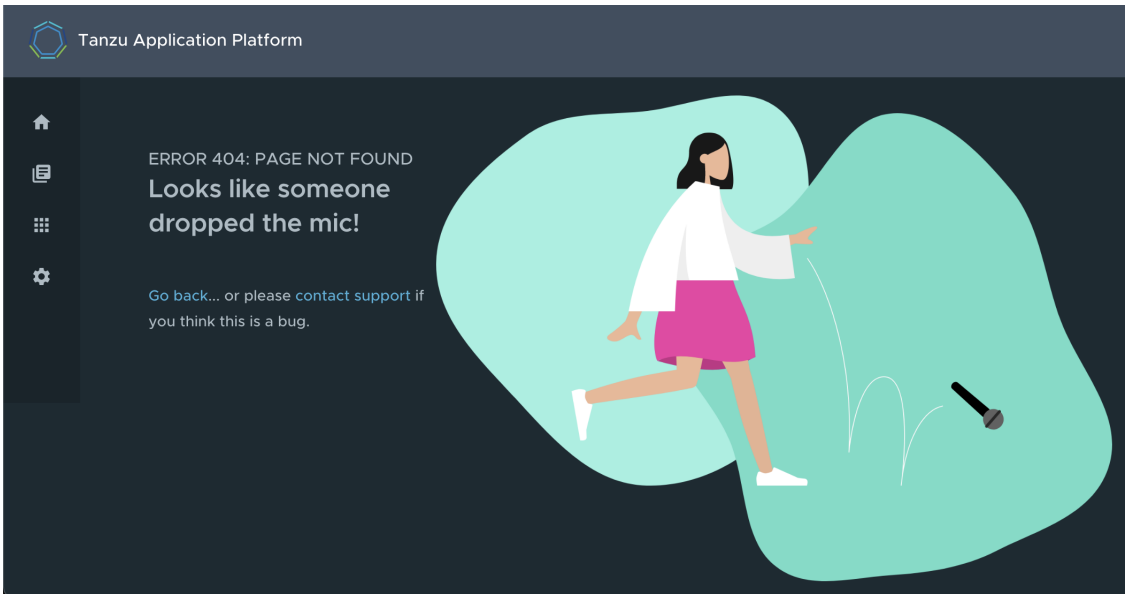
Structure of the support configuration

URL

The `url` field under the `support` section, for example,

```
    support:
      url: https://tanzu.vmware.com/support
```

provides the address of the **contact support** link that appears on error pages.



Items

The `items` field under the `support` section, for example, provides the set of support item groupings to display when the support menu is expanded.

Title

The `title` field on a support item grouping, for example,

```
      items:
        - title: Contact Support
```

provides the label for the grouping.

Icon

The `icon` field on a support item grouping, for example,

```
      items:
        - icon: email
```

provides the icon to use for that grouping. The valid choices are:

- `brokenImage`
- `catalog`
- `chat`
- `dashboard`
- `docs`
- `email`
- `github`

- `group`
- `help`
- `user`
- `warning`

Links

The `links` field on a support item grouping, for example,

```
        items:
          - links:
              - url: https://tanzu.vmware.com/support
                title: Tanzu Support Page
```

is a list of YAML objects that render as links. Each link has the text given by the `title` field and links to the value of the `url` field.

Customize the Tanzu Developer Portal telemetry collection

This section tells you how to customize telemetry collection for Tanzu Developer Portal.

Customize organization ID

By default, each instance of Tanzu Developer Portal is assigned to a random organization ID to ensure that your sensitive information is not revealed.

However, you can choose to customize your organization ID and self-identify. Doing so allows VMware to observe account-level telemetry, such as frequency of portal use, most popular function, and so on. All personally identifiable information remains anonymized in any case. The organization name is hashed to prevent VMware from identifying you by the value.

To customize:

1. Provide additional configuration parameters to the `app_config` section of `tap-values.yaml`:

   ```
   tap_gui:
    app_config:
      pendoAnalytics:
        organizationId: 'ORGANIZATION-NAME'
   ```

   Where `ORGANIZATION-NAME` is the name of your organization or the name of the Tanzu Developer Portal instance of your choice. `ORGANIZATION-NAME` must be unique and static across an instance of Tanzu Developer Portal so that your organization name remains the same across refreshes of the Tanzu Application Platform database.

2. Reinstall your Tanzu Developer Portal package by following the steps in Upgrade Tanzu Application Platform.

After the updated values configuration file is applied in Tanzu Developer Portal, your organization ID is updated.

Access Tanzu Developer Portal

This topic tells you how to access Tanzu Developer Portal by using one of the following methods:

- Access with the LoadBalancer method (default)
- Access with the shared Ingress method

Access with the LoadBalancer method (default)

1. Verify that you specified the `service_type` for Tanzu Developer Portal in `tap-values.yaml`, as in this example:

   ```
   tap_gui:
     service_type: LoadBalancer
   ```

2. Obtain the external IP address of your LoadBalancer by running:

   ```
   kubectl get svc -n tap-gui
   ```

3. Access Tanzu Developer Portal by using the external IP address with the default port of 7000. It has the following form:

   ```
   http://EXTERNAL-IP:7000
   ```

   Where `EXTERNAL-IP` is the external IP address of your LoadBalancer.

Access with the shared Ingress method

The Ingress method of access for Tanzu Developer Portal uses the shared `tanzu-system-ingress` instance of Contour that is installed as part of the Profile installation.

1. The Ingress method of access requires that you have a DNS host name that you can point at the External IP address of the `envoy` service that the shared `tanzu-system-ingress` uses. Retrieve this IP address by running:

   ```
   kubectl get service envoy -n tanzu-system-ingress
   ```

   This returns a value similar to this example:

   ```
   $ kubectl get service envoy -n tanzu-system-ingress
   NAME    TYPE           CLUSTER-IP     EXTERNAL-IP      PORT(S)
   AGE
   envoy   LoadBalancer   10.0.242.171   40.118.168.232   80:31389/TCP,443:31780/T
   CP   27h
   ```

   The IP address in the `EXTERNAL-IP` field is the one that you point a DNS host record to. Tanzu Developer Portal prepends `tap-gui` to your provided subdomain. This makes the final host name `tap-gui.YOUR-SUBDOMAIN`. You use this host name in the appropriate fields in the `tap-values.yaml` file mentioned later.

2. Specify parameters in `tap-values.yaml` related to Ingress. For example:

   ```
   shared:
     ingress_domain: "example.com"
   ```

3. Update your other host names in the `tap_gui` section of your `tap-values.yaml` with the new host name. For example:

   ```
   shared:
     ingress_domain: "example.com"

   tap_gui:
   # Existing tap-values.yaml above
     app_config:
       app:
         baseUrl: http://tap-gui.example.com # No port needed with Ingress
   ```

```
    integrations:
      github: # Other are integrations available
        - host: github.com
          token: GITHUB-TOKEN
    catalog:
      locations:
        - type: url
          target: https://GIT-CATALOG-URL/catalog-info.yaml
    backend:
      baseUrl: http://tap-gui.example.com # No port needed with Ingress
      cors:
        origin: http://tap-gui.example.com # No port needed with Ingress
```

4. Update your package installation with your changed `tap-values.yaml` file by running:

   ```
   tanzu package installed update tap --package tap.tanzu.vmware.com --version VER
   SION-NUMBER \
   --values-file tap-values.yaml -n tap-install
   ```

   Where `VERSION-NUMBER` is your Tanzu Application Platform version. For example, `1.9.1`.

5. Use a web browser to access Tanzu Developer Portal at the host name that you provided.

Catalog operations

The software catalog setup procedures in this topic make use of Backstage. For more information about Backstage, see the Backstage documentation.

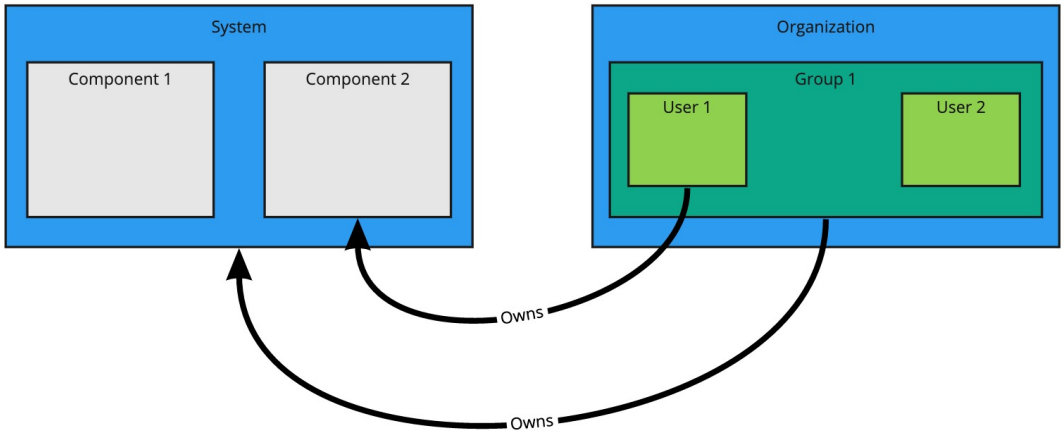
Adding catalog entities

This section describes how you can format your own catalog. Creating catalogs consists of building metadata YAML files stored together with the code. This information is read from a Git-compatible repository consisting of these YAML catalog definition files. Changes made to the catalog definitions on your Git infrastructure are automatically reflected every 200 seconds or when manually registered.

For each catalog entity kind you create, there is a file format you must follow. For information about all types of entities, see the Backstage documentation.

You can use the example blank catalog described in the Tanzu Developer Portal prerequisites as a foundation for creating user, group, system, and main component YAML files.

The organization contains Group 1, and Group 1 contains Users 1 and 2. System contains Components 1 and 2. User 1 owns Component 2. Group 1 owns System.



Users and groups

A user entity describes a specific person and is used for identity purposes. Users are members of one or more groups. A group entity describes an organizational team or unit.

Users and groups have different descriptor requirements in their descriptor files:

- User descriptor files require `apiVersion`, `kind`, `metadata.name`, and `spec.memberOf`.
- Group descriptor files require `apiVersion`, `kind`, and `metadata.name`. They also require `spec.type` and `spec.children` where `spec.children` is another group.

To link a logged-in user to a user entity, include the optional `spec.profile.email` field.

Sample user entity:

```
apiVersion: backstage.io/v1alpha1
kind: User
metadata:
  name: default-user
spec:
  profile:
    displayName: Default User
    email: guest@example.com
    picture: https://avatars.dicebear.com/api/avataaars/guest@example.com.svg?backgrou
nd=%23fff
  memberOf: [default-team]
```

Sample group entity:

```
apiVersion: backstage.io/v1alpha1
kind: Group
metadata:
  name: default-team
  description: Default Team
spec:
  type: team
  profile:
    displayName: Default Team
    email: team-a@example.com
    picture: https://avatars.dicebear.com/api/identicon/team-a@example.com.svg?backgro
und=%23fff
  parent: default-org
  children: []
```

For more information about user entities and group entities, see the Backstage documentation.

Systems

A system entity is a collection of resources and components.

System descriptor files require values for `apiVersion`, `kind`, `metadata.name`, and also `spec.owner` where `spec.owner` is a user or group.

A system has components when components specify the system name in the field `spec.system`.

Sample system entity:

```
apiVersion: backstage.io/v1alpha1
kind: System
metadata:
  name: backstage
  description: Tanzu Developer Portal System
spec:
  owner: default-team
```

For more information about system entities, see the Backstage documentation.

Components

A component describes a software component, or what might be described as a unit of software.

Component descriptor files require values for `apiVersion`, `kind`, `metadata.name`, `spec.type`, `spec.lifecycle`, and `spec.owner`.

Some useful optional fields are `spec.system` and `spec.subcomponentOf`, both of which link a component to an entity that it is part of.

```
apiVersion: backstage.io/v1alpha1
kind: Component
metadata:
  name: backstage-component
  description: Tanzu Developer Portal Component
  annotations:
    'backstage.io/kubernetes-label-selector': 'app=backstage' #Identifies the Kubernet
es objects that make up this component
    'backstage.io/techdocs-ref': dir:. #TechDocs label
spec:
  type: service
  lifecycle: alpha
  owner: default-team
  system: backstage
```

For more information about component entities, see the Backstage documentation.

Update software catalogs

The following procedures describe how to update software catalogs.

Register components

To update your software catalog with new entities without re-deploying the entire `tap-gui` package:

1. Go to your **Software Catalog** page.
2. Click **Register Entity** at the top-right of the page.
3. Enter the full path to link to an existing entity file and start tracking your entity.
4. Import the entities and view them in your **Software Catalog** page.

Deregister components

To deregister an entity:

1. Go to your **Software Catalog** page.
2. Select the entity to deregister, such as component, group, or user.
3. Click the three dots at the top-right of the page and then click **Unregister...**.

Add or change organization catalog locations

To add or change organization catalog locations, you can use static configuration or you can use `GitLabDiscoveryProcessor` to discover and register catalog entities that match the configured path.

Use static configuration
To use static configuration to add or change catalog locations:

1. Update components by changing the catalog location in either the `app_config` section of `tap-gui-values.yaml` or the custom values file you used when installing. For example:

   ```
   tap_gui:
     app_config:
       catalog:
         locations:
           - type: url
             target: UPDATED-CATALOG-LOCATION
   ```

2. Register components by adding the new catalog location in either the `app_config` section of `tap-gui-values.yaml` or the custom values file you used when installing. For example:

   ```
   tap_gui:
     app_config:
       catalog:
         locations:
           - type: url
             target: EXISTING-CATALOG-LOCATION
           - type: url
             target: EXTRA-CATALOG-LOCATION
   ```

   When targeting GitHub, don't write the raw URL. Instead, use the URL that appears when you navigate to the file in the browser. The catalog processor cannot set up the files properly if you use the raw URL.

   - Example raw URL: `https://raw.githubusercontent.com/user/repo/catalog.yaml`
   - Example target URL: `https://github.com/user/repo/blob/main/catalog.yaml`

   When targeting GitLab, use a scoped route to the catalog file. This is a route with the `/-/` separator after the project name. If you don't use a scoped route, your entity fails to appear in the catalog.

   - Example unscoped URL: `https://gitlab.com/group/project/blob/main/catalog.yaml`
   - Example target URL: `https://gitlab.com/group/project/-/blob/main/catalog.yaml`

   For more information about static catalog configuration, see the Backstage documentation.

Use GitLabDiscoveryProcessor

To use `GitLabDiscoveryProcessor` to discover and register catalog entities:

1. Use `type: gitlab-discovery` to make `GitLabDiscoveryProcessor` crawl the GitLab instance to discover and register catalog entities that match the configured path. For more information, see the Backstage documentation.
2. Update the package to include the catalog:
   - If you installed Tanzu Developer Portal by using a profile, run:

     ```
     tanzu package installed update tap \
     --package tap.tanzu.vmware.com \
     --version PACKAGE-VERSION \
     --values-file tap-values.yaml \
     --namespace tap-install
     ```

   - If you installed Tanzu Developer Portal as an individual package, run:

```
tanzu package installed update tap-gui \
--package tap-gui.tanzu.vmware.com \
--version PACKAGE-VERSION \
--values-file tap-gui-values.yaml \
--namespace tap-install
```

3. Verify the status of this update by running:

```
tanzu package installed list -n tap-install
```

Install demo apps and their catalogs

To set up one of the demos, you can choose a blank catalog or a sample catalog.

Yelb system

The Yelb demo catalog in GitHub includes all the components that make up the Yelb system and the default Backstage components.

Install Yelb

To install Yelb:

1. Download the necessary file for running the Yelb application itself from GitHub.
2. Install the application on the Kubernetes cluster that you used for Tanzu Application Platform. Preserve the metadata labels on the Yelb application objects.

Install the Yelb catalog

To install the Yelb catalog:

1. In Tanzu Network, select your release from the drop-down menu.
2. Click **tanzu-developer-portal-catalogs-latest** > **Tanzu Application Platform Developer Portal Yelb Catalog** and download the catalog.
3. Unpack the downloaded TAR archive to a local drive.
4. Follow the earlier steps for Register components to register the `catalog-info.yaml` in the root of the unpacked archive and register all the catalog entities that constitute the Yelb system.

View resources on multiple clusters in Tanzu Developer Portal

You can configure Tanzu Developer Portal to retrieve Kubernetes object details from multiple clusters and then surface those details in the various Tanzu Developer Portal plug-ins.

Important

In this topic the terms `Build`, `Run`, and `View` describe the cluster's roles and distinguish which steps to apply to which cluster.

`Build` clusters are where the code is built and packaged, ready to be run.

`Run` clusters are where the Tanzu Application Platform workloads themselves run.

`View` clusters are where the Tanzu Developer Portal is run from.

In multicluster configurations, these can be separate clusters. However, in many configurations these can also be the same cluster.

Set up a Service Account to view resources on a cluster

To view resources on the `Build` or `Run` clusters, create a service account on the `View` cluster that can `get`, `watch`, and `list` resources on those clusters.

You first create a `ClusterRole` with these rules and a `ServiceAccount` in its own `Namespace`, and then bind the `ClusterRole` to the `ServiceAccount`. Depending on your topology, not every cluster has all of the following objects. For example, the `Build` cluster doesn't have any of the `serving.knative.dev` objects, by design, because it doesn't run the workloads themselves. You can edit the following object lists to reflect your topology.

To set up a Service Account to view resources on a cluster:

1. Copy this YAML content into a file called `tap-gui-viewer-service-account-rbac.yaml`.

```
apiVersion: v1
kind: Namespace
metadata:
  name: tap-gui
---
apiVersion: v1
kind: ServiceAccount
metadata:
  namespace: tap-gui
  name: tap-gui-viewer
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: tap-gui-read-k8s
subjects:
- kind: ServiceAccount
  namespace: tap-gui
  name: tap-gui-viewer
roleRef:
  kind: ClusterRole
  name: k8s-reader
  apiGroup: rbac.authorization.k8s.io
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: k8s-reader
rules:
- apiGroups: ['']
  resources:
  - pods
  - pods/log
  - services
  - configmaps
  - limitranges
  - namespaces
  verbs: ['get', 'watch', 'list']
- apiGroups: ['metrics.k8s.io']
  resources: ['pods']
  verbs: ['get', 'watch', 'list']
- apiGroups: ['apps']
  resources: ['deployments', 'replicasets', 'statefulsets', 'daemonsets']
  verbs: ['get', 'watch', 'list']
- apiGroups: ['autoscaling']
```

```
  resources: ['horizontalpodautoscalers']
  verbs: ['get', 'watch', 'list']
- apiGroups: ['networking.k8s.io']
  resources: ['ingresses']
  verbs: ['get', 'watch', 'list']
- apiGroups: ['networking.internal.knative.dev']
  resources: ['serverlessservices']
  verbs: ['get', 'watch', 'list']
- apiGroups: [ 'autoscaling.internal.knative.dev' ]
  resources: [ 'podautoscalers' ]
  verbs: [ 'get', 'watch', 'list' ]
- apiGroups: ['serving.knative.dev']
  resources:
  - configurations
  - revisions
  - routes
  - services
  verbs: ['get', 'watch', 'list']
- apiGroups: ['carto.run']
  resources:
  - clusterconfigtemplates
  - clusterdeliveries
  - clusterdeploymenttemplates
  - clusterimagetemplates
  - clusterruntemplates
  - clustersourcetemplates
  - clustersupplychains
  - clustertemplates
  - deliverables
  - runnables
  - workloads
  verbs: ['get', 'watch', 'list']
- apiGroups: ['source.toolkit.fluxcd.io']
  resources:
  - gitrepositories
  verbs: ['get', 'watch', 'list']
- apiGroups: ['source.apps.tanzu.vmware.com']
  resources:
  - imagerepositories
  - mavenartifacts
  verbs: ['get', 'watch', 'list']
- apiGroups: ['conventions.apps.tanzu.vmware.com']
  resources:
  - podintents
  verbs: ['get', 'watch', 'list']
- apiGroups: ['kpack.io']
  resources:
  - images
  - builds
  verbs: ['get', 'watch', 'list']
- apiGroups: ['scanning.apps.tanzu.vmware.com']
  resources:
  - sourcescans
  - imagescans
  - scanpolicies
  - scantemplates
  verbs: ['get', 'watch', 'list']
- apiGroups: ['app-scanning.apps.tanzu.vmware.com']
  resources:
  - imagevulnerabilityscans
  verbs: ['get', 'watch', 'list']
- apiGroups: ['tekton.dev']
  resources:
  - taskruns
  - pipelineruns
  verbs: ['get', 'watch', 'list']
```

```
- apiGroups: ['kappctrl.k14s.io']
  resources:
  - apps
  verbs: ['get', 'watch', 'list']
- apiGroups: [ 'batch' ]
  resources: [ 'jobs', 'cronjobs' ]
  verbs: [ 'get', 'watch', 'list' ]
- apiGroups: ['conventions.carto.run']
  resources:
  - podintents
  verbs: ['get', 'watch', 'list']
- apiGroups: ['appliveview.apps.tanzu.vmware.com']
  resources:
  - resourceinspectiongrants
  verbs: ['get', 'watch', 'list', 'create']
- apiGroups: ['apiextensions.k8s.io']
  resources: ['customresourcedefinitions']
  verbs: ['get', 'watch', 'list']
- apiGroups: [data.packaging.carvel.dev]
  resources: [packages]
  verbs: ['get', 'watch', 'list']
```

This YAML content creates `Namespace`, `ServiceAccount`, `ClusterRole`, and `ClusterRoleBinding`.

2. On the `Build` and `Run` clusters, create `Namespace`, `ServiceAccount`, `ClusterRole`, and `ClusterRoleBinding` by running:

```
kubectl create -f tap-gui-viewer-service-account-rbac.yaml
```

3. Again, on the `Build` and `Run` clusters, discover the `CLUSTER_URL` and `CLUSTER_TOKEN` values.

v1.23 or earlier Kubernetes cluster

If you're watching a v1.23 or earlier Kubernetes cluster, run:

```
CLUSTER_URL=$(kubectl config view --minify -o jsonpath='{.clusters[0].cluste
r.server}')

CLUSTER_TOKEN=$(kubectl -n tap-gui get secret $(kubectl -n tap-gui get sa tap
-gui-viewer -o=json \
| jq -r '.secrets[0].name') -o=json \
| jq -r '.data["token"]' \
| base64 --decode)

echo CLUSTER_URL: $CLUSTER_URL
echo CLUSTER_TOKEN: $CLUSTER_TOKEN
```

v1.24 or later Kubernetes cluster

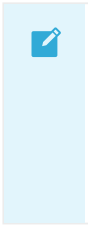
If you're watching a v1.24 or later Kubernetes cluster, run:

```
CLUSTER_URL=$(kubectl config view --minify -o jsonpath='{.clusters[0].cluste
r.server}')

kubectl apply -f - <<EOF
apiVersion: v1
kind: Secret
metadata:
  name: tap-gui-viewer
  namespace: tap-gui
  annotations:
    kubernetes.io/service-account.name: tap-gui-viewer
type: kubernetes.io/service-account-token
EOF
```

```
CLUSTER_TOKEN=$(kubectl -n tap-gui get secret tap-gui-viewer -o=json \
| jq -r '.data["token"]' \
| base64 --decode)

echo CLUSTER_URL: $CLUSTER_URL
echo CLUSTER_TOKEN: $CLUSTER_TOKEN
```



Note

You can create a short-lived token with the `kubectl create token` command if that is the preferred method. This method requires frequent token rotation.

4. (Optional) Configure the Kubernetes client to verify the TLS certificates presented by a cluster's API server. To do this, discover `CLUSTER_CA_CERTIFICATES` by running:

```
CLUSTER_CA_CERTIFICATES=$(kubectl config view --raw -o jsonpath='{.clusters[?
(@.name=="CLUSTER-NAME")].cluster.certificate-authority-data}')

echo CLUSTER_CA_CERTIFICATES: $CLUSTER_CA_CERTIFICATES
```

   Where `CLUSTER-NAME` is your cluster name.

5. Record the `Build` and `Run` clusters' `CLUSTER_URL` and `CLUSTER_TOKEN` values for when you Update Tanzu Developer Portal to view resources on multiple clusters later.

Update Tanzu Developer Portal to view resources on multiple clusters

The clusters must be identified to Tanzu Developer Portal with the `ServiceAccount` token and the cluster Kubernetes control plane URL.

You must add a `kubernetes` section to the `app_config` section in the `tap-values.yaml` file that Tanzu Application Platform used when you installed it. This section must have an entry for each `Build` and `Run` cluster that has resources to view.

To do so:

1. Copy this YAML content into `tap-values.yaml`:

```
tap_gui:
## Previous configuration above
  app_config:
    kubernetes:
      serviceLocatorMethod:
        type: 'multiTenant'
      clusterLocatorMethods:
        - type: 'config'
          clusters:
          ## Cluster 1
            - url: CLUSTER-URL
              name: CLUSTER-NAME
              authProvider: serviceAccount
              serviceAccountToken: "CLUSTER-TOKEN"
              skipTLSVerify: true
              skipMetricsLookup: true
          ## Cluster 2+
            - url: CLUSTER-URL
              name: CLUSTER-NAME
```

```
      authProvider: serviceAccount
      serviceAccountToken: "CLUSTER-TOKEN"
      skipTLSVerify: true
      skipMetricsLookup: true
```

Where:

- `CLUSTER-URL` is the value you discovered earlier.
- `CLUSTER-TOKEN` is the value you discovered earlier.
- `CLUSTER-NAME` is a unique name of your choice.

If there are resources to view on the `View` cluster that hosts Tanzu Developer Portal, add an entry to `clusters` for it as well.

If you would like the Kubernetes client to verify the TLS certificates presented by a cluster's API server, set the following properties for the cluster:

```
skipTLSVerify: false
caData: CLUSTER-CA-CERTIFICATES
```

Where `CLUSTER-CA-CERTIFICATES` is the value you discovered earlier.

2. Update the `tap` package by running this command:

```
tanzu package installed update tap -n tap-install --values-file tap-values.yaml
```

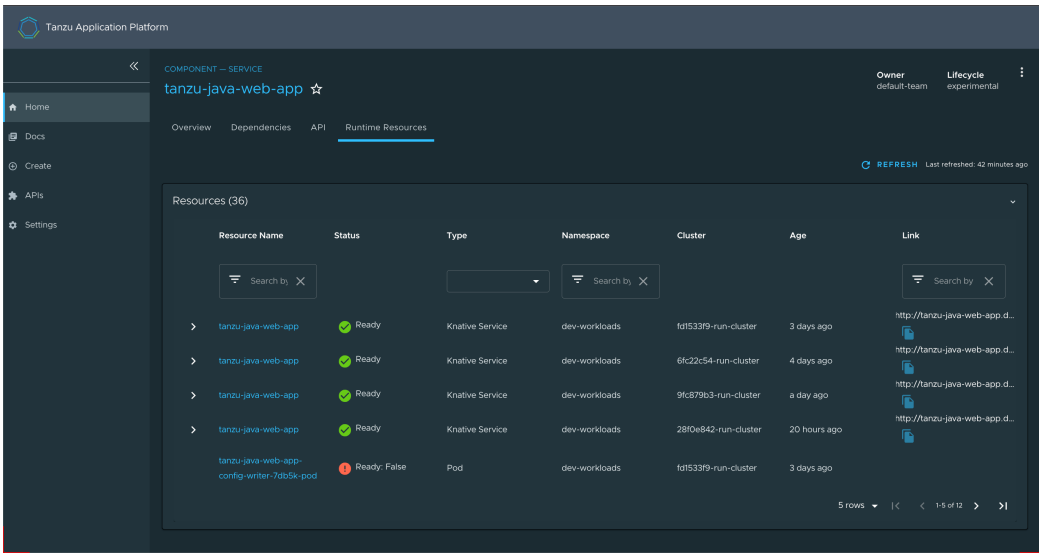
3. Wait a moment for the `tap` and `tap-gui` packages to update and then verify that `STATUS` is `Reconcile succeeded` by running:

```
tanzu package installed get all -n tap-install
```

View resources on multiple clusters in the Runtime Resources Visibility plug-in

To view resources on multiple clusters in the Runtime Resources Visibility plug-in:

1. Go to the Runtime Resources Visibility plug-in for a component that is running on multiple clusters.
2. View the multiple resources and their statuses across the clusters.



Set up authentication for Tanzu Developer Portal

Tanzu Developer Portal extends the current Backstage authentication plug-in so that you can see a login page based on the authentication providers configured at installation. This feature is a work in progress.

Tanzu Developer Portal currently supports the following authentication providers:

- Auth0
- Azure
- Bitbucket
- GitHub
- GitLab
- Google
- Okta
- OneLogin

You can also configure a custom OpenID Connect (OIDC) provider.

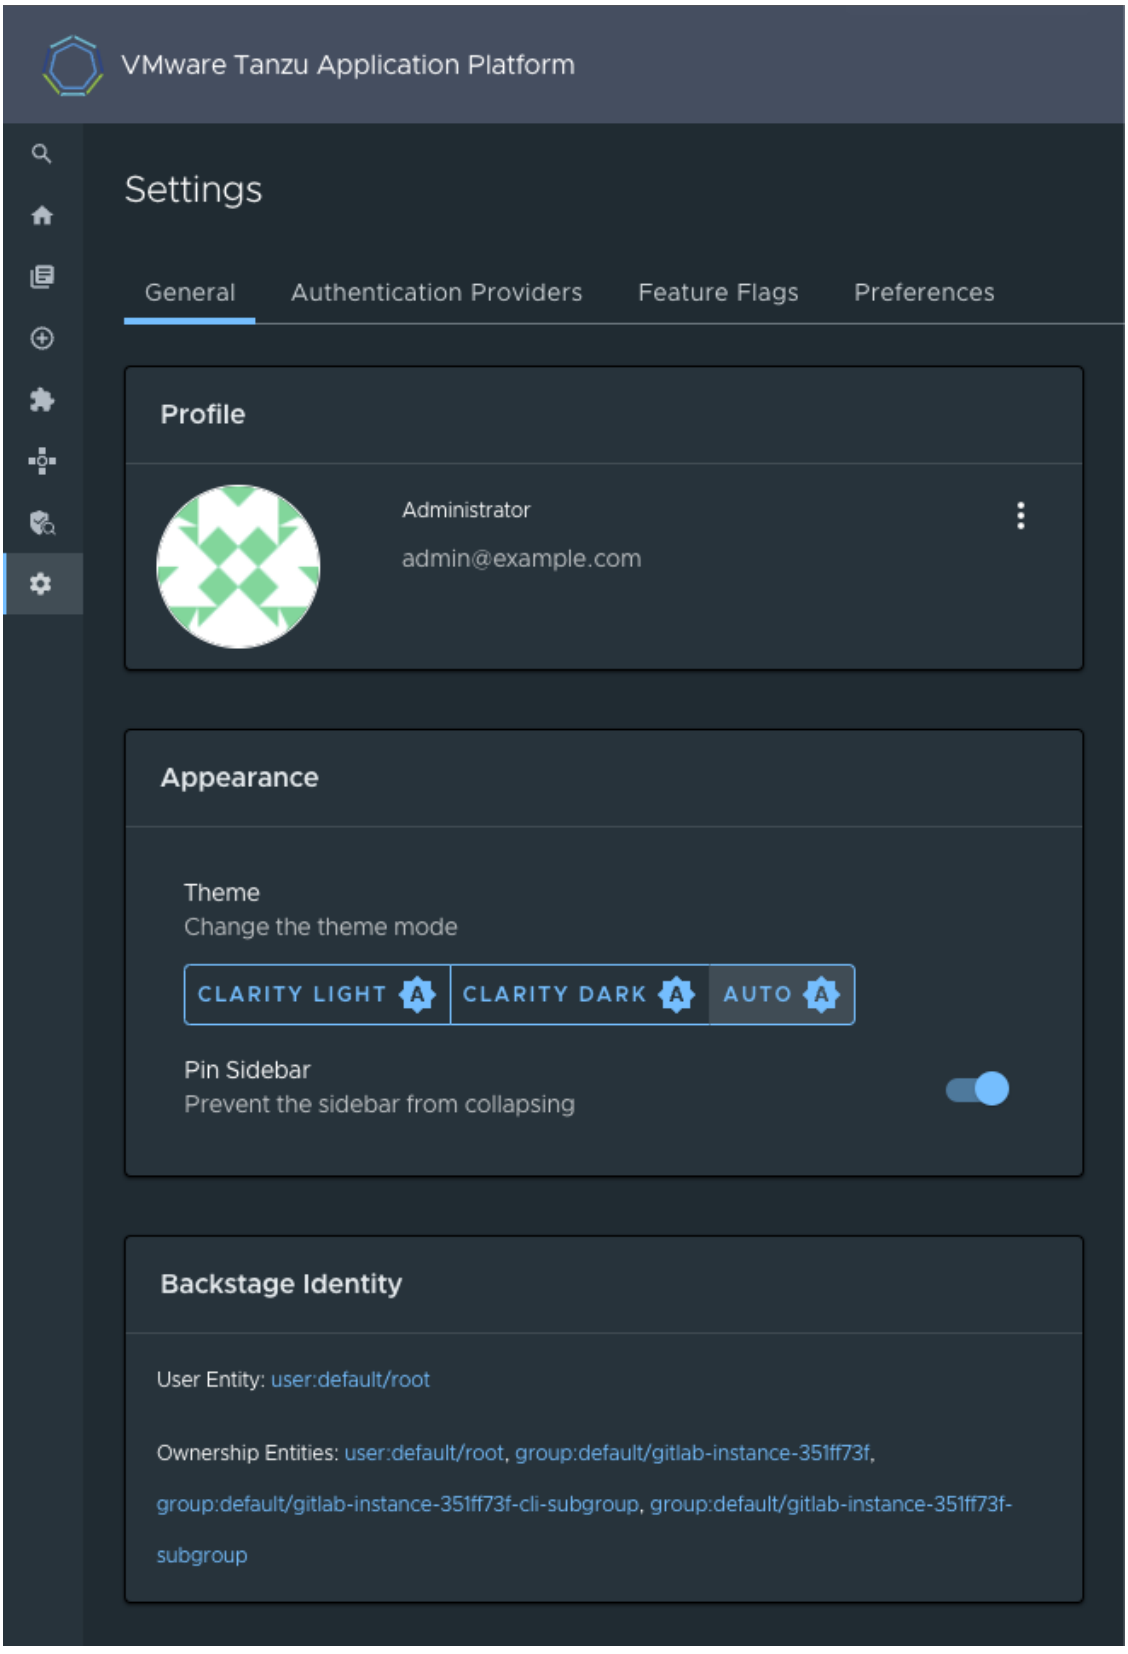
View your Backstage Identity

A Backstage identity is defined as a combination of:

- The user reference: each entity in the catalog is uniquely identified by the triplet of its kind
- A namespace
- A name

For example, the user Jane can be assigned to the user entity `user:default/jane` and an ownership reference, which is used to determine what that user owns. Jane (`user:default/jane`) might have the ownership references `user:default/jane`, `group:default/team-a`, and `group:default/admins`. This would mean that Jane belongs to those groups and, therefore, owns those references.

To view your current Backstage identity, in the **Settings** section of the left side navigation pane click the **General** tab.



Configure an authentication provider

Configure a supported authentication provider or a custom OIDC provider:

- To configure a supported authentication provider, see the Backstage authentication documentation.

- To configure a custom OIDC provider, edit your `tap-values.yaml` file or your custom configuration file to include an OIDC authentication provider. Configure the OIDC provider with your OAuth App values. For example:

```
shared:
  ingress_domain: "INGRESS-DOMAIN"

# ... any existing values

tap_gui:
  # ... any other Tanzu Developer Portal values
  app_config:
    auth:
      environment: development
      session:
        secret: custom session secret
      providers:
        oidc:
          development:
            metadataUrl: AUTH-OIDC-METADATA-URL
            clientId: AUTH-OIDC-CLIENT-ID
            clientSecret: AUTH-OIDC-CLIENT-SECRET
            tokenSignedResponseAlg: AUTH-OIDC-TOKEN-SIGNED-RESPONSE-ALG # defau
lt='RS256'
            scope: AUTH-OIDC-SCOPE # default='openid profile email'
            prompt: auto # default=none (allowed values: auto, none, consent, l
ogin)
```

  Where `AUTH-OIDC-METADATA-URL` is a JSON file with generic OIDC provider configuration. It contains `authorizationUrl` and `tokenUrl`. Tanzu Developer Portal reads these values from `metadataUrl`, so you must not specify these values explicitly in the earlier authentication configuration.

  You must also the provide the redirect URI of the Tanzu Developer Portal instance to your identity provider. The redirect URI is sometimes called the redirect URL, the callback URL, or the callback URI. The redirect URI takes the following form:

```
SCHEME://tap-gui.INGRESS-DOMAIN/api/auth/oidc/handler/frame
```

  Where:

  - `SCHEME` is the URI scheme, most commonly `http` or `https`
  - `INGRESS-DOMAIN` is the host name you selected for your Tanzu Developer Portal instance

  When using `https` and `example.com` as examples for the two placeholders respectively, the redirect URI reads as follows:

```
https://tap-gui.example.com/api/auth/oidc/handler/frame
```

  For more information, see this example in GitHub.

- (Optional) Configure offline access scope for the OIDC provider by adding the `scope` parameter `offline_access` to either `tap-values.yaml` or your custom configuration file. For example:

```
auth:
  providers:
    oidc:
      development:
```

```
        ... # auth configs
        scope: 'openid profile email offline_access'
```

By default, `scope` is not configured to provide persistence to user login sessions, such as in the case of a page refresh. Not all identity providers support the `offline_access` scope. For more information, see your identity provider documentation.

(Optional) Allow guest access

Enable guest access with other providers by adding the following flag under your authentication configuration:

```
auth:
  allowGuestAccess: true
```

(Optional) Customize the login page

Change the card's title or description for a specific provider with the following configuration:

```
auth:
  environment: development
  providers:
    ... # auth providers config
  loginPage:
    github:
      title: Github Login
      message: Enter with your GitHub account
```

For a provider to appear on the login page, ensure that it is properly configured under the `auth.providers` section of your values file.

View resources on remote clusters

You can control the access to Kubernetes runtime resources on Tanzu Developer Portal (commonly called TDP) based on user roles and permissions for each of the visible remote clusters.

Caution

In Tanzu Application Platform v1.6 and earlier, setting up role-based access control (RBAC) might impact your ability to view workloads in the Security Analysis GUI and the Workloads table of the Supply Chain Choreographer plug-in GUI.

RBAC is currently supported for the following Kubernetes cluster providers:

- EKS (Elastic Kubernetes Service) on AWS
- GKE (Google Kubernetes Engine) on Google Cloud Platform (GCP)

Support for other Kubernetes providers is planned for future releases of Tanzu Application Platform.

Tanzu Developer Portal is designed under the assumption that the roles and permissions for the Kubernetes clusters are already defined and that the users are already assigned to their roles. For information about assigning roles and permissions to users, see Assigning roles and permissions on Kubernetes clusters.

Adding access-controlled visibility for a remote cluster is similar to Setting up unrestricted remote cluster visibility.

The steps are:

1. Set up the OIDC provider
2. Configure the Kubernetes cluster with the OIDC provider
3. Configure the Tanzu Developer Portal to view the remote cluster
4. Upgrade the Tanzu Developer Portal package

After following these steps, you can view your runtime resources on a remote cluster in Tanzu Developer Portal. For more information, see View runtime resources on remote clusters.

View resources on remote clusters

You can control the access to Kubernetes runtime resources on Tanzu Developer Portal (commonly called TDP) based on user roles and permissions for each of the visible remote clusters.

Caution

In Tanzu Application Platform v1.6 and earlier, setting up role-based access control (RBAC) might impact your ability to view workloads in the Security Analysis GUI and the Workloads table of the Supply Chain Choreographer plug-in GUI.

RBAC is currently supported for the following Kubernetes cluster providers:

- EKS (Elastic Kubernetes Service) on AWS
- GKE (Google Kubernetes Engine) on Google Cloud Platform (GCP)

Support for other Kubernetes providers is planned for future releases of Tanzu Application Platform.

Tanzu Developer Portal is designed under the assumption that the roles and permissions for the Kubernetes clusters are already defined and that the users are already assigned to their roles. For information about assigning roles and permissions to users, see Assigning roles and permissions on Kubernetes clusters.

Adding access-controlled visibility for a remote cluster is similar to Setting up unrestricted remote cluster visibility.

The steps are:

1. Set up the OIDC provider
2. Configure the Kubernetes cluster with the OIDC provider
3. Configure the Tanzu Developer Portal to view the remote cluster
4. Upgrade the Tanzu Developer Portal package

After following these steps, you can view your runtime resources on a remote cluster in Tanzu Developer Portal. For more information, see View runtime resources on remote clusters.

View resources on remote EKS clusters

This topic tells you how to view your runtime resources on a remote EKS cluster in Tanzu Developer Portal. For more information, see View runtime resources on remote clusters.

Set up the OIDC provider

You must set up the OIDC provider to enable RBAC visibility of remote EKS clusters. You can see the list of supported OIDC providers in Setting up a Tanzu Developer Portal authentication

provider.

Tanzu Developer Portal supports multiple OIDC providers. Auth0 is used here as an example.

1. Log in to the Auth0 dashboard.
2. Go to **Applications**.
3. Create an application of the type `Single Page Web Application` named `TAP-GUI` or a name of your choice.
4. Click the **Settings** tab.
5. Under **Application URIs > Allowed Callback URLs**, add

   ```
   https://tap-gui.INGRESS-DOMAIN/api/auth/auth0/handler/frame
   ```

   Where `INGRESS-DOMAIN` is the domain you chose for your Tanzu Developer Portal in Installing the Tanzu Application Platform package and profiles.
6. Click **Save Changes**.

After creating an application with your OIDC provider, you receive the following credentials for setting up RBAC for your remote cluster:

- **Domain**, which is used as `ISSUER-URL` in the following sections (`AUTH0_DOMAIN` for Auth0)
- **Client ID**, which is used as `CLIENT-ID` in the following sections
- **Client Secret**, which is used as `CLIENT-SECRET` in the following sections

For more information, see Auth0 Setup Walkthrough in the Backstage documentation. To configure other OIDC providers, see Authentication in Backstage in the Backstage documentation.

Configure the Kubernetes cluster with the OIDC provider

To configure the cluster with the OIDC provider's credentials:

1. Create a file with the following content and name it `rbac-setup.yaml`. This content applies to EKS clusters.

   ```
   apiVersion: eksctl.io/v1alpha5
   kind: ClusterConfig
   metadata:
     name: "CLUSTER-NAME"
     region: "AWS-REGION"
   identityProviders:
     - name: auth0
       type: oidc
       issuerUrl: "ISSUER-URL"
       clientId: "CLIENT-ID"
       usernameClaim: email
   ```

   Where:

   - `CLUSTER-NAME` is the cluster name for your EKS cluster as an AWS identifier
   - `AWS-REGION` is the AWS region of the EKS cluster
   - `CLIENT-ID` is the Client ID you obtained while setting up the OIDC provider
   - `ISSUER-URL` is the Issuer URL you obtained while setting up the OIDC provider. For Auth0, this is `https://${AUTH0_DOMAIN}/`.
2. Using `eksctl`, run:

```
eksctl associate identityprovider -f rbac-setup.yaml
```

3. Verify that the association of the OIDC provider with the EKS cluster was successful by running:

   ```
   eksctl get identityprovider --cluster CLUSTER-NAME
   ```

   Where `CLUSTER-NAME` is the cluster name for your EKS cluster as an AWS identifier

   Verify that the output shows `ACTIVE` in the `STATUS` column.

Configure the Tanzu Developer Portal

Configure visibility of the remote cluster in Tanzu Developer Portal:

1. Obtain your cluster's URL by running:

   ```
   CLUSTER_URL=$(kubectl config view --minify -o jsonpath='{.clusters[0].cluster.s
   erver}')

   echo CLUSTER-URL: $CLUSTER_URL
   ```

   This command returns the URL of the first configured cluster in your `kubeconfig` file. To view other clusters one by one, edit the number in `.clusters[0].cluster.server` or edit the command to view all the configured clusters.

2. Ensure you have an `auth` section in the `app_config` section that Tanzu Developer Portal uses. In the example for Auth0, copy this YAML content into `tap-values.yaml`:

   ```
   auth:
     environment: development
     providers:
       auth0:
         development:
           clientId: "CLIENT-ID"
           clientSecret: "CLIENT-SECRET"
           domain: "ISSUER-URL"
   ```

   Where:

   - `CLIENT-ID` is the Client ID you obtained while setting up the OIDC provider.
   - `CLIENT-SECRET` is the Client Secret you obtained while setting up the OIDC provider.
   - `ISSUER-URL` is the Issuer URL you obtained while setting up the OIDC provider. For Auth0, it is only `AUTH0_DOMAIN`.

3. Add a `kubernetes` section to the `app_config` section that Tanzu Developer Portal uses. This section must have an entry for each cluster that has resources to view. To do so, copy this YAML content into `tap-values.yaml`:

   ```
   kubernetes:
     serviceLocatorMethod:
       type: 'multiTenant'
     clusterLocatorMethods:
       - type: 'config'
         clusters:
           - name: "CLUSTER-NAME-UNCONSTRAINED"
             url: "CLUSTER-URL"
             authProvider: oidc
             oidcTokenProvider: auth0
   ```

```
          skipTLSVerify: true
          skipMetricsLookup: true
```

Where:

- `CLUSTER-NAME-UNCONSTRAINED` is the cluster name of your choice for your EKS cluster
- `CLUSTER-URL` is the URL for the remote cluster you are connecting to Tanzu Developer Portal. You obtained this earlier in the procedure.

If there are any other clusters that you want to make visible in Tanzu Developer Portal, add their entries to `clusters` as well.

Upgrade the Tanzu Developer Portal package

After the new configuration file is ready, update the `tap` package:

1. Run:

   ```
   tanzu package installed update tap --values-file tap-values.yaml
   ```

2. Wait a moment for the `tap-gui` package to update and then verify that `STATUS` is `Reconcile succeeded` by running:

   ```
   tanzu package installed get tap-gui -n tap-install
   ```

View resources on remote GKE clusters

This topic tells you about two supported options to add access-controlled visibility for a remote GKE cluster:

- Leverage an external OIDC provider
- Leveraging Google's OIDC provider

After the authorization is enabled, you can view your runtime resources on a remote cluster in Tanzu Developer Portal. For more information, see View runtime resources on remote clusters.

Leverage an external OIDC provider

To leverage an external OIDC provider, such as Auth0:

1. Set up the OIDC provider
2. Configure the GKE cluster with the OIDC provider
3. Configure the Tanzu Developer Portal to view the remote GKE cluster
4. Update the `tap-gui` package

Set up the OIDC provider

You must set up the OIDC provider to enable RBAC visibility of remote clusters. You can see the list of supported OIDC providers in Setting up a Tanzu Developer Portal authentication provider.

Tanzu Developer Portal supports multiple OIDC providers. Auth0 is used here as an example.

1. Log in to the Auth0 dashboard.
2. Go to **Applications**.
3. Create an application of the type `Single Page Web Application` named `TAP-GUI` or a name of your choice.

4. Click the **Settings** tab.
5. Under **Application URIs** > **Allowed Callback URLs**, add

   ```
   https://tap-gui.INGRESS-DOMAIN/api/auth/auth0/handler/frame
   ```

   Where `INGRESS-DOMAIN` is the domain you chose for your Tanzu Developer Portal in Installing the Tanzu Application Platform package and profiles.
6. Click **Save Changes**.

After creating an application with your OIDC provider, you receive the following credentials for setting up RBAC for your remote cluster:

- **Domain**, which is used as `issuerURL` in the following sections
- **Client ID**, which is used as `CLIENT-ID` in the following sections
- **Client Secret**, which is used as `CLIENT-SECRET` in the following sections

For more information, see Auth0 Setup Walkthrough in the Backstage documentation. To configure other OIDC providers, see Authentication in Backstage in the Backstage documentation.

Configure the GKE cluster with the OIDC provider

Add redirect configuration on the OIDC side by following the Google Cloud documentation.

Configure visibility of the remote cluster

Configure visibility of the remote cluster in Tanzu Developer Portal:

1. Obtain your cluster's URL by running:

   ```
   CLUSTER_URL=$(kubectl config view --minify -o jsonpath='{.clusters[0].cluster.s
   erver}')

   echo CLUSTER-URL: $CLUSTER_URL
   ```

   This command returns the URL of the first configured cluster in your `kubeconfig` file. To view other clusters one by one, edit the number in `.clusters[0].cluster.server` or edit the command to view all the configured clusters.
2. Ensure you have an `auth` section in the `app_config` section that Tanzu Developer Portal uses. In the example for Auth0, copy this YAML content into `tap-values.yaml`:

   ```
   auth:
     environment: development
     providers:
       auth0:
         development:
           clientId: "CLIENT-ID"
           clientSecret: "CLIENT-SECRET"
           domain: "ISSUER-URL"
   ```

   Where:

   - `CLIENT-ID` is the Client ID you obtained while setting up the OIDC provider
   - `CLIENT-SECRET` is the Client Secret you obtained while setting up the OIDC provider
   - `ISSUER-URL` is the Issuer URL you obtained while setting up the OIDC provider
3. Add a `kubernetes` section to the `app_config` section that Tanzu Developer Portal uses. This section must have an entry for each cluster that has resources to view. To do so, copy this YAML content into `tap-values.yaml`:

```
kubernetes:
  serviceLocatorMethod:
    type: 'multiTenant'
  clusterLocatorMethods:
    - type: 'config'
      clusters:
        - name: "CLUSTER-NAME-UNCONSTRAINED"
          url: "CLUSTER-URL"
          authProvider: oidc
          oidcTokenProvider: auth0
          skipTLSVerify: true
          skipMetricsLookup: true
```

Where:

- `CLUSTER-NAME-UNCONSTRAINED` is the cluster name of your choice for your GKE cluster
- `CLUSTER-URL` is the URL for the remote cluster you are connecting to Tanzu Developer Portal. You obtained this earlier in the procedure.

If there are any other clusters that you want to make visible in Tanzu Developer Portal, add their entries to `clusters` as well.

Update the `tap-gui` package to finish leveraging the external OIDC provider

After the new configuration file is ready, update the `tap-gui` package:

1. Run:

   ```
   tanzu package installed update tap --values-file tap-values.yaml
   ```

2. Wait a moment for the `tap-gui` package to update and then verify that `STATUS` is `Reconcile succeeded` by running:

   ```
   tanzu package installed get tap-gui -n tap-install
   ```

Leverage Google's OIDC provider

When leveraging Google's OIDC provider, fewer steps are needed to enable authorization:

1. Add redirect configuration on the OIDC side.
2. Configure the Tanzu Developer Portal to view the remote GKE cluster
3. Upgrade the Tanzu Developer Portal package

Add redirect configuration on the OIDC side

Add redirect configuration on the OIDC side by following the Google Cloud documentation.

Configure visibility of the remote GKE cluster

Configure visibility of the remote GKE cluster in Tanzu Developer Portal:

1. Obtain your cluster's URL by running:

   ```
   CLUSTER_URL=$(kubectl config view --minify -o jsonpath='{.clusters[0].cluster.s
   erver}')

   echo CLUSTER-URL: $CLUSTER_URL
   ```

This command returns the URL of the first configured cluster in your `kubeconfig` file. To view other clusters one by one, edit the number in `.clusters[0].cluster.server` or edit the command to view all the configured clusters.

2. Ensure you have an `auth` section in the `app_config` section that Tanzu Developer Portal uses. In the example for Auth0, copy this YAML content into `tap-values.yaml`:

```
auth:
  environment: development
  providers:
    google:
      development:
        clientId: "CLIENT-ID"
        clientSecret: "CLIENT-SECRET"
```

Where:

- `CLIENT-ID` is the Client ID you obtained while setting up the OIDC provider
- `CLIENT-SECRET` is the Client Secret you obtained while setting up the OIDC provider

3. Add a `kubernetes` section to the `app_config` section that Tanzu Developer Portal uses. This section must have an entry for each cluster that has resources to view. To do so, copy this YAML content into `tap-values.yaml`:

```
kubernetes:
  clusterLocatorMethods:
    - type: 'config'
      clusters:
        - name: "CLUSTER-NAME-UNCONSTRAINED"
          url: "CLUSTER-URL"
          authProvider: google
          caData: "CA-DATA"
```

Where:

- `CLUSTER-NAME-UNCONSTRAINED` is the cluster name of your choice for your GKE cluster.
- `CLUSTER-URL` is the URL for the remote cluster you are connecting to Tanzu Developer Portal. You obtained this earlier in the procedure.
- `CA-DATA` is the CA certificate data.

If there are any other clusters that you want to make visible in Tanzu Developer Portal, add their entries to `clusters` as well.

Update the `tap-gui` package to finish leveraging the Google OIDC provider

After the new configuration file is ready, update the `tap-gui` package:

1. Run:

```
tanzu package installed update tap --values-file tap-values.yaml
```

2. Wait a moment for the `tap-gui` package to update and then verify that `STATUS` is `Reconcile succeeded` by running:

```
tanzu package installed get tap-gui -n tap-install
```

Enable role-based access control for the Secure Supply Chains UI and Security Analysis UI plug-ins

This topic tells you how to make workloads visible on the Secure Supply Chains UI and the Security Analysis UI when using a cluster with role-based access control (RBAC) and namespace-scoped access.

Add permissions to list namespaces

To be able to get the information from the scoped namespaces, users must have permission to list namespaces. To grant this permission, create a new `ClusterRole` and `ClusterRoleBinding`:

1. Add the following to `namespace-cluster-role.yaml`:

```
# namespace-cluster-role.yaml
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: namespaces-role
rules:
- apiGroups: ['']
  resources: ['namespaces']
  verbs: ['get', 'list']
```

2. Add the following to `namespace-cluster-role-binding.yaml`:

```
# namespace-cluster-role-binding.yaml
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: namespaces-rolebinding
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: namespaces-role
subjects:
- apiGroup: rbac.authorization.k8s.io
  kind: User
  name: YOUR-USER-ID
```

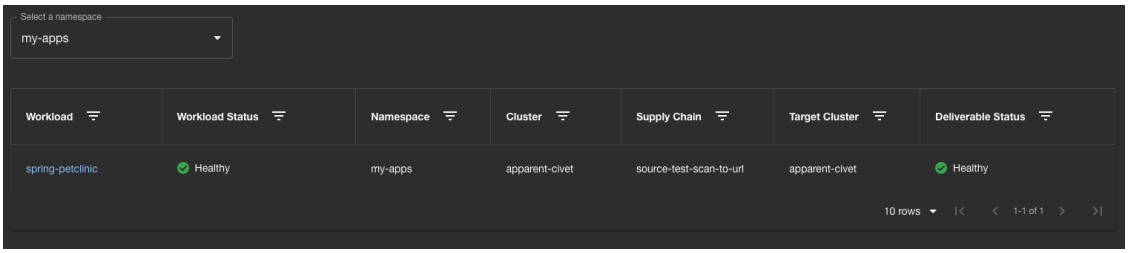
Add a label to the scoped namespaces

The current implementation requires the scoped namespaces to have a specific label or annotation. If you are using Namespace Provisioner, one of the required labels is present. However, to be safe, add the supported annotation to the scoped namespaces by running:

```
kubectl annotate namespaces NAMESPACE apps.tanzu.vmware.com/tap-managed-ns=""
```

Where `NAMESPACE` is your namespace

With this annotation the UI can target the scoped namespaces and show you workloads on such namespaces.



Set up the Backstage RBAC plug-in for Tanzu Developer Portal

This topic gives you an overview of the Backstage role-based access control (RBAC) plug-in and demonstrates how to enable it in Tanzu Developer Portal. For more information about the plug-in, see the:

- Backstage official website
- Front-end plug-in documentation
- Back-end plug-in documentation

Overview of the RBAC plug-in

The Backstage RBAC plug-in works with the permission framework to enable support for RBAC for Tanzu Application Platform operators. For more information, see Set up the permission framework for your Tanzu Developer Portal.

Install the RBAC plug-in

Creating a customized Tanzu Developer Portal with the RBAC plug-in is similar to building a customized Tanzu Developer Portal with Configurator.

To create a customized Tanzu Developer Portal with the RBAC plug-in:

1. Create a `tdp-config.yaml` file with the following structure:

```
app:
  plugins:
    - name: "@vmware-tanzu/tdp-plugin-rbac"
      version: "2.0.0"

backend:
  plugins:
    - name: "@vmware-tanzu/tdp-plugin-rbac-backend"
      version: "2.0.0"
    - name: "@vmware-tanzu/tdp-plugin-permission-backend"
      version: "2.0.0"
```

> **Important**
>
> If you want to install additional plug-ins, `@vmware-tanzu/tdp-plugin-rbac-backend` must still come before `@vmware-tanzu/tdp-plugin-permission-backend` in the `backend.plugins` section in `tdp-config.yaml`.

2. Encode the `tdp-config.yaml` file in Base64 by running:

```
base64 -i tdp-config.yaml
```

3. In your `tdp-workload.yaml` file, replace `ENCODED-TDP-CONFIG-VALUE` with the result of the Base64-encoded value from the prior step. Here is an example of what the `tdp-workload.yaml` file can look like:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: tdp-configurator
  labels:
    apps.tanzu.vmware.com/workload-type: web
    app.kubernetes.io/part-of: tdp-configurator
spec:
  build:
    env:
      - name: BP_NODE_RUN_SCRIPTS
        value: "set-tdp-config,portal:pack"
      - name: TPB_CONFIG
        value: /tmp/tdp-config.yaml
      - name: TPB_CONFIG_STRING
        value: YXBwOgogIHBsdWdpbnM6CiAgICAtIG5hbWU6ICJAdm13YXJlLXRhbnp1L3RkcC1w
bHVnaW4tcmJhYyIKICAgICAgdmVyc2lvbjogIjIuMC4wIgoKYmFja2VuZDoKICBwbHVnaW5zOgogICA
gLSBuYW1lOiAiQHZtd2FyZS10YW56dS90ZHAtcGx1Z2luLXJiYWMtYmFja2VuZCIKICAgICAgdmVyc2
lvbjogIjIuMC4wIgogICAgLSBuYW1lOiAiQHZtd2FyZS10YW56dS90ZHAtcGx1Z2luLXBlcm1pc3Npb
24tYmFja2VuZCIKICAgICAgdmVyc2lvbjogIjIuMC4wIgo=
  source:
    image: TDP-IMAGE-LOCATION
    subPath: builder
```

   Where `TDP-IMAGE-LOCATION` is the location of the Configurator image.

4. Apply the `tdp-workload.yaml` file as a workload by running:

```
tanzu apps workload apply -f tdp-workload.yaml -n DEVELOPER-NAMESPACE
```

   Where `DEVELOPER-NAMESPACE` is the Kubernetes namespace you created to run your workloads.

   An example command to create such a namespace is:

```
$ kubectl create ns my-apps
```

5. Wait for the workload to go through the `image-provider` stage in the supply chain.
6. Follow the steps in running a customized Tanzu Developer Portal to retrieve the location of the customized Tanzu Developer Portal image that the workload produces and overlay the customized image on to the instance of Tanzu Developer Portal currently running.

Enable the RBAC plug-in

To enable the RBAC plug-in:

1. Ensure that the permission framework is enabled in the `tap_gui.app_config` section of `tap-values.yaml`:

```
permission:
  enabled: true
```

2. Add the plug-ins that use permissions and entity references for users and groups that you want to permit to configure RBAC. Also add the license key to use the RBAC plug-in:

```
permission:
  enabled: true
```

```
  permissionedPlugins:
    - PLUG-IN-NAME
  rbac:
    authorizedUsers:
      - group:NAMESPACE/NAME
      - user:NAMESPACE/NAME
spotify:
  licenseKey: SPOTIFY-LICENSE-KEY
```

Where:

- `PLUG-IN-NAME` is a plug-in that includes permissions. Currently, the Catalog plug-in is the only first-party Backstage plug-in that includes permissions.
- `NAMESPACE` is usually `default` unless defined otherwise in the definition file.
- `NAME` is the name of the group or user.
- `SPOTIFY-LICENSE-KEY` is the license key that you received from Spotify.

Example:

```
tap_gui:
  app_config:
    ... # other Tanzu Developer Portal app configuration
    permission:
      enabled: true
      permissionedPlugins:
        - PLUG-IN-NAME
      rbac:
        authorizedUsers:
          - group:NAMESPACE/NAME
          - user:NAMESPACE/NAME
    spotify:
      licenseKey: SPOTIFY-LICENSE-KEY
```

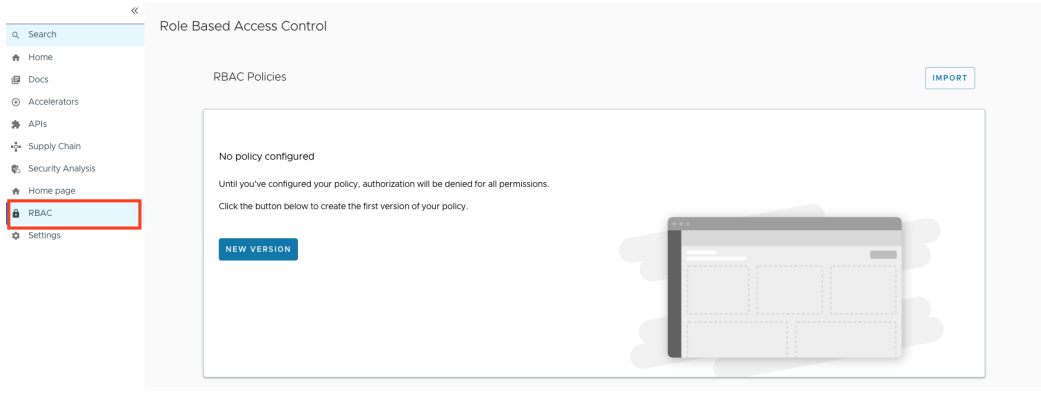
3. With the overlay from running a customized Tanzu Developer Portal, ensure that the `tap-values.yaml` file has the `tap_gui` section and `package_overlays` section.

   Example:

```
tap_gui:
  app_config:
    ... # other Tanzu Developer Portal app configuration
    permission:
      enabled: true
      permissionedPlugins:
        - PLUG-IN-NAME
      rbac:
        authorizedUsers:
          - group:NAMESPACE/NAME
          - user:NAMESPACE/NAME
    spotify:
      licenseKey: SPOTIFY-LICENSE-KEY

package_overlays:
- name: tap-gui
  secrets:
  - name: tdp-app-image-overlay-secret
```

4. Reinstall the Tanzu Developer Portal package by following the steps in Upgrade Tanzu Application Platform.
5. Open Tanzu Developer Portal in your browser and verify that the **RBAC** tab is in the sidebar.



(Optional) Identify a user authorized to author RBAC policies

You can identify someone who used an authentication provider to log in as a user authorized to author RBAC policies.

To do so, edit your `tap_gui` section in `tdp-values.yaml` to look similar to this example that uses Google authentication:

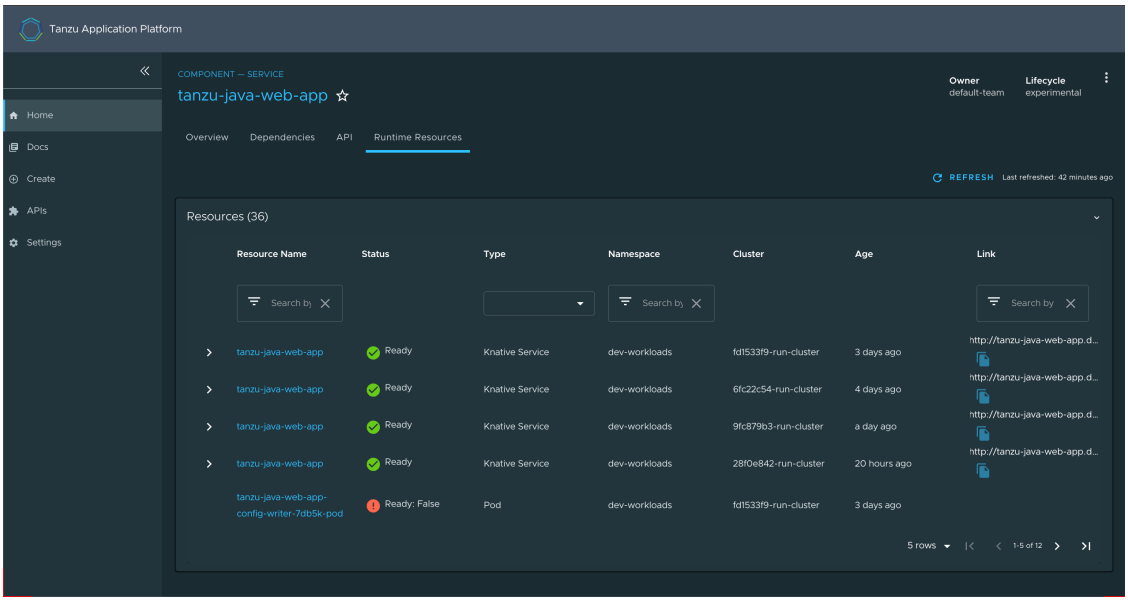
```
tap_gui:
  app_config:
    auth:
      environment: development
      providers:
        google: # https://backstage.io/docs/auth/google/provider/
          development:
            clientId: GOOGLE-CLIENT-ID
            clientSecret: GOOGLE-CLIENT-SECRET
    permission:
      enabled: true
      permissionedPlugins:
      - catalog
      rbac:
        authorizedUsers:
        - group:default/admins
        - user:default/USER-GOOGLE-EMAIL
    spotify:
      licenseKey: SPOTIFY-LICENSE-KEY
```

Where:

- `GOOGLE-CLIENT-ID` and `GOOGLE-CLIENT-SECRET` are credentials provided after setting up Google authentication by following steps in the Backstage documentation
- `USER-GOOGLE-EMAIL` is the Google account email address used to log in to Tanzu Developer Portal
- `SPOTIFY-LICENSE-KEY` is the license key provided by Spotify

View runtime resources on authorization-enabled clusters

To visualize runtime resources on authorization-enabled clusters in Tanzu Developer Portal, proceed to the software catalog component of choice and click the **Runtime Resources** tab on top of the ribbon.



After you click **Runtime Resources**, Tanzu Developer Portal uses your credentials to query the clusters for the respective runtime resources. The system verifies that you are authenticated with the OIDC providers configured for the remote clusters. If you are not authenticated, the system prompts you for your OIDC credentials.

Remote clusters that are not restricted by authorization are visible by using the general Service Account of Tanzu Developer Portal. It is not restricted for users. For more information about how to set up unrestricted remote cluster visibility, see Viewing resources on multiple clusters in Tanzu Developer Portal.

The type of query to the remote cluster depends on the definition of the software catalog component. In Tanzu Developer Portal, there are globally-scoped components and namespace-scoped components.

This property of the component affects runtime resource visibility, depending on your permissions on a specific cluster.

If your permissions on the authorization-enabled cluster are limited to specific namespaces, you do not have visibility into runtime resources of globally-scoped components.

You need cluster-scoped access to have visibility into runtime resources of globally-scoped components.

Globally-scoped components

For globally-scoped components, when you access **Runtime Resources** Tanzu Developer Portal queries all Kubernetes namespaces for runtime resources that have a matching `kubernetes-label-selector`, usually with a `part-Of` prefix.

For example, `demo-component-a` does not have a `backstage.io/kubernetes-namespace` in the `metadata.annotations` section. This makes it a globally-scoped component. See the following example YAML.

```
apiVersion: backstage.io/v1alpha1
kind: Component
metadata:
  name: demo-component-a
  description: Demo Component A
  tags:
    - java
  annotations:
```

```
    'backstage.io/kubernetes-label-selector': 'app.kubernetes.io/part-of=component-a'
spec:
  type: service
  lifecycle: experimental
  owner: team-a
```

Namespace-scoped components

If a component is namespace-scoped, when you access **Runtime Resources** Tanzu Developer Portal queries only the associated Kubernetes namespace for each remote cluster that is visible to Tanzu Developer Portal.

To make a component namespace-scoped, pass the following annotation to the definition YAML file of the component:

```
annotations:
  'backstage.io/kubernetes-namespace': NAMESPACE-NAME
```

Where `NAMESPACE-NAME` is the Kubernetes namespace you want to associate your component with.

For example, `demo-component-b` has a `kubernetes-namespace` in the `metadata.annotations` section, which associates it with the `component-b` namespaces on each of the visible clusters. This makes it a namespace-scoped component. See the following example YAML.

```
apiVersion: backstage.io/v1alpha1
kind: Component
metadata:
  name: demo-component-b
  description: Demo Component B
  tags:
    - java
  annotations:
    'backstage.io/kubernetes-label-selector': 'app.kubernetes.io/part-of=component-b'
    'backstage.io/kubernetes-namespace': component-b
spec:
  type: service
  lifecycle: experimental
  owner: team-b
```

When the `kubernetes-namespace` annotation is absent, the component is considered globally-scoped by default. For more information, see Adding Namespace Annotation in the Backstage documentation.

Assign roles and permissions on Kubernetes clusters

This topic gives you an overview of creating roles and permissions on Kubernetes clusters and assigning these roles to users. For more information, see Using RBAC Authorization in the Kubernetes documentation.

The steps to define and assign roles are:

1. Create roles
2. Create users
3. Assign users to their roles

Create roles

To control the access to Kubernetes runtime resources on Tanzu Developer Portal based on users' roles and permissions for each of visible remote clusters, VMware recommends two role types:

- Cluster-scoped roles
- Namespace-scoped roles

Cluster-scoped roles

Cluster-scoped roles provide cluster-wide privileges. They enable visibility into runtime resources across all of a cluster's namespaces.

In this example YAML snippet, the `pod-viewer` role enables pod visibility on the cluster:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: pod-viewer
rules:
- apiGroups: [""]
  resources: ["pods"]
  verbs: ["get", "watch", "list"]
```

Namespace-scoped roles

Namespace-scoped roles provide privileges that are limited to a certain namespace. They enable visibility into runtime resources inside namespaces.

In this example YAML snippet, the `pod-viewer-app1` role enables pod visibility in the `app1` namespace:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: Role
metadata:
  namespace: app1
  name: pod-viewer-app1
rules:
- apiGroups: [""]
  resources: ["pods"]
  verbs: ["get", "list"]
```

Create users

You can create users by running the `kubectl create` command. In this example YAML snippet, the user `john` is defined:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: User
metadata:
  namespace: default
  name: john
```

Assign users to their roles

After the users and role are created, the next step is to bind them together.

To bind a Tanzu Application Platform default role, see Bind a user or group to a default role.

In this example YAML snippet, the user `john` is bound with the `pod-viewer` cluster role:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: john-pod-viewer
  namespace: default
subjects:
- kind: User
  name: john
  apiGroup: rbac.authorization.k8s.io
roleRef:
  kind: ClusterRole
  name: pod-viewer
  apiGroup: rbac.authorization.k8s.io
```

In this example YAML snippet, the user `john` is bound with the `pod-viewer-app1` namespace-specific role:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: john-pod-viewer-app1
  namespace: app1
subjects:
- kind: User
  name: john
  apiGroup: rbac.authorization.k8s.io
roleRef:
  kind: Role
  name: pod-viewer-app1
  apiGroup: rbac.authorization.k8s.io
```

To verify the user's permissions, run the `can-i` commands to get a `yes` or `no` answer. To verify that you can list pods in your cluster-wide role, run:

```
kubectl auth can-i get pods --all-namespaces
```

To verify that you can list pods in namespace `app1` in your namespace-specific role, run:

```
kubectl auth can-i get pods --namespace app1
```

Set up the permission framework for your Tanzu Developer Portal

This topic gives you an overview of the Backstage permission framework and tells you how to enable it for Tanzu Developer Portal. For more information, see the Backstage documentation.

Caution

The permission framework functions are in alpha. It is not recommended for use in production environment.

Overview of the permission framework

The permission framework enables Tanzu Application Platform operators to enforce policies that limit visibility of certain parts of Tanzu Developer Portal.

The current release features the alpha version of this function and only applies to the Software Catalog entities. `owner-of` is the only policy available and it is embedded in the GUI.

`owner-of` enables the operator to define which admin groups and users have unrestricted visibility of the Software Catalog entities. If a user is not listed as an admin or part of the admin group, that user can see only the Software Catalog entities that are owned by their teams.

Important

The permission framework is deactivated by default. The built-in `owner-of` policy is primarily applied to the component entities of the software catalog. Accelerators (templates) in Application Accelerator become invisible if the permission framework is enabled.

Enable the permission framework

To enable the permission framework and limit Software Catalog entities' visibility to owners, allowlist users, allowlist groups, and catalog admins, add the following parameters to the `tap_gui.app_config` section:

```
permission:
  enabled: true
  adminRefs:
    - user:NAMESPACE/NAME
    - group:NAMESPACE/NAME
```

Where:

- `NAMESPACE` is usually `default` unless defined otherwise in the definition file
- `NAME` is the name of the group or user

The `adminRefs` section lists all users and groups to grant access to. Each user and group is defined by the `NAMESPACE` and the `NAME`.

You can view your user entity in the `Settings`/`General` section in your Tanzu Application Platform GUI, or in the YAML definition file of the user or group.

For example:

```
- user:default/admin
- group:test-namespace/operators
```

After you have updated your configuration file, reinstall your Tanzu Developer Portal package by following the steps in Upgrade Tanzu Application Platform.

After the updated values configuration file is applied in Tanzu Developer Portal, the permission framework is enabled.

Important

After the permission framework is enabled, all Software Catalog entities without proper annotations are invisible to all users except admins.

Enable catalog entity visibility

With the permission framework enabled, annotate entities in your Software Catalog to make the relevant users or groups, who are not the owner of the entity, visible. To do this, add annotations to the `metadata.annotations` section of the entity's definition file:

```
metadata:
  annotations:
    backstage.tanzu.vmware.com/GROUP-OR-USER.NAMESPACE.NAME: 'COMMA-SEPARATED-PERMISSI
ONS'
```

Where:

- `GROUP-OR-USER` is either a `group` to describe a group or a `user` to describe an individual user
- `NAMESPACE` is the namespace that the group or user is attributed to. If this value is not specified, it is `default`.
- `NAME` is the name of the user or group
- `COMMA-SEPARATED-PERMISSIONS` is the list of comma-delimited permissions for the specified user or group. Valid catalog entity permissions include:
  - `catalog.entity.read`
  - `catalog.entity.update`
  - `catalog.entity.delete`

Note

`catalog.entity.create` is another permission that is valid for the permission framework, but it is not meaningful for the Software Catalog entities that have already been created.

You can add several groups or users by adding new annotations with their respective comma-delimited permissions, for example:

```
metadata:
  annotations:
    backstage.tanzu.vmware.com/user.default.user-a: 'catalog.entities.read'
    backstage.tanzu.vmware.com/user.default.user-b: 'catalog.entities.read,catalog.ent
ities.update'
```

For example, this annotation enables users that are part of `group-a` to read and delete `component-a`:

```
apiVersion: backstage.io/v1alpha1
kind: Component
metadata:
  name: component-a
  annotations:
    backstage.tanzu.vmware.com/group.test-namespace.group-a: 'catalog.entity.read, cat
alog.entity.delete'
```

If a group is granted ownership or access to an entity, all users within that group automatically inherit the same access. But it does not work for nested group ownerships, when a group is listed as a member of another group.

Caution

When the permission plug-in is turned on with the default permission policy, API Auto Registration no longer works due to the lack of user identities. Requests against the Catalog API will no longer work as before. For more information, see the known issues in the release notes.

Add Tanzu Developer Portal integrations

You can integrate Tanzu Developer Portal with several Git providers. To use an integration, you must enable it and provide the necessary token or credentials in `tap-values.yaml`.

Add a GitHub provider integration

To add a GitHub provider integration, edit `tap-values.yaml` as in this example:

```
app_config:
  app:
    baseUrl: http://EXTERNAL-IP:7000
  # Existing tap-values.yaml above
  integrations:
    github: # Other integrations available see NOTE below
      - host: github.com
        token: GITHUB-TOKEN
```

Where:

- `EXTERNAL-IP` is the external IP address.
- `GITHUB-TOKEN` is a valid token generated from your Git infrastructure of choice. Ensure that `GITHUB-TOKEN` has the necessary read permissions for the catalog definition files you extracted from the blank software catalog introduced in the Tanzu Developer Portal prerequisites.

Add a Git-based provider integration that isn't GitHub

To enable Tanzu Developer Portal to read Git-based non-GitHub repositories containing component information:

1. Add the following YAML to `tap-values.yaml`:

   ```
   app_config:
     # Existing tap-values.yaml above
     backend:
       reading:
         allow:
           - host: "GIT-CATALOG-URL-1"
           - host: "GIT-CATALOG-URL-2" # Including more than one URL is optional
   ```

   Where `GIT-CATALOG-URL-1` and `GIT-CATALOG-URL-2` are URLs in a list of URLs that Tanzu Developer Portal can read when registering new components. For example, `git.example.com`. For more information about registering new components, see Adding catalog entities.

2. Adding the YAML from the previous step currently causes the **Accelerators** page to break and not show any accelerators. Provide a value for Application Accelerator as a workaround, as in this example:

   ```
   app_config:
     # Existing tap-values.yaml above
     backend:
       reading:
         allow:
           - host: acc-server.accelerator-system.svc.cluster.local
   ```

Add a non-Git provider integration

To add an integration for a provider that isn't associated with GitHub, see the Backstage documentation.

Update the package profile

After changing `tap-values.yaml`, update the package profile by running:

```
tanzu package installed update  tap --package tap.tanzu.vmware.com --version VERSION-N
UMBER \
--values-file tap-values.yaml -n tap-install
```

Where `VERSION-NUMBER` is the Tanzu Application Platform version. For example, `1.9.1`.

For example:

```
$ tanzu package installed update  tap --package tap.tanzu.vmware.com --version \
1.9.1 --values-file tap-values.yaml -n tap-install
| Updating package 'tap'
| Getting package install for 'tap'
| Getting package metadata for 'tap.tanzu.vmware.com'
| Updating secret 'tap-tap-install-values'
| Updating package install for 'tap'
/ Waiting for 'PackageInstall' reconciliation for 'tap'

Updated package install 'tap' in namespace 'tap-install'
```

Configure the Tanzu Developer Portal database

The Tanzu Developer Portal catalog gives you two approaches for storing catalog information:

- **In-memory database:**

  The default option uses an in-memory database and is suitable for test and development scenarios only. The in-memory database reads the catalog data from Git URLs that you write in `tap-values.yaml`.

  This data is temporary. Any operations that cause the `server` pod in the `tap-gui` namespace to be re-created also cause this data to be rebuilt from the Git location.

  This can cause issues when you manually register entities by using the UI because they only exist in the database and are lost when that in-memory database is rebuilt. If you choose this method, you lose all user preferences and any manually registered entities when the Tanzu Developer Portal server pod is re-created.

- **PostgreSQL database:**

  For production use-cases, use a PostgreSQL database that exists outside the Tanzu Application Platform packaging. The PostgreSQL database stores all the catalog data persistently both from the Git locations and the UI manual entity registrations.

For production or general-purpose use-cases, a PostgreSQL database is recommended.

Configure a PostgreSQL database

See the following sections for configuring Tanzu Developer Portal to use a PostgreSQL database.

Edit `tap-values.yaml`

Apply the following values in `tap-values.yaml`:

```
# ... existing tap-values.yaml above
tap_gui:
  # ... existing tap_gui values
  app_config:
    backend:
      database:
        client: pg
        connection:
          host: PG-SQL-HOSTNAME
          port: 5432
          user: PG-SQL-USERNAME
          password: PG-SQL-PASSWORD
          ssl: {rejectUnauthorized: false} # Set to true if using SSL
```

Where:

- `PG-SQL-HOSTNAME` is the host name of your PostgreSQL database
- `PG-SQL-USERNAME` is the user name of your PostgreSQL database
- `PG-SQL-PASSWORD` is the password of your PostgreSQL database

(Optional) Configure extra parameters

Beyond the minimum configuration options needed to make Tanzu Developer Portal work with the `pg` driver, there are many more configuration options for other purposes. For example, you can restrict Tanzu Developer Portal to a single database. For more information about this restriction, see the Backstage documentation.

By default, Tanzu Developer Portal creates a database for each plug-in, but you can configure it to divide plug-ins based on different PostgreSQL schemas and use a single specified database.

See the following example of extra configuration parameters:

```
# ... existing tap-values.yaml above
tap_gui:
  # ... existing tap_gui values
  app_config:
    backend:
      # ... other backend details
      database:
        client: pg

        # This parameter tells Tanzu Developer Portal to put plug-ins in their own sch
ema instead
        # of their own database.
        # default: database
        pluginDivisionMode: schema

        connection:
          # ... other connection details
          database: PG-SQL-DATABASE
```

Where `PG-SQL-DATABASE` is the database name for Tanzu Developer Portal to use

For the complete list of these configuration options, see the node-postgres documentation.

Update the package profile

You can apply your new configuration by updating Tanzu Application Platform with your modified values. Doing so updates Tanzu Developer Portal because it belongs to Tanzu Application Platform.

To apply your new configuration, run:

```
tanzu package installed update  tap --package tap.tanzu.vmware.com --version VERSION-N
UMBER --values-file tap-values.yaml -n tap-install
```

Where `VERSION-NUMBER` is your Tanzu Application Platform version. For example, `1.9.1`.

For example:

```
$ tanzu package installed update  tap --package tap.tanzu.vmware.com --version {{ var
s.tap_version }} --values-file tap-values.yaml -n tap-install
| Updating package 'tap'
| Getting package install for 'tap'
| Getting package metadata for 'tap.tanzu.vmware.com'
| Updating secret 'tap-tap-install-values'
| Updating package install for 'tap'
/ Waiting for 'PackageInstall' reconciliation for 'tap'

Updated package install 'tap' in namespace 'tap-install'
```

Generate and publish TechDocs

This topic tells you how to generate and publish TechDocs for catalogs as part of Tanzu Developer Portal. For more information about TechDocs, see the Backstage.io documentation.

Create an Amazon S3 bucket

To create an Amazon S3 bucket:

1. Go to Amazon S3.
2. Click **Create bucket**.
3. Give the bucket a name.
4. Select the AWS region.
5. Keep **Block all public access** checked.
6. Click **Create bucket**.

Configure Amazon S3 access

The TechDocs are published to the S3 bucket that was recently created. You need an AWS user's access key to read from the bucket when viewing TechDocs.

Create an AWS IAM user group

To create an AWS IAM User Group:

1. Click **Create Group**.
2. Give the group a name.
3. Click **Create Group**.
4. Click the new group and navigate to **Permissions**.
5. Click **Add permissions** and click **Create Inline Policy**.
6. Click the **JSON** tab and replace contents with this JSON replacing `BUCKET-NAME` with the bucket name.

```
{
  "Version": "2012-10-17",
  "Statement": [
      {
          "Sid": "ReadTechDocs",
          "Effect": "Allow",
          "Action": [
              "s3:ListBucket",
              "s3:GetObject"
          ],
          "Resource": [
              "arn:aws:s3:::BUCKET-NAME",
              "arn:aws:s3:::BUCKET-NAME/*"
          ]
      }
  ]
}
```

7. Click **Review policy**.
8. Give the policy a name and click **Create policy**.

Create an AWS IAM user

To create an AWS IAM User to add to this group:

1. Click **Add users**.
2. Give the user a name.
3. Verify **Access key - Programmatic access** and click **Next: Permissions**.
4. Verify the IAM Group to add the user to and click **Next: Tags**.
5. Click **Next: Review** then click **Create user**.
6. Record the **Access key ID** (`AWS_READONLY_ACCESS_KEY_ID`) and the **Secret access key** (`AWS_READONLY_SECRET_ACCESS_KEY`) and click **Close**.

Find the catalog locations and their entities' namespace, kind, and name

TechDocs are generated for catalogs that have Markdown source files for TechDocs. To find the catalog locations and their entities' namespace, kind, and name:

1. The catalogs appearing in Tanzu Developer Portal are listed in the config values under `app_config.catalog.locations`.
2. For a catalog, clone the catalog's repository to the local file system.
3. Find the `mkdocs.yml` that is at the root of the catalog. There is a YAML file describing the catalog at the same level called `catalog-info.yaml`.
4. Record the values for `namespace`, `kind`, and `metadata.name`, and the directory path containing the YAML file.
5. Record the `spec.targets` in that file.
6. Find the namespace, kind, or name for each of the targets:
    1. Go to the target's YAML file.
    2. The `namespace` value is the value of `namespace`. If it is not specified, it has the value `default`.
    3. The `kind` value is the value of `kind`.

4. The `name` value is the value of `metadata.name`.
5. Record the directory path containing the YAML file.

Use the TechDocs CLI to generate and publish TechDocs

VMware uses `npx` to run the TechDocs CLI, which requires `Node.js` and `npm`. To generate and publish TechDocs by using the TechDocs CLI:

1. Download and install Node.js and npm.
2. Install `npx` by running:

   ```
   npm install -g npx
   ```

3. Generate the TechDocs for the root of the catalog by running:

   ```
   npx @techdocs/cli generate --source-dir DIRECTORY-CONTAINING-THE-ROOT-YAML-FILE
   --output-dir ./site
   ```

   Note

   This creates a temporary `site` directory in your current working directory that contains the generated TechDocs files.

4. Review the contents of the `site` directory to verify the TechDocs were generated.
5. Set environment variables for authenticating with Amazon S3 with an account that has read/write access:

   ```
   export AWS_ACCESS_KEY_ID=AWS-ACCESS-KEY-ID
   export AWS_SECRET_ACCESS_KEY=AWS-SECRET-ACCESS-KEY
   export AWS_REGION=AWS-REGION
   ```

6. Publish the TechDocs for the root of the catalog to the Amazon S3 bucket you created earlier by running:

   ```
   npx @techdocs/cli publish --publisher-type awsS3 --storage-name BUCKET-NAME --e
   ntity \
   NAMESPACE/KIND/NAME --directory ./site
   ```

   Where `NAMESPACE/KIND/NAME` are the values for `namespace`, `kind`, and `metadata.name` you recorded earlier. For example, `default/location/yelb-catalog-info`.

7. For each of the `spec.targets` found earlier, repeat the `generate` and `publish` commands.

   Note

   The `generate` command erases the contents of the `site` directory before creating new TechDocs files. Therefore, the `publish` command must follow the `generate` command for each target.

Update the `techdocs` section in `app-config.yaml` to point to the Amazon S3 bucket

Update the config values you used during installation to point to the Amazon S3 bucket that has the published TechDocs files:

1. Add or edit the `techdocs` section under `app_config` in the config values with the following YAML, replacing placeholders with the appropriate values.

   ```
   techdocs:
     builder: 'external'
     publisher:
       type: 'awsS3'
       awsS3:
         bucketName: BUCKET-NAME
         accountId: ACCOUNT-ID
         region: AWS-REGION
   aws:
     accounts:
       - accountId: ACCOUNT-ID
         accessKeyId: AWS-READONLY-ACCESS-KEY-ID
         secretAccessKey: AWS-READONLY-SECRET-ACCESS-KEY
   ```

   For more information about authentication to an Amazon S3 bucket through an assumed role, see the Backstage documentation.

2. Update your installation from the Tanzu CLI:

   Tanzu Application Platform package installation
   If you installed Tanzu Developer Portal as part of the Tanzu Application Platform package (in other words, if you installed it by running `tanzu package install tap ...`) then run:

   ```
   tanzu package installed update tap \
     --version PACKAGE-VERSION \
     --values-file VALUES-FILE
   ```

   Where `PACKAGE-VERSION` is your package version and `VALUES-FILE` is your values file

   Separate package installation
   If you installed Tanzu Developer Portal as its own package (in other words, if you installed it by running `tanzu package install tap-gui ...`) then run:

   ```
   tanzu package installed update tap-gui \
     --version PACKAGE-VERSION \
     --values-file VALUES-FILE
   ```

   Where `PACKAGE-VERSION` is your package version and `VALUES-FILE` is your values file

3. Verify the status of the update by running:

   ```
   tanzu package installed list
   ```

4. Go to the **Docs** section of your catalog and view the TechDocs pages to verify the content is loaded from the S3 bucket.

Overview of Configurator

Use the Tanzu Developer Portal Configurator tool to add custom functions to Tanzu Developer Portal.

Differences between the pre-built Tanzu Developer Portal and a customized portal

Tanzu Application Platform (commonly known as TAP) has a pre-built version of Tanzu Developer Portal. The pre-built Tanzu Developer Portal includes all the core functions of Backstage (software catalog, TechDocs, API Docs, templates, accelerators, and Kubernetes).

You can choose to use just the pre-built Tanzu Developer Portal and the integrations with Tanzu Application Platform. Alternatively, you can customize Tanzu Developer Portal for your needs by using the Configurator tool to add additional Tanzu Developer Portal plug-ins.

Tanzu Developer Portal plug-ins

Tanzu Developer Portal is built using the Cloud Native Computing Foundation's project Backstage.

Backstage offers Backstage plug-ins for adding custom functions, and Tanzu Developer Portal does the same. A Tanzu Developer Portal plug-in is simply a Backstage plug-in that is wrapped in a small amount of code to make integrating with Configurator and Tanzu Developer Portal easier.

How Configurator works

Configurator takes a list of Tanzu Developer Portal plug-ins that you want to integrate with your Tanzu Developer Portal. With that plug-in list, Configurator generates a portal customized to your specifications.

With these new plug-ins, maintaining a customized portal remains similar to maintaining a pre-built Tanzu Developer Portal. Tanzu Application Platform automation handles the maintenance.

Next steps

- Learn the Tanzu Developer Portal Configurator concepts.
- See the list of Tanzu Developer Portal plug-ins currently available for use.
- When you are ready, build your customized Tanzu Developer Portal with Configurator.
- Learn how to create your own Tanzu Developer Portal plug-in of an existing Backstage plug-in.
- For more information about how to create Backstage plug-ins, see the Backstage plug-in documentation.

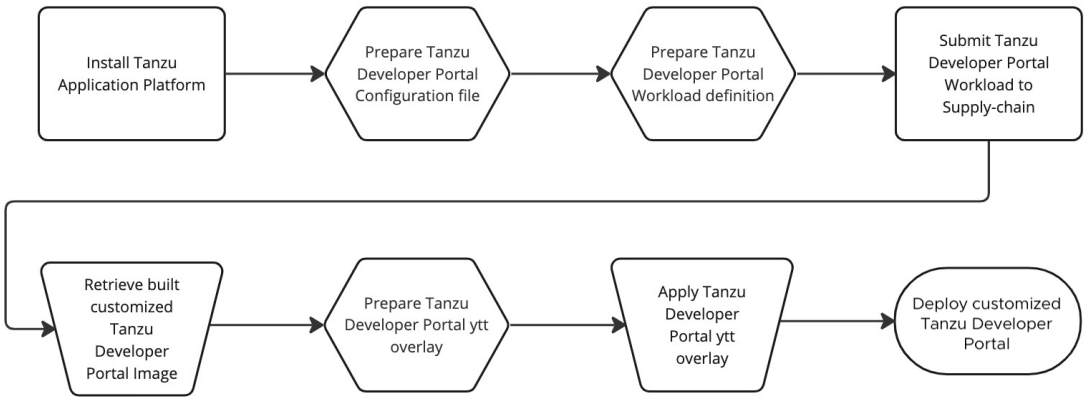
Tanzu Developer Portal Configurator Concepts

This topic gives you conceptual overviews of how Tanzu Developer Portal Configurator works.

Overview of how to customize your portal



To use your customized portal with all the runtime configuration values used in your pre-built version:

1. Install a working installation of Tanzu Application Platform with a working instance of the pre-built Tanzu Developer Portal.
2. Prepare your Configurator buildtime configuration file.

3. Prepare your Configurator workload definition YAML.
4. Submit your Configurator workload definition YAML to your supplychain.
5. After the image is built, retrieve your customized Tanzu Developer Portal image from your supplychain deliverables.
6. To run your customized portal, prepare a ytt overlay to replace the pre-built Tanzu Developer Portal in Tanzu Application Platform with your customized version. For more information about ytt, see the Carvel documentation.
7. Apply the ytt overlay to your cluster.

Overviews of buildtime configuration and runtime configuration

The following sections describe the differences between buildtime configuration and runtime configuration.

Runtime configuration

Runtime configuration refers to the values that you use to configure your existing portal image. You provide these values in `tap-values.yaml` when you install and run your portal. Runtime configuration values can include:

- The name of your portal
- Integrations (GitHub or GitLab keys, identity provider configuration, and so on)
- The locations of any catalogs on GitHub or GitLab
- Security credentials
- Configuration made available by any Tanzu Developer Portal plug-ins

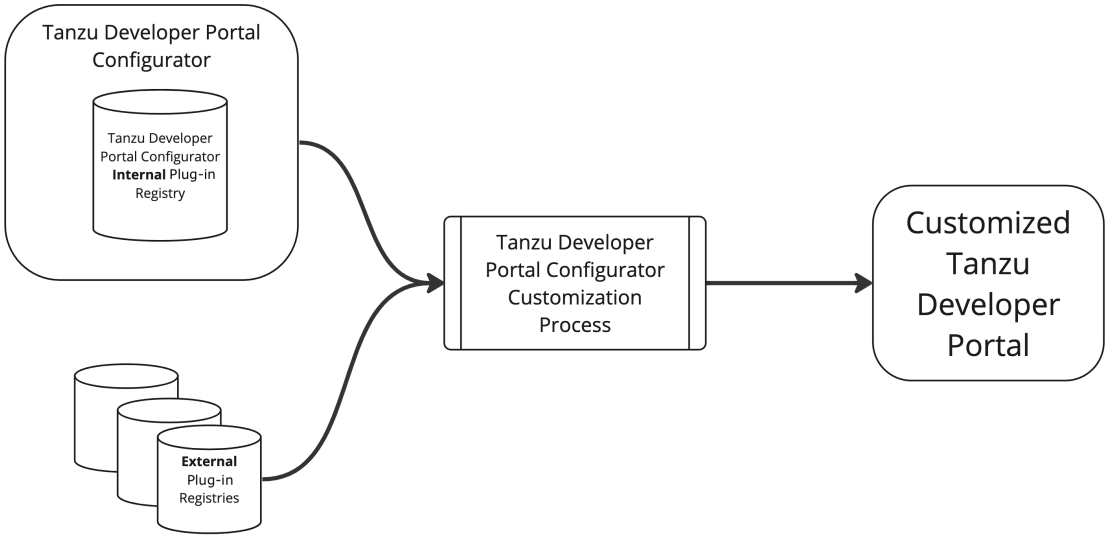
Buildtime configuration

Buildtime configuration refers to the values that you pass to Configurator to generate a new portal image. This configuration consists of a list of Tanzu Developer Portal plug-ins and any default runtime configuration for the portal image.

Tanzu Developer Portal Configurator

Tanzu Developer Portal Configurator is the image that contains everything necessary to build a customized version of Tanzu Developer Portal.

Configurator includes a templated version of Tanzu Developer Portal, an internal registry of Tanzu Developer Portal plug-ins, and tools to enable the build process to incorporate external plug-ins.



Tanzu Developer Portal plug-ins

While Backstage uses Backstage plug-ins to enable the user to customize functions, Tanzu Developer Portal uses Tanzu Developer Portal plug-ins to do the same thing.

A Tanzu Developer Portal plug-in is simply a Backstage plug-in wrapped in a small amount of code to facilitate easy integration into Configurator and Tanzu Developer Portal.

Internal plug-ins and external plug-ins

Internal Tanzu Developer Portal plug-ins are included inside the Tanzu Developer Portal Configurator image. These include:

- Tanzu Developer Portal plug-ins specifically built for Tanzu Application Platform
- Tanzu Developer Portal plug-ins for core Backstage plug-ins

External Tanzu Developer Portal plug-ins are not in the Tanzu Developer Portal Configurator image. They are hosted in, and installed, from an external registry, such as npmjs.com. External Tanzu Developer Portal plug-ins can include custom functions or wrap existing third-party Backstage plug-ins.

Tanzu Developer Portal plug-in surfaces

Tanzu Developer Portal plug-in surfaces are the mechanism that allows Tanzu Developer Portal plug-ins to change the behavior of the portal.

When adding a Backstage plug-in to an instance of Backstage, code modifications are required. Rather than editing code, Tanzu Developer Portal exposes extension points where Tanzu Developer Portal plug-ins can inject code. These extension points are known as surfaces.

The pre-built version of Tanzu Developer Portal has several surfaces to edit existing functions, including:

- Allowing new items to be added to the sidebar
- Adding new routes, such as `https://YOUR_PORTAL_URL/plugin`
- The ability to appear as a Catalog Overview tab

This pattern of exposing surfaces where Tanzu Developer Portal plug-ins can inject new behavior is not limited to what is offered in the pre-built version of Tanzu Developer Portal.

This pattern can also be applied on top of Tanzu Developer Portal plug-ins themselves. This allows for one Tanzu Developer Portal plug-in to build on top of another Tanzu Developer Portal plug-in.

Build your customized Tanzu Developer Portal with Configurator

This topic tells you how to build your customized Tanzu Developer Portal with Configurator.

Prerequisites

Ensure that the following is true:

- Configurator has a running and operating Tanzu Application Platform instance to build the customized portal and run the resulting customized image. You can use a `full` profile for everything or you can use a `build` profile for customizing the portal and a `view` profile for running the customized portal. For more information, see Components and installation profiles for Tanzu Application Platform.
- Your instance of Tanzu Application Platform has a working supply chain that can build the Tanzu Developer Portal bundle. It doesn't need to be able to deliver it because currently an overlay is used to place the built image on the cluster where the pre-built Tanzu Developer Portal resides.
- Your developer namespace has access to both:
  - Your installation registry where the source Tanzu Application bundles are located
  - Your build registry where your built images are staged
- You have a working Tanzu Application Platform installation and you can build a sample application, such as `Tanzu-Java-Web-App` in Generate an application with Application Accelerator.
- Your extra plug-ins are in the npmjs.com registry or a private registry.
- Carvel tools is installed on your workstation. `imgpkg`, in particular, must be installed to perform some of the build steps.
- The yq tool is installed.
- The Docker CLI is installed and you are logged into your registry.

Important

Tanzu Application Platform plug-ins cannot be removed from customized portals. However, if you decide you want to hide them, you can use the runtime configuration options in your `tap-values.yaml` file.

Prepare your Configurator configuration file

To prepare your Configurator configuration file:

1. Create a new file called `tdp-config.yaml` by using the following template:

```
app:
  plugins:
    - name: "NPM-PLUGIN-FRONTEND"
      version: "NPM-PLUGIN-FRONTEND-VERSION"
backend:
  plugins:
```

```
    - name: "NPM-PLUGIN-BACKEND"
      version: "NPM-PLUGIN-BACKEND-VERSION"
```

Where:

- `NPM-PLUGIN-FRONTEND` is the npm registry and module name of the front-end plug-in
- `NPM-PLUGIN-FRONTEND-VERSION` is the version of your desired front-end plug-in that exists in the npm registry
- `NPM-PLUGIN-BACKEND` is the npm registry and module name of the back-end plug-in that you want
- `NPM-PLUGIN-BACKEND-VERSION` is the version of your desired back-end plug-in that exists in the npm registry

The following example adds the sample `techinsights` plug-in. The plug-in wrapper is available in the VMware NPM repository:

```
app:
  plugins:
    - name: "@vmware-tanzu/tdp-plugin-techinsights"
      version: "0.0.2"

backend:
  plugins:
    - name: "@vmware-tanzu/tdp-plugin-techinsights-backend"
      version: "0.0.2"
```

2. If you plan to add plug-ins that exist in a private registry, configure the Configurator with a private registry.
3. Encode the file in Base64, to later embed `tdp-config.yaml` in the workload definition file, by running:

   ```
   base64 -i tdp-config.yaml
   ```

   If no plug-ins are specified in your `tdp-config.yaml` file, the following plug-ins are present by default:

   - Runtime Resources Visibility
   - Application Live View
   - Application Accelerator
   - API Documentation
   - Supply Chain Choreographer
   - Security Analysis
   - DORA Metrics

Identify your Configurator image

To build a customized Tanzu Developer Portal, you must identify the Configurator image to pass through the supply chain. Depending on your choices during installation, this is on either `registry.tanzu.vmware.com` or the local image registry (`imgpkg`) that you moved the installation packages to.

Using imgpkg v0.39.0 or earlier
If using imgpkg v0.39.0 or earlier:

1. Using the `imgpkg` tool, retrieve the image location by running:

   ```
   imgpkg describe -b $(kubectl get -n tap-install $(kubectl get package -n tap-
   install \
   --field-selector spec.refName=tpb.tanzu.vmware.com -o name) -o \
   jsonpath="{.spec.template.spec.fetch[0].imgpkgBundle.image}") -o yaml --tty=t
   rue | grep -A 1 \
   "kbld.carvel.dev/id:[[:blank:]]*[^[:blank:]]*configurator" | grep "image:" |
   sed 's/[[:blank:]]*image:[[:blank:]]*//g'
   ```

   Output similar to the following appears:

   ```
   IMAGE-REGISTRY/tap-packages@sha256:bea2f5bec5c5102e2a69a4c5047fae3d51f2974191
   1cf5bb588893aa4e03ca27
   ```

2. Record this value to later use it in place of the `TDP-IMAGE-LOCATION` placeholder in the workload definition.

Using imgpkg v0.40.0 or later

If using imgpkg v0.40.0 or later:

1. Using the `imgpkg` tool, download the bundle by running:

   ```
   imgpkg pull -b $(kubectl get -n tap-install $(kubectl get package -n tap-inst
   all \
   --field-selector spec.refName=tpb.tanzu.vmware.com -o name) -o \
   jsonpath="{.spec.template.spec.fetch[0].imgpkgBundle.image}") -o bundle
   ```

2. Retrieve the image location by running:

   ```
   cat bundle/.imgpkg/images.yml | grep -A 1 "kbld.carvel.dev/id:[[:blank:]]*[^
   [:blank:]]*configurator" | \
   grep "image:" | sed 's/[[:blank:]]*image:[[:blank:]]*//g'
   ```

   Output similar to the following appears:

   ```
   IMAGE-REGISTRY/tap-packages@sha256:bea2f5bec5c5102e2a69a4c5047fae3d51f2974191
   1cf5bb588893aa4e03ca27
   ```

3. Record this value to later use it in place of the `TDP-IMAGE-LOCATION` placeholder in the workload definition.

Build your customized portal

There are two options for passing your workload through a supply chain and building your customized portal:

Use an existing supply chain

To use an existing supply chain to build your custom portal:

1. Create a file called `tdp-workload.yaml` with the following content:

   ```
   apiVersion: carto.run/v1alpha1
   kind: Workload
   metadata:
     name: tdp-configurator
     namespace: DEVELOPER-NAMESPACE
     labels:
       apps.tanzu.vmware.com/workload-type: web
       app.kubernetes.io/part-of: tdp-configurator
   ```

```
spec:
  build:
    env:
      - name: BP_NODE_RUN_SCRIPTS
        value: 'set-tpb-config,portal:pack'
      - name: TPB_CONFIG
        value: /tmp/tpb-config.yaml
      - name: TPB_CONFIG_STRING
        value: ENCODED-TDP-CONFIG-VALUE

  source:
    image: TDP-IMAGE-LOCATION
    subPath: builder
```

Where:

- `DEVELOPER-NAMESPACE` is an appropriately configured developer namespace on the cluster.
- `ENCODED-TDP-CONFIG-VALUE` is the Base64-encoded value that you encoded earlier.
- `TDP-IMAGE-LOCATION` is the location of the Configurator image in the image registry from which you installed Tanzu Application Platform. You discovered this location earlier when you identified your Configurator image.

Depending on which supply chain you're using or how you configured it, you might need to add extra sections to your workload definition file to accommodate activities such as testing.

For example:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: tdp-configurator
  namespace: default
  labels:
    apps.tanzu.vmware.com/workload-type: web
    app.kubernetes.io/part-of: tdp-configurator
spec:
  build:
    env:
      - name: BP_NODE_RUN_SCRIPTS
        value: "set-tpb-config,portal:pack"
      - name: TPB_CONFIG
        value: /tmp/tpb-config.yaml
      - name: TPB_CONFIG_STRING
        value: YXBwOgogIHBsdWdpbnM6CiAgICAtIG5hbWU6ICdAdm13YXJlLXRhbnp1L3RkcC
1wbHVnaW4tdGVjaGluc2lnaHRzJwogICAgICB2ZXJzaW9uOiAnMC4wLjInCgpiYWNrZW5kOgogIHB
sdWdpbnM6IAogICAgLSBuYW1lOiAnQHZtd2FyZS10YW56dS90dS1wbHVnaW4tdGVjaHBsNpZ2h0
cy1iYWNrZW5kJwogICAgICB2ZXJzaW9uOiAnMC4wLjIn
  source:
    image: TDP-IMAGE-LOCATION
    subPath: builder
```

The `TPB_CONFIG_STRING` value can be decoded as the earlier example that includes the TechInsights front-end and back-end plug-ins.

`TDP-IMAGE-LOCATION` is the location of your Configurator image identified in earlier steps.

2. Submit the workload definition file by running:

```
kubectl apply -f tdp-workload.yaml
```

The supply chain does not need to go beyond the image-provider stage. After an image is built, you can proceed to run your customized Tanzu Developer Portal.

Use a custom supply chain

To use a custom supply chain to build your custom portal, follow these steps. This method creates a custom supply chain for `workload-type: tdp` that encompasses only the steps necessary to build the customized image:

1. Create a file called `tdp-sc.yaml` with the following content:

```
apiVersion: carto.run/v1alpha1
kind: ClusterSupplyChain
metadata:
  name: tdp-configurator
spec:
  resources:
  - name: source-provider
    params:
    - default: default
      name: serviceAccount
    - default: TDP-IMAGE-LOCATION
      name: tdp_configurator_bundle
    templateRef:
      kind: ClusterSourceTemplate
      name: tdp-source-template
  - name: image-provider
    params:
    - default: default
      name: serviceAccount
    - name: registry
      default:
        ca_cert_data: ""
        repository: IMAGE-REPOSITORY
        server: REGISTRY-HOSTNAME
    - default: default
      name: clusterBuilder
    sources:
    - name: source
      resource: source-provider
    templateRef:
      kind: ClusterImageTemplate
      name: tdp-kpack-template

  selectorMatchExpressions:
  - key: apps.tanzu.vmware.com/workload-type
    operator: In
    values:
    - tdp
---
apiVersion: carto.run/v1alpha1
kind: ClusterImageTemplate
metadata:
  name: tdp-kpack-template
spec:
  healthRule:
    multiMatch:
      healthy:
        matchConditions:
        - status: "True"
          type: BuilderReady
        - status: "True"
          type: Ready
      unhealthy:
        matchConditions:
        - status: "False"
```

```
        type: BuilderReady
      - status: "False"
        type: Ready
imagePath: .status.latestImage
lifecycle: mutable
params:
- default: default
  name: serviceAccount
- default: default
  name: clusterBuilder
- name: registry
  default: {}
ytt: |
  #@ load("@ytt:data", "data")
  #@ load("@ytt:regexp", "regexp")

  #@ def merge_labels(fixed_values):
  #@   labels = {}
  #@   if hasattr(data.values.workload.metadata, "labels"):

          value: #@ data.values.source.revision
        #@  if regexp.match("^([a-zA-Z0-9\/_-]+)(\@sha1:)?[0-9a-f]{40}$", dat
a.values.source.revision):
        - name: BP_OCI_REVISION
          value: #@ data.values.source.revision
        #@ end
        - name: BP_NODE_RUN_SCRIPTS
          value: #@ bp_node_run_scripts
        - name: TPB_CONFIG
          value: #@ tpb_config
        - name: TPB_CONFIG_STRING
          value: #@ tpb_config_string

---
apiVersion: carto.run/v1alpha1
kind: ClusterSourceTemplate
metadata:
  name: tdp-source-template
spec:
  healthRule:
    singleConditionType: Ready
  lifecycle: mutable
  params:
  - default: default
    name: serviceAccount
  revisionPath: .status.artifact.revision
  urlPath: .status.artifact.url
  ytt: |
    #@ load("@ytt:data", "data")

    #@ def merge_labels(fixed_values):
    #@   labels = {}
    #@   if hasattr(data.values.workload.metadata, "labels"):
    #@     exclusions = ["kapp.k14s.io/app", "kapp.k14s.io/association"]
    #@     for k,v in dict(data.values.workload.metadata.labels).items():
    #@       if k not in exclusions:
    #@         labels[k] = v
    #@       end
    #@     end
    #@   end
    #@   labels.update(fixed_values)
    #@   return labels
    #@ end

    ---
    apiVersion: source.apps.tanzu.vmware.com/v1alpha1
    kind: ImageRepository
    metadata:
      name: #@ data.values.workload.metadata.name
      labels: #@ merge_labels({ "app.kubernetes.io/component": "source" })
    spec:
      serviceAccountName: #@ data.values.params.serviceAccount
      interval: 10m0s
      #@ if hasattr(data.values.workload.spec, "source") and hasattr(data.val
ues.workload.spec.source, "image"):
      image: #@ data.values.workload.spec.source.image
      #@ else:
```

```
      image: #@ data.values.params.tdp_configurator_bundle
      #@ end
```

Where:

- `TDP-IMAGE-LOCATION` is the location of the Configurator image in the image registry from which you installed Tanzu Application Platform. You discovered this location earlier when you identified your Configurator image.
- `REGISTRY-HOSTNAME` is the name of the container registry that your developer namespace was configured to push artifacts to.
- `IMAGE-REPOSITORY` is the name of the repository (folder) on the `REGISTRY-HOSTNAME` that you want to push built artifacts to.

2. Submit the custom supply chain file by running:

```
kubectl apply -f tdp-sc.yaml
```

3. Create a file called `tdp-workload.yaml` with the following content:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: tdp-configurator-1-sc
  namespace: DEVELOPER-NAMESPACE
  labels:
    apps.tanzu.vmware.com/workload-type: tdp
    app.kubernetes.io/part-of: tdp-configurator-1-custom
spec:
  build:
    env:
      - name: TPB_CONFIG_STRING
        value: ENCODED-TDP-CONFIG-VALUE
```

Where:

- `DEVELOPER-NAMESPACE` is an appropriately configured developer namespace on the cluster
- `ENCODED-TDP-CONFIG-VALUE` is the Base64-encoded value that you encoded earlier

4. Submit the workload definition file by running:

```
tanzu apps workload create -f tdp-workload.yaml
```

After the job finishes the Image Provider stage of your supply chain, run your customized Tanzu Developer Portal instance.

Create a Tanzu Developer Portal plug-in

This topic teaches you how to create a Tanzu Developer Portal plug-in by wrapping an existing Backstage plug-in. After you create a Tanzu Developer Portal plug-in, you can build a customized Tanzu Developer Portal with Configurator.

Prerequisites

Meet the following prerequisites before creating a Tanzu Developer Portal plug-in.

Software

Ensure that you have the following software installed locally to develop a Tanzu Developer Portal plug-in:

- Node 18: `nvm` is recommended. For how to install `nvm`, see the `nvm` GitHub repository. For how to install a specific version of `nvm`, see the NodeJS documentation.
- yarn v1
- (Optional) A UNIX-based OS: If you use Windows, you must find alternatives to some commands in this topic.

A Backstage plug-in in an accessible npm registry

Ensure that the Backstage plug-in you want to wrap is in an npm registry. You can use your own private registry or a public registry, such as npm JS. Both your development machine and your Tanzu Application Platform cluster must have access to the registry.

This topic tells you, by way of example, how to wrap the Backstage TechInsights plug-in. This plug-in consists of back-end and front-end components, both of which are available on npm JS:

- @backstage/plugin-tech-insights v0.3.19
- @backstage/plugin-tech-insights-backend v0.5.21

Set up a development environment

This topic tells you how to create two Tanzu Developer Portal plug-ins by wrapping the `@backstage/plugin-tech-insights` and `@backstage/plugin-tech-insights-backend` Backstage plug-ins. You can create a separate repository for each of these plug-ins, but it's easier and simpler to do the work for both in a single monorepo.

Generate a Backstage app for the monorepo

This topic describes how to use the Backstage tools `@backstage/create-app` and `backstage-cli` to manage your monorepo. The Backstage tools make managing packages easier. However, you will not develop a traditional Backstage app, and you will remove some portions of generated code later.

1. This tutorial uses `plugin-wrappers` as the app name. Run the `create-app` script and, when prompted, enter a name for your app:

   ```
   npx @backstage/create-app@0.5.7 --skip-install
   ```

   `@backstage/create-app` v0.5.7 is used because the Tanzu Developer Portal version that ships with Tanzu Application Platform v1.8 uses Backstage v1.20.3. Backstage v1.20.3 uses `@backstage/create-app` v0.5.7. For more information, see the Backstage version manifest.

   Important

   Ensure that you use the correct versions of dependencies for your Tanzu Application Platform version. Use the Backstage version compatibility reference table to find which versions of Backstage dependencies work with your version of Tanzu Application Platform.

   The `--skip-install` flag tells the script to not run `yarn install`. This is because you will remove the unnecessary dependencies that would have been needed if you were building a traditional Backstage app before installing your dependencies.

The `create-app` command scaffolds a Backstage project structure under a directory matching your project name.

2. Run:

```
cd APP-NAME
```

Where `APP-NAME` is your application name. For example, `plugin-wrappers`.

Remove some dependencies

To remove unnecessary dependencies you must:

1. Remove the packages directory by running:

```
rm -rf packages/
```

The packages directory contains a scaffolded Backstage `app` and `backend`, which are only necessary for a traditional Backstage app.

2. Remove the packages directory from the `yarn` workspaces by deleting the `"packages/*"` line within the `workspaces` attribute in `package.json`. For example:

```
diff --git a/package.json b/package.json
index 00d64c9..77f38f3 100644
--- a/package.json
+++ b/package.json
@@ -24,7 +24,6 @@
  },
  "workspaces": {
    "packages": [
-      "packages/*",
      "plugins/*"
    ]
  },
```

3. Install the dependencies by running:

```
yarn install
```

This command installs `backstage-cli` and a few other dependencies.

Create the Tech Insights front-end Tanzu Developer Portal plug-in

Now that you have an environment to develop your Tanzu Developer Portal plug-ins, you can begin wrapping Backstage plug-ins. You will start with the Tech Insight front-end plug-in.

Generate a front-end plug-in

This section describes how to generate a front-end plug-in:

1. Generate a front-end plug-in by running the following command, replacing `PACKAGE-NAMESPACE` with your namespace (for example, `@mycompany`):

```
yarn backstage-cli new --select plugin --option id=tech-insights-wrapper --scop
e PACKAGE-NAMESPACE --no-private
```

Important

> The `yarn install` step of the previous command fails because of a Node version issue. This is handled in a later step.

Here is a summary of what the `backstage-cli new` script does:

- `--select plugin` creates a front-end plug-in
- `--option id=tech-insights-wrapper` names the plug-in `tech-insights-wrapper`
- `--scope PACKAGE-NAMESPACE` scopes the package under the `PACKAGE-NAMESPACE` namespace
- `--no-private` sets the package to public

2. Open the `plugins/tech-insights-wrapper/package.json` to see how these options were mapped to the generated `package.json`.

Add dependencies for the front-end plug-in

Update your dependencies for the specific Backstage plug-in you want to wrap:

1. Replace the `dependencies` in the `package.json` with:

```
...
"dependencies": {
 "@backstage/plugin-tech-insights": "0.3.19",
 "@backstage/plugin-catalog": "1.15.1",
 "@vmware-tanzu/core-common": "2.0.0",
 "@vmware-tanzu/core-frontend": "2.0.0"
},
...
```

2. The dependency on `@backstage/plugin-tech-insights` is obvious, but verify the version is compatible with your Tanzu Application Platform version by reading the Backstage version compatibility table and checking the version listed in the Backstage Manifest file for your specific Tanzu Application Portal version.
3. `@backstage/plugin-catalog` is needed for a UI component that you use later. Verify its version by using the Backstage version compatibility table.
4. Verify that you are using the correct versions of `@vmware-tanzu/core-common` and `@vmware-tanzu/core-frontend` by cross-referencing the dependency name with your Tanzu Application Platform version in the Tanzu Developer Portal plug-in libraries compatibility tables. You use `@vmware-tanzu/core-common` and `@vmware-tanzu/core-frontend` later for integrating the Backstage plug-in with Tanzu Developer Portal.
5. Install the dependencies you added by running:

```
cd plugins/tech-insights-wrapper
yarn install --ignore-engines
```

Remove unnecessary code for the front-end plug-in

The `backstage-cli new` command created example code that you don't need. Remove this code and start with an empty `src` directory by running:

```
rm -rf dev/ src/ && mkdir src
```

Wrap the Backstage front-end plug-in

1. Read the documentation for @backstage/plugin-tech-insights. You will see that to use this Backstage plug-in, you must edit the content of the serviceEntityPage constant. Because you do not have access to the Tanzu Developer Portal source code, you cannot change that constant directly. Instead, you must use a surface to make the equivalent change.
2. Create the file where you will use a surface to edit the `serviceEntityPage` constant by running:

   ```
   touch src/TechInsightsFrontendPlugin.tsx
   ```

3. In the `TechInsightsFrontendPlugin.tsx` file, add the following code:

   ```
   import { EntityLayout } from '@backstage/plugin-catalog';
   import { EntityTechInsightsScorecardContent } from '@backstage/plugin-tech-insi
   ghts';
   import {
    AppPluginInterface,
    SurfaceStoreInterface,
    EntityPageSurface,
   } from '@vmware-tanzu/core-frontend';
   import React from 'react';

   export const TechInsightsFrontendPlugin: AppPluginInterface =
    () => (context: SurfaceStoreInterface) => {
      context.applyTo(
        EntityPageSurface,
        (entityPageSurface) => {
          entityPageSurface.servicePage.addTab(
            <EntityLayout.Route path="/techinsights" title="TechInsights">
              <EntityTechInsightsScorecardContent
                title="TechInsights Scorecard."
                description="TechInsight's default fact-checkers"
              />
            </EntityLayout.Route>,
          );
        },
      );
    };
   ```

   Where:

   - `context.applyTo` is a function that takes the class of the surface you want to interact with, and a function that is passed the instance of that class.
   - The `EntityPageSurface` keeps track of tabs that appear on the service page. You add a new tab by calling `entityPageSurface.servicePage.addTab` and passing it the UI component you want it to render.
   - `TechInsightsFrontendPlugin: AppPluginInterface = () => (context: SurfaceStoreInterface) => {}` is boilerplate code that enables you to interact with the various front-end surfaces in Tanzu Developer Portal.
   - `EntityPageSurface` is one example of the many surfaces available in Tanzu Developer Portal. To discover all the surfaces currently available, see How to use surfaces. For surface API reference information, see API documentation for surfaces.

   This code accomplishes the same thing as the @backstage/plugin-tech-insights, but for an integration with Tanzu Developer Portal instead of a traditional Backstage app.

Expose and build the Tanzu Developer Portal front-end plug-in

To expose and then build the front-end plug-in:

1. Create an `index.ts` file under the `plugins/tech-insights-wrapper/src` directory:

   ```
   touch src/index.ts
   ```

2. In the `index.ts` file write:

   ```
   export { TechInsightsFrontendPlugin as plugin } from './TechInsightsFrontendPlu
   gin';
   ```

   This exports `TechInsightsFrontendPlugin` in a way that enables Configurator to use your plug-in. You need to alias `TechInsightsFrontendPlugin` to `plugin` because the Tanzu Developer Portal Configurator expects compatible plug-ins to export a symbol with the name `plugin`.

3. Build your Tanzu Developer Portal plug-in by running:

   ```
   yarn tsc && yarn build
   ```

You can now publish this plug-in to your npm registry. However, you cannot use the plug-in functions without the back-end portion.

Create the Tech Insights back-end Tanzu Developer Portal plug-in

Creating the back-end plug-in is very similar to the work you did for the front-end plug-in. This section does not describe in detail what is happening at each step except for where it differs from the previous work.

Generate a back-end plug-in

This describes how to generate a back-end plug-in.

From the root of your project, generate a back-end plug-in by running:

```
yarn backstage-cli new --select backend-plugin --option id=tech-insights-wrapper --sco
pe PACKAGE-NAMESPACE --no-private
```

Where:

- `PACKAGE-NAMESPACE` is the namespace for your package. For example, `@mycompany`.
- `--select backend-plugin` tells the `backstage-cli` to generate a back-end plug-in.
- `--option id=tech-insights-wrapper` provides the name for the plug-in. The ID you provide is the same as the front-end plug-in. `backstage-cli` automatically appends `-backend` to the directory and package-name of back-end plug-ins to prevent conflict with the front-end plug-in.

Add dependencies for the back-end plug-in

To add your dependencies for the specific Backstage plug-in you want to wrap:

1. Update the dependencies in `package.json` as follows:

   ```
   "dependencies": {
    "@backstage/plugin-tech-insights-backend": "0.5.21",
    "@backstage/plugin-tech-insights-backend-module-jsonfc": "0.1.39",
    "@vmware-tanzu/core-backend": "2.0.1",
    "express": "4.18.2"
   },
   ```

2. Install your dependencies by running:

```
cd plugins/tech-insights-wrapper-backend/
yarn install --ignore-engines
```

Remove unnecessary code for the back-end plug-in

Remove the Backstage scaffolded example code by running:

```
rm -rf src/ && mkdir src
```

Wrap the Backstage back-end plug-in

1. Within the `src/` directory, create a file called `TechInsightsBackendPlugin.ts` by running:

```
touch src/TechInsightsBackendPlugin.ts
```

2. In `TechInsightsBackendPlugin.ts`, add the following code:

```
import {
 createRouter,
 buildTechInsightsContext,
 createFactRetrieverRegistration,
 entityOwnershipFactRetriever,
 entityMetadataFactRetriever,
 techdocsFactRetriever,
} from '@backstage/plugin-tech-insights-backend';
import { Router } from 'express';
import {
 JsonRulesEngineFactCheckerFactory,
 JSON_RULE_ENGINE_CHECK_TYPE,
} from '@backstage/plugin-tech-insights-backend-module-jsonfc';
import {
 BackendPluginInterface,
 BackendPluginSurface,
 PluginEnvironment,
} from '@vmware-tanzu/core-backend';

const ttlTwoWeeks = { timeToLive: { weeks: 2 } };

export default async function createPlugin(
       env: PluginEnvironment,
): Promise<Router> {
 const techInsightsContext = await buildTechInsightsContext({
   logger: env.logger,
   config: env.config,
   database: env.database,
   discovery: env.discovery,
   tokenManager: env.tokenManager,
   scheduler: env.scheduler,
   factRetrievers: [
     createFactRetrieverRegistration({
       cadence: '0 */6 * * *', // Run every 6 hours - https://crontab.guru/#0_
*/6_*_*_*
       factRetriever: entityOwnershipFactRetriever,
       lifecycle: ttlTwoWeeks,
     }),
     createFactRetrieverRegistration({
       cadence: '0 */6 * * *',
       factRetriever: entityMetadataFactRetriever,
       lifecycle: ttlTwoWeeks,
     }),
     createFactRetrieverRegistration({
```

```
      cadence: '0 */6 * * *',
      factRetriever: techdocsFactRetriever,
      lifecycle: ttlTwoWeeks,
    }),
  ],
  factCheckerFactory: new JsonRulesEngineFactCheckerFactory({
    logger: env.logger,
    checks: [
      {
        id: 'groupOwnerCheck',
        type: JSON_RULE_ENGINE_CHECK_TYPE,
        name: 'Group Owner Check',
        description:
                'Verifies that a Group has been set as the owner for this enti
ty',
        factIds: ['entityOwnershipFactRetriever'],
        rule: {
          conditions: {
            all: [
              {
                fact: 'hasGroupOwner',
                operator: 'equal',
                value: true,
              },
            ],
          },
        },
      },
      {
        id: 'titleCheck',
        type: JSON_RULE_ENGINE_CHECK_TYPE,
        name: 'Title Check',
        description:
                'Verifies that a Title, used to improve readability, has been
set for this entity',
        factIds: ['entityMetadataFactRetriever'],
        rule: {
          conditions: {
            all: [
              {
                fact: 'hasTitle',
                operator: 'equal',
                value: true,
              },
            ],
          },
        },
      },
      {
        id: 'techDocsCheck',
        type: JSON_RULE_ENGINE_CHECK_TYPE,
        name: 'TechDocs Check',
        description:
                'Verifies that TechDocs has been enabled for this entity',
        factIds: ['techdocsFactRetriever'],
        rule: {
          conditions: {
            all: [
              {
                fact: 'hasAnnotationBackstageIoTechdocsRef',
                operator: 'equal',
                value: true,
              },
            ],
          },
        },
```

```
        },
      ],
    }),
  });

  return await createRouter({
    ...techInsightsContext,
    logger: env.logger,
    config: env.config,
  });
}

export const TechInsightsBackendPlugin: BackendPluginInterface =
  () => surfaces =>
    surfaces.applyTo(BackendPluginSurface, backendPluginSurface => {
      backendPluginSurface.addPlugin({
        name: 'tech-insights',
        pluginFn: createPlugin,
      });
    });
```

The majority of this code comes from the npm JS documentation. The Backstage plug-in documentation instructs you to create a constant for `techInsightsEnv` and then configure the router by using `apiRouter.use('/tech-insights', await techInsights(techInsightsEnv))` all in the Backstage source code. Because you are unable to edit the source code of Tanzu Developer Portal, this code accomplishes the same thing by:

- Getting an instance of `BackendPluginSurface`. This surface keeps track of all the back-end plug-ins.
- Adding your plug-in by using the `addPlugin` function. The `name` argument is used to configure the path in the router.

Expose and build the Tanzu Developer Portal back-end plug-in

To expose and then build the back-end plug-in:

1. Create an `index.ts` file by running:

   ```
   touch src/index.ts
   ```

2. In the `index.ts` file, write:

   ```
   export { TechInsightsBackendPlugin as plugin } from './TechInsightsBackendPlugi
   n';
   ```

   This exposes the Tanzu Developer Portal plug-in.

3. Build your plug-in by running:

   ```
   yarn tsc && yarn build
   ```

Next steps

You can now publish your Tanzu Developer Portal plug-ins to your registry of choice. If you want to publish your plug-ins to a private registry, see Configure the Configurator with a private registry.

After publishing your plug-ins, you can build a customized Tanzu Developer Portal with Configurator.

Configure the Configurator with a private registry

If you have plug-ins stored in a private registry that you want to include in your customized Tanzu Developer Portal, you can configure Configurator in the `tdp-config.yaml` file.

Caution

This feature is in the alpha stage. Do not use this feature in a production environment.

Methods

Use one of two methods to configure Configurator:

- Provide the private registry token in the `tpb` configuration
- Store the private registry token in a secret

tpb config method

This method makes your credentials Base64-encoded in the workload definition. Therefore, use this method with caution.

1. In your `tdp-config.yaml` file, add a `registry.uplinks` section to include your private registry. Add the `auth` property to the `registry.uplinks` section, as seen in the Verdaccio documentation.
2. Use an authentication token with the uplink by using one of three methods:
    - Use the default environment variable
    - Use a specified custom environment variable
    - Directly specify a token in the configuration file

    You cannot create an uplink with the name `tpb` or `npmjs` because these packages are reserved and cannot be overridden.
3. In your `tdp-config.yaml` file, add a `registry.packages` section. This section lists access rules for different packages. For more information about this section, see the Verdaccio documentation. You cannot create a package with the name `@tpb/*` because these packages are reserved and cannot be overridden.

    Here is a full example that directly specifies the authentication token in the configuration file:

```
registry:
 uplinks:
   private-registry:
     url: PRIVATE-REGISTRY-ENDPOINT
     auth:
       type: bearer
       token: VALID-TOKEN-FOR-PRIVATE-REGISTRY
 packages:
   '@company/*':
     access: $all
     proxy: private-registry
app:
 plugins:
   - name: '@tpb/plugin-hello-world'
backend:
```

```
 plugins:
   - name: '@tpb/plugin-hello-world-backend'
```

This configuration instructs to download any package with the scope `@company` from the `private-registry` registry with the specified credentials.

secret method

This method is more appropriate if you don't want the registry token to appear in the workload. It is based on the secrets mechanism available in Kubernetes.

1. Create a secret resource that will contain the private registry token. For example:

   ```
   apiVersion: v1
   kind: Secret
   metadata:
    namespace: DEVELOPER-NAMESPACE
    name: private-registry
   data:
    registry_token: A-TOKEN
   ```

   Where `A-TOKEN` is the token value encoded in Base64.

2. In your `tdp-config.yaml` file, add a `registry.uplinks` section to include your private registry. Add the `auth` property to the `registry.uplinks` section, as seen in the Verdaccio documentation, to use an authentication token with an uplink.

   You cannot create an uplink with the name `tpb` or `npmjs` because these uplinks are reserved and cannot be overridden.

3. In your `tdp-config.yaml` file, add a `registry.packages` section. This section lists access rules for different packages. For more information about this section, see the Verdaccio documentation.

   You cannot create a package with the name `@tpb/*` because these packages are reserved and cannot be overridden.

   Here is the full example that uses an `NPM_TOKEN` environment variable:

   ```
   registry:
    uplinks:
      private:
        url: PRIVATE-REGISTRY-ENDPOINT
        auth:
          type: bearer
          token_env: NPM_TOKEN
    packages:
      '@company/*':
        access: $all
        proxy: private
   app:
    plugins:
      - name: '@company/company-plugin'
   backend:
    plugins:
      - name: '@company/company-plugin-backend'
   ```

   This configuration instructs to download any package with the scope `@company` from the `private-registry` registry with the specified credentials.

4. Populate the environment variable value with the secret value in the workload file:

   ```
   apiVersion: carto.run/v1alpha1
   kind: Workload
   # ... remaining of the workload file
   ```

```
spec:
 build:
   env:
     - name: NPM_TOKEN
       valueFrom:
         secretKeyRef:
           key: registry_token
           name: private-registry
# ... remaining of the workload file
```

(Optional) Redirect all the npm requests to a private registry

By default, Configurator redirects all the external requests to `npmjs`. If, for some reason, you need to redirect those requests to your private registry, edit the `registry.packages` section as follows:

```
registry:
  uplinks:
    private:
      url: PRIVATE-REGISTRY-ENDPOINT
      auth:
        type: bearer
        token_env: NPM_TOKEN
  packages:
    '**':
      access: $all
      proxy: private
```

Run your Customized Tanzu Developer Portal

At this stage, you have built your customized Tanzu Developer Portal with Configurator.

After the build has completed, you retrieve the image reference of the built portal. You then use the image reference to perform a ytt overlay to substitute that image name for the one running the pre-built Tanzu Developer Portal on your cluster.

Identify the customized image reference

Identify the image that the supply chain built so that you can use the image reference in your ytt overlay in the next section. There are several ways to retrieve this image name, including using the Kubernetes command-line tool (kubectl) or using the Tanzu Developer Portal GUI.

kubectl
Run:

```
kubectl -n DEVELOPER-NAMESPACE get images.kpack.io WORKLOAD-NAME -o jsonpath={.statu
s.latestImage}
```

Where:

- `DEVELOPER-NAMESPACE` is the configured developer namespace on the cluster where you ran the workload.
- `WORKLOAD-NAME` is the name of the workload you used.

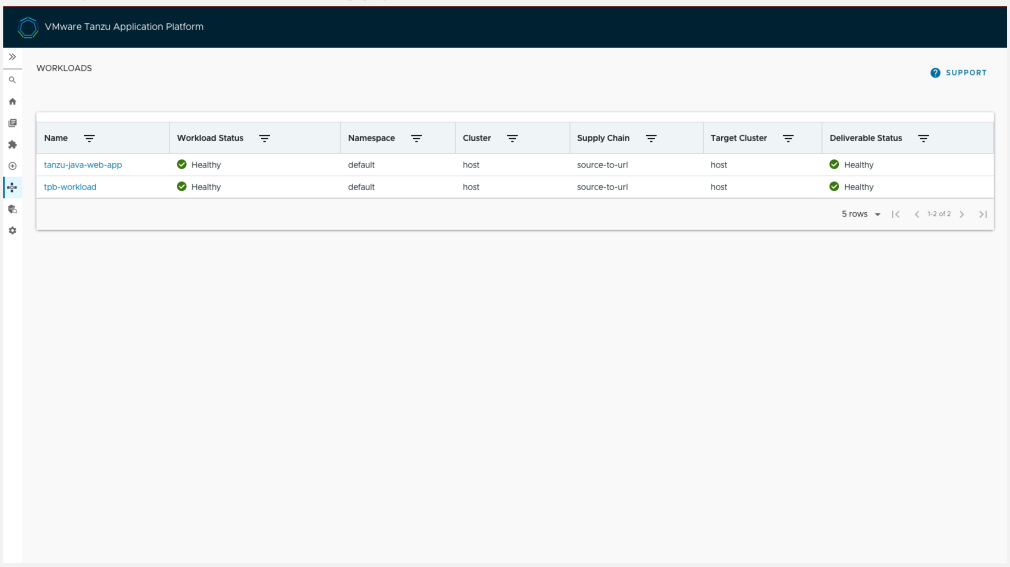
For example:

```
> kubectl -n default get images.kpack.io tdp-workload -o jsonpath={.status.latestIma
ge}
> kapplegate.azurecr.io/demo/workloads/tdp-workload-default@sha256:bae710386f7d81a72
5ce5ab15d76a3dd4f6ea79804ae0a475cf98f5e3dd6cf82
```

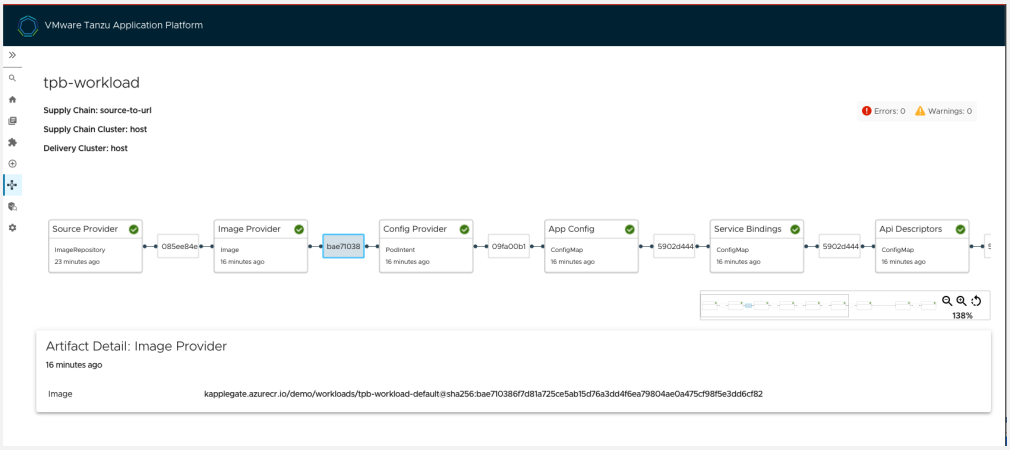
Tanzu Developer Portal GUI

Within the Tanzu Developer Portal GUI:

1. Select your workload in the Supply Chain view.



2. Record the Artifact Detail image value you see in the detailed view of the workload.



Prepare to overlay your customized image onto the currently running instance

To prepare to overlay your customized image onto the currently running instance:

1. Create the ytt overlay secret.
2. Create a file called `tdp-overlay-secret.yaml` with the following content to replace `IMAGE-REFERENCE` with the customized image you retrieved earlier. There is one of two possible values. The value depends on whether you installed Tanzu Application Platform with the `lite` dependencies (default) or the `full` dependencies.

Content for lite

This is the content for `tdp-overlay-secret.yaml` if you installed the `lite` dependencies (default):

```
apiVersion: v1
kind: Secret
metadata:
  name: tdp-app-image-overlay-secret
  namespace: tap-install
stringData:
  tdp-app-image-overlay.yaml: |
    #@ load("@ytt:overlay", "overlay")

    #! makes an assumption that tap-gui is deployed in the namespace: "tap-gu
i"
    #@overlay/match by=overlay.subset({"kind": "Deployment", "metadata": {"na
me": "server", "namespace": "tap-gui"}}), expects="1+"
    ---
    spec:
      template:
        spec:
          containers:
            #@overlay/match by=overlay.subset({"name": "backstage"}),expects
="1+"
            #@overlay/match-child-defaults missing_ok=True
            - image: IMAGE-REFERENCE
            #@overlay/replace
              args:
              - -c
              - |
                export KUBERNETES_SERVICE_ACCOUNT_TOKEN="$(cat /var/run/secre
ts/kubernetes.io/serviceaccount/token)"
                exec /layers/tanzu-buildpacks_node-engine-lite/node/bin/node
portal/dist/packages/backend  \
                --config=portal/app-config.yaml \
                --config=portal/runtime-config.yaml \
                --config=/etc/app-config/app-config.yaml
```

Content for full

This is the content for `tdp-overlay-secret.yaml` if you installed the `full` dependencies:

```
apiVersion: v1
kind: Secret
metadata:
  name: tdp-app-image-overlay-secret
  namespace: tap-install
stringData:
  tdp-app-image-overlay.yaml: |
    #@ load("@ytt:overlay", "overlay")

    #! makes an assumption that tap-gui is deployed in the namespace: "tap-gu
i"
    #@overlay/match by=overlay.subset({"kind": "Deployment", "metadata": {"na
me": "server", "namespace": "tap-gui"}}), expects="1+"
    ---
    spec:
      template:
        spec:
          containers:
            #@overlay/match by=overlay.subset({"name": "backstage"}),expects
="1+"
            #@overlay/match-child-defaults missing_ok=True
            - image: IMAGE-REFERENCE
            #@overlay/replace
              args:
              - -c
```

```
              - |
                export KUBERNETES_SERVICE_ACCOUNT_TOKEN="$(cat /var/run/secre
ts/kubernetes.io/serviceaccount/token)"
                exec /layers/tanzu-buildpacks_node-engine/node/bin/node porta
l/dist/packages/backend  \
                --config=portal/app-config.yaml \
                --config=portal/runtime-config.yaml \
                --config=/etc/app-config/app-config.yaml
```

3. Apply the secret by running:

```
kubectl apply -f tdp-overlay-secret.yaml
```

4. Add the secret to `tap-values.yaml`, the file used to install Tanzu Application Platform. For example:

```
profile: full
tap_gui:
  ...
package_overlays:
- name: tap-gui
  secrets:
  - name: tdp-app-image-overlay-secret
```

5. Update your installation to use the modified `tap-values.yaml` file. The exact steps vary depending on your installation method (GitOps, online install, or offline install).

   For how to do so for an online installation, see Install your Tanzu Application Platform package.

Important

The cluster that is running Tanzu Developer Portal (formerly known as `TAP-GUI`) needs the relevant credentials to pull images from the container registry that contains your customized portal.

If the cluster is in a `full` profile, it likely has the necessary credentials. In a multicluster installation (`view` profile) you likely need to use the Tanzu CLI to add the relevant credentials.

Troubleshoot Tanzu Developer Portal Configurator

This topic helps you troubleshoot Tanzu Developer Portal Configurator.

No supply chain found in `tdp-workload.yaml`

Symptom

No supply chain is found in `tdp-workload.yaml`

Cause

You might not have specified all of the correct information regarding your workload if you're using a supply chain other than `basic`. This documentation has the assumption that you're running the `basic` supply chain, so it doesn't tell you to add any tests. Because supply chains are configurable, there might be stages unique to your configuration.

Solution

If you have a supply chain that requires testing, use a no-op set of tests to make the workload pass through. For more information about no-op, see Wikipedia.

Add the following test YAML to your developer namespace:

```
apiVersion: tekton.dev/v1beta1
kind: Pipeline
metadata:
  labels:
    apps.tanzu.vmware.com/pipeline: noop-pipeline
  name: developer-defined-noop-tekton-pipeline
  namespace: DEVELOPER-NAMESPACE
spec:
  params:
  - name: source-url
    type: string
  - name: source-revision
    type: string
  tasks:
  - name: noop-task
    params:
    - name: source-url
      value: $(params.source-url)
    - name: source-revision
      value: $(params.source-revision)
    taskSpec:
      metadata: {}
      params:
      - name: source-url
        type: string
      - name: source-revision
        type: string
      steps:
      - image: bash
        name: noop
        resources: {}
        script: |
          echo "Nothing to do for $(params.source-url)/$(params.source-revision)"%
```

Where `DEVELOPER-NAMESPACE` is an appropriately configured developer namespace on the cluster

Add the following YAML to your workload definition:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  labels:
    # Existing labels
    apps.tanzu.vmware.com/has-tests: 'true'
spec:
  # Existing parameters
  params:
    - name: testing_pipeline_matching_labels
      value:
        apps.tanzu.vmware.com/pipeline: noop-pipeline
    - name: testing_pipeline_params
      value: {}
```

Now when you submit your workload, the testing stage finishes.

Convention controller fails frequently

Symptom

Convention controller fails frequently and prevents other workloads from completing.

Cause

The frequent failures are caused by the large memory limit of the Software Bill of Materials (SBOM). The Tanzu Developer Portal Configurator build process produces this SBOM, and `PodIntent` reports an out-of-memory error.

Solution

Create an overlay to increase the memory limit of `PodIntent` to 512 MB. To learn how to do so, see Troubleshoot Cartographer Conventions.

Using surfaces

This topic gives you small basic examples of how to use the various surfaces when creating a Tanzu Developer Portal plug-in.

BackendPluginSurface

Use `BackendPluginSurface` if you must add routes to the `apiRouter` commonly found in `packages/backend/src/index.ts`.

Example:

```
import {
  createRouter,
  buildTechInsightsContext,
  createFactRetrieverRegistration,
  entityOwnershipFactRetriever,
  entityMetadataFactRetriever,
  techdocsFactRetriever,
} from '@backstage/plugin-tech-insights-backend';
import { Router } from 'express';
import {
  JsonRulesEngineFactCheckerFactory,
  JSON_RULE_ENGINE_CHECK_TYPE,
} from '@backstage/plugin-tech-insights-backend-module-jsonfc';
import {
  BackendPluginInterface,
  BackendPluginSurface,
  PluginEnvironment,
} from '@vmware-tanzu/core-backend';

const ttlTwoWeeks = { timeToLive: { weeks: 2 } };

export default async function createPlugin(
        env: PluginEnvironment,
): Promise<Router> {
  const techInsightsContext = await buildTechInsightsContext({
    logger: env.logger,
    config: env.config,
    database: env.database,
    discovery: env.discovery,
    tokenManager: env.tokenManager,
    scheduler: env.scheduler,
    factRetrievers: [
      createFactRetrieverRegistration({
        cadence: '0 */6 * * *', // Run every 6 hours - https://crontab.guru/#0_*/6_*_*
_*
```

```
        factRetriever: entityOwnershipFactRetriever,
        lifecycle: ttlTwoWeeks,
      }),
      createFactRetrieverRegistration({
        cadence: '0 */6 * * *',
        factRetriever: entityMetadataFactRetriever,
        lifecycle: ttlTwoWeeks,
      }),
      createFactRetrieverRegistration({
        cadence: '0 */6 * * *',
        factRetriever: techdocsFactRetriever,
        lifecycle: ttlTwoWeeks,
      }),
    ],
    factCheckerFactory: new JsonRulesEngineFactCheckerFactory({
      logger: env.logger,
      checks: [
        {
          id: 'groupOwnerCheck',
          type: JSON_RULE_ENGINE_CHECK_TYPE,
          name: 'Group Owner Check',
          description:
                  'Verifies that a Group has been set as the owner for this entity',
          factIds: ['entityOwnershipFactRetriever'],
          rule: {
            conditions: {
              all: [
                {
                  fact: 'hasGroupOwner',
                  operator: 'equal',
                  value: true,
                },
              ],
            },
          },
        },
        {
          id: 'titleCheck',
          type: JSON_RULE_ENGINE_CHECK_TYPE,
          name: 'Title Check',
          description:
                  'Verifies that a Title, used to improve readability, has been set fo
r this entity',
          factIds: ['entityMetadataFactRetriever'],
          rule: {
            conditions: {
              all: [
                {
                  fact: 'hasTitle',
                  operator: 'equal',
                  value: true,
                },
              ],
            },
          },
        },
        {
          id: 'techDocsCheck',
          type: JSON_RULE_ENGINE_CHECK_TYPE,
          name: 'TechDocs Check',
          description:
                  'Verifies that TechDocs has been enabled for this entity',
          factIds: ['techdocsFactRetriever'],
          rule: {
            conditions: {
              all: [
```

```
                {
                  fact: 'hasAnnotationBackstageIoTechdocsRef',
                  operator: 'equal',
                  value: true,
                },
              ],
            },
          },
        },
      ],
    }),
  });

  return await createRouter({
    ...techInsightsContext,
    logger: env.logger,
    config: env.config,
  });
}

export const TechInsightsBackendPlugin: BackendPluginInterface =
  () => surfaces =>
    surfaces.applyTo(BackendPluginSurface, backendPluginSurface => {
      backendPluginSurface.addPlugin({
        name: 'tech-insights',
        pluginFn: createPlugin,
      });
    });
```

BannerSurface

`BannerSurface` enables you to add to the DOM at the top of the page before the content, which is commonly used for banners. The only elements that can appear before the banners in the DOM are `AlertDisplay` and `OAuthRequestDialog`. You can add multiple banners to the surface. The multiple banners are rendered in order of registration.

Example:

```
import React from 'react';
import {
  AppPluginInterface,
  BannerSurface,
} from '@vmware-tanzu/core-frontend';

export const HelloWorldPlugin: AppPluginInterface = () => context => {
  context.applyTo(BannerSurface, banners => {
    banners.add(<div>Hello World Banner</div>);
  });
};
```

EntityPageSurface

Use `EntityPageSurface` if you must add to the `serviceEntityPage` constant found in `packages/app/src/components/catalog/EntityPage.tsx`.

Example:

```
import { EntityLayout } from '@backstage/plugin-catalog';
import { EntityTechInsightsScorecardContent } from '@backstage/plugin-tech-insights';
import {
  AppPluginInterface,
  SurfaceStoreInterface,
```

```
  EntityPageSurface,
} from '@vmware-tanzu/core-frontend';
import React from 'react';

export const TechInsightsFrontendPlugin: AppPluginInterface =
  () => (context: SurfaceStoreInterface) => {
    context.applyTo(
      EntityPageSurface,
      (entityPageSurface) => {
        entityPageSurface.servicePage.addTab(
          <EntityLayout.Route path="/techinsights" title="TechInsights">
            <EntityTechInsightsScorecardContent
              title="TechInsights Scorecard."
              description="TechInsight's default fact-checkers"
            />
          </EntityLayout.Route>,
        );
      },
    );
  };
```

SettingsTabsSurface

Use `SettingsTabsSurface` if you want to add child routes to the `/settings` route defined in the `route` constant of `packages/app/src/App.tsx`. This action also adds a tab to the settings page so that you can use the UI to access your new route.

Example:

```
import React from 'react';
import {
  AppPluginInterface,
  SettingsTabsSurface,
} from '@vmware-tanzu/core-frontend';
import { SettingsLayout } from '@backstage/plugin-user-settings';

export const HelloWorldPlugin: AppPluginInterface = () => context => {
  context.applyTo(SettingsTabsSurface, tabs =>
    tabs.add(
      <SettingsLayout.Route path="/hello-world" title="Hello World Tab">
        <div>Hello World Settings Tab Content</div>
      </SettingsLayout.Route>,
    ),
  );
};
```

SidebarItemSurface

`SidebarItemSurface` enables you to render links in the sidebar to quickly access your plug-in. `SidebarItemsSurface` enables you to change the content of the `root` constant in `packages/app/src/components/Root/Root.tsx`. All items you add to the sidebar appear at the bottom of existing sidebar items, in the order that they were registered.

Example:

```
import React from 'react';
import { SidebarItem } from '@backstage/core-components';
import {
  AppPluginInterface,
  SidebarItemSurface,
} from '@vmware-tanzu/core-frontend';
```

```
import AlarmIcon from '@material-ui/icons/Alarm';

export const HelloWorldPlugin: AppPluginInterface = () => context => {
  context.applyTo(SidebarItemSurface, sidebar =>
    sidebar.addMainItem(
      <SidebarItem icon={AlarmIcon} to="hello-world" text="Hello" />,
    ),
  );
};
```

API documentation for surfaces

This topic tells you about API references for surfaces in Tanzu Developer Portal.

The following packages are described:

- @tpb/plugin-catalog
- @vmware-tanzu/core-backend
- @vmware-tanzu/core-frontend
- @vmware-tanzu/tdp-plugin-auth-backend
- @vmware-tanzu/tdp-plugin-custom-logger
- @vmware-tanzu/tdp-plugin-home
- @vmware-tanzu/tdp-plugin-ldap-backend
- @vmware-tanzu/tdp-plugin-login
- @vmware-tanzu/tdp-plugin-microsoft-graph-org-reader-processor
- @vmware-tanzu/tdp-plugin-permission-backend

Package `@tpb/plugin-catalog`

The following sections describe the package.

Class `EntityPageSurface`

This class can manipulate the contents of pages for Backstage catalog entities.

Each catalog entity subtype can specify a dedicated template. This surface standardizes the contents of those templates and allows for some amount of external configuration.

This example adds a tab to the template for Backstage Service entities:

```
context.applyWithDependency(
  AppRouteSurface,
  EntityPageSurface,
  (_, surface) => {
       surface.servicePage.addTab(
         <EntityLayout.Route path="/some-subpath" title="Additional content for Servic
es">
           <MyAdditionalContent />
         </EntityLayout.Route>,
       );
     },
  );
```

Properties

This table describes the properties.

Property	Type	Description
apiPage	ApiPage	
componentPageCases	ReactElement[]

Constructors

The package has the following constructor.

constructor()

This constructor constructs a new instance of the `EntityPageSurface` class.

Methods

The package has the following methods.

`addComponentPageCase(pageCase: ReactElement)`: void

This table describes the parameters.

Parameter	Type	Description
pageCase	ReactElement	

`addOverviewContent(content: ReactElement)`: void

This table describes the parameters.

Parameter	Type	Description
content	ReactElement	

Package `@vmware-tanzu/core-backend`

The following sections describe the package.

Types

The package has the following types.

```
BackendPluginInterface<T = {}> = (config?: T & BackendPluginConfig) =>
TpbPluginInterface;
```

```
CatalogProcessorBuilder = (env: PluginEnvironment) => CatalogProcessor[] |
CatalogProcessor;

EntityProviderBuilder = (env: PluginEnvironment) => EntityProvider[] | EntityProvider;

PermissionRuleBuilder = (env: PluginEnvironment) => CatalogPermissionRule[] |
CatalogPermissionRule;

PluginFn = (env: PluginEnvironment) => Promise<Router>;

RouterBuilder = (env: PluginEnvironment) => Promise<Router>;
```

Class `BackendCatalogSurface`

This class can manipulate the catalog backend.

This class provides extension points for registering catalog processors, entity providers, routes, and permissions.

Constructors

The package has the following constructor.

constructor()

This constructor constructs a new instance of the `BackendCatalogSurface` class.

Methods

The package has the following methods.

`addCatalogProcessorBuilder(builder: CatalogProcessorBuilder)`: void

This method registers a Backstage `CatalogProcessor` that applies transformations to unprocessed entities.

For more information about processors, see the Backstage documentation.

For more information about processing, see the Backstage documentation.

Parameter	Type	Description
`builder`	CatalogProcessorBuilder	Builds a `CatalogProcessor` for a given `PluginEnvironment`.

`addEntityProviderBuilder(builder: EntityProviderBuilder)`: void

This method registers a Backstage `EntityProvider` to ingest generate catalog entries for further processing.

For more information about ingestion, see the Backstage documentation.

Parameter	Type	Description
`builder`	EntityProviderBuilder	Builds an `EntityProvider` for a given `PluginEnvironment`.

`addPermissionRuleBuilder(builder: PermissionRuleBuilder)`: void

This method registers Backstage `CatalogPermissionRules` to limit access to catalog entries.

For more information about custom permission rules, see the Backstage documentation.

Parameter	Type	Description
`builder`	PermissionRuleBuilder	Builds `CatalogPermissionRules` for a given `PluginEnvironment`.

`addRouterBuilder(routerBuilder: RouterBuilder)`: void

This method registers an Express Router to handle arbitrary requests made to the Backstage backend.

Parameter	Type	Description
`routerBuilder`	RouterBuilder	Builds an Express Router for a given `PluginEnvironment`.

Class `BackendPluginSurface`

You can use this class to add plug-ins to the Backstage backend.

Constructors

The package has the following constructor.

constructor()

This constructor constructs a new instance of the `BackendPluginSurface` class.

Methods

The package has the following methods.

`addPlugin(plugin: Plugin)`: void

This method registers a named plug-in to handle backend requests at a subpath. Plug-ins must have unique names. The first plug-in registered with a given name wins.

Parameter	Type	Description
`plugin`	Plugin	Plug-in to add

Package `@vmware-tanzu/core-frontend`

The following sections describe the package.

Types

The package has the following type.

```
AppPluginInterface<T = {}> = (config?: T) => TpbPluginInterface;
```

Class `ApiSurface`

You can use this class to add Backstage `ApiFactories`.

Methods

The package has the following methods.

`add(factory: AnyApiFactory)`: void

This method registers a new Backstage `ApiFactory`. Factories must specify an API with a unique ID. The last factory registered with a given ID wins. Factories that specify APIs with IDs on the ignored list will not be registered.

Parameter	Type	Description
`factory`	`AnyApiFactory`	

Class `AppComponentSurface`

You can use this class to replace core components of the Backstage app.

Constructors

The package has the following constructor.

constructor()

This constructor constructs a new instance of the `AppComponentSurface` class.

Methods

The package has the following methods.

`add&lt;K extends keyof AppComponents&gt;(key: K, component: AppComponents\[K\])`: void

This method replaces a given Backstage `AppComponent` with another. `AppComponents` must be unique by key. The last `AppComponent` registered with a given key wins.

Parameter	Type	Description
`key`		Unique key for the `AppComponent`.
`component`	`AppComponents`	Custom `AppComponent` to substitute for Backstage's default.

Class `AppPluginSurface`

You can use this class to register additional frontend plug-ins with the Backstage app.

https://backstage.io/docs/plugins/

Constructors

The package has the following constructor.

constructor()

This constructor constructs a new instance of the `AppPluginSurface` class.

Methods

The package has the following methods.

`add(plugin: BackstagePlugin)`: void

This method registers a frontend `BackstagePlugin`.

Parameter	Type	Description
`plugin`	`BackstagePlugin`	

Class `AppRouteSurface`

Manipulate routes in the frontend Backstage app.

https://backstage.io/docs/plugins/composability/#routing-system

Constructors

The package has the following constructor.

constructor()

Constructs a new instance of the `AppRouteSurface` class

Methods

The package has the following methods.

`add(route: ReactElement)`: void

This method registers a react-router route.

Parameter	Type	Description
`route`	`ReactElement`	Route to register. Intended to be a react-router#Route or a subclass of it.

`addRouteBinder(routeBinder: RouteBinder)`: void

This method binds external routes. For more information about binding external routes to apps, see the Backstage documentation.

Parameter	Type	Description
`routeBinder`	`RouteBinder`	

Class `BannerSurface`

You can use this class to add page-level banners to the Backstage app.

Constructors

The package has the following constructor.

constructor()

This constructor constructs a new instance of the `BannerSurface` class.

Methods

The package has the following methods.

`add(banner: ReactElement)`: void

This method adds a new page-level banner.

Parameter	Type	Description
`banner`	`ReactElement`	

Class `SettingsTabsSurface`

You can use this class to add tabs to the Settings page.

Constructors

The package has the following constructor.

constructor()

This constructor constructs a new instance of the `SettingsTabsSurface` class.

Methods

The package has the following methods.

`add(tab: ReactElement)`: void

This method adds a new tab to the **Settings** page.

Parameter	Type	Description
`tab`	`ReactElement`	Typically an instance of @backstage/@plugin-user-settings#SettingsLayout.Route

Class `SidebarItemSurface`

You can use this class to manipulate entries in sidebar.

Entries are split into two sections: top items appear above a divider and main items appear below it. Tabs within each section appear in order of registration.

Constructors

The package has the following constructor.

constructor()

This constructor constructs a new instance of the `SidebarItemSurface` class.

Methods

The package has the following methods.

`addMainItem(item: ReactElement)`: void

This method adds an item to the main items section.

Parameter	Type	Description
`item`	`ReactElement`	

`addTopItem(item: ReactElement)`: void

This method adds an item to the top items section.

Parameter	Type	Description
item	ReactElement	

Class ThemeSurface

You can use this class to manipulate themes available to the Backstage application.

Constructors

The package has the following constructor.

constructor()

This constructor constructs a new instance of the ThemeSurface class.

Methods

The package has the following methods.

addTheme(theme: AppTheme): void

This method registers an additional theme.

Parameter	Type	Description
theme	AppTheme	

setRootBuilder(builder: (children: JSX.Element) => ReactElement): void

This method registers the factory that renders the application's root element.

Parameter	Type	Description
builder	JSX.ElementReactElement	

Package @vmware-tanzu/tdp-plugin-auth-backend

The following sections describe the package.

Class SignInProviderSurface

You can use this class to register additional Auth Providers.

https://backstage.io/docs/auth/add-auth-provider

Methods

The package has the following methods.

add(signInProvider: SignInProvider): void

This method registers an additional Auth Provider. The Auth Provider named last wins.

Parameter	Type	Description
signInProvider	SignInProvider	Map of @backstage/plugin-auth-backend#AuthProviderFactory instances.

Class SignInResolverSurface

You can use this class to register SignInResolvers and provide utility methods to log in with them.

Methods

The package has the following methods.

add(authProviderKey: string, resolver: SignInResolver<any>): void

This method registers a new SignInResolver.

Parameter	Type	Description
authProviderKey		Name resolver to add. Uniqueness of name is not enforced, but the behavior of duplicate named entries is undefined.
resolver	SignInResolver	Resolver to add.

getResolver<TAuthResult>(authProviderKey: string): SignInResolver<TAuthResult>

This method gets the first named provider, or falls back to the guest resolver.

Parameter	Type	Description
authProviderKey		

signInAsGuestResolver<TAuthResult>(): SignInResolver<TAuthResult>

This method gets a resolver that creates an ad-hoc guest user.

signInWithEmail(email: string, context: AuthResolverContext): Promise<BackstageSignInResult>

This method provides a utility function to sign in as a user by email address.

The method attempts to match the given email address with a catalog user's email address for sign-in. If that fails, the method signs the user in without associating with a catalog user.

Parameter	Type	Description
email		Email address to attempt sign-in with.
context	AuthResolverContext	

signInWithName(name: string, context: AuthResolverContext): Promise<BackstageSignInResult>

This method provides a utility function to sign in as a user by name.

The method attempts to match the name with a catalog user for signing in. If that fails, the method signs the user in with that name without associating with a catalog user.

Parameter	Type	Description
name		Username to attempt sign-in with.

Parameter	Type	Description
context	AuthResolverContext	

Package @vmware-tanzu/tdp-plugin-custom-logger

The following sections describe the package.

Class LoggerOptionsSurface

You can use this class to allow for configuration of the Backstage logger.

Constructors

The package has the following constructor.

constructor()

This constructor constructs a new instance of the LoggerOptionsSurface class.

Methods

The package has the following methods.

setLoggerOptions(loggerOptions: LoggerOptions): void

This method sets options for the Backstage logger. This method can be invoked multiple times. The last invocation wins.

Parameter	Type	Description
loggerOptions	LoggerOptions	

Package @vmware-tanzu/tdp-plugin-home

The following sections describe the package.

Class HomeSurface

You can use this class to add content to the Backstage Home screen.

Constructors

The package has the following constructor.

constructor()

This constructor constructs a new instance of the HomeSurface class.

Methods

The package has the following methods.

addContent(item: ReactElement): void

This method adds content to the main section below the widget grid.

Parameter	Type	Description
`item`	`ReactElement`	Item to add.

`addWidget(item: ReactElement, config?: LayoutConfiguration)`: void

This method adds a widget to the Home screen's widget grid.

Parameter	Type	Description
`item`	`ReactElement`	Widget to add.
`config`	`LayoutConfiguration`	(Optional) layout configuration for the widget. The `config.component` field must match the added widget either by name (if provided as string) or by direct reference (if provided as a React element).

`addWidgetConfig(config: LayoutConfiguration)`: void

This method specifies the layout configuration for a widget.

Parameter	Type	Description
`config`	`LayoutConfiguration`	Optional layout configuration for a widget. The `config.component` field must match some registered widget either by name (if provided as string) or by direct reference (if provided as a React element).

Package `@vmware-tanzu/tdp-plugin-ldap-backend`

The following sections describe the package.

Class `LdapSurface`

You can use this class to allow for manipulation of LDAP groups and users during ingestion.

Constructors

The package has the following constructor.

constructor()

This constructor constructs a new instance of the `LdapSurface` class.

Methods

The package has the following methods.

`setGroupTransformerBuilder(builder: GroupTransformerBuilder)`: void

This method specifies the transformation of LDAP groups during ingestion.

Parameter	Type	Description
`builder`	`GroupTransformerBuilder`	

`setUserTransformerBuilder(builder: UserTransformerBuilder)`: void

This method specifies the transformation of LDAP users during ingestion.

Parameter	Type	Description
builder	UserTransformerBuilder	

Package @vmware-tanzu/tdp-plugin-login

The following sections describe the package.

Class LoginSurface

You can use this class to register new login providers with Backstage's SignIn page.

For more information about sign-in configuration, see the Backstage documentation.

Methods

The package has the following methods.

add(provider: Provider): void

This method registers a login provider.

Parameter	Type	Description
provider	Provider	

Package @vmware-tanzu/tdp-plugin-microsoft-graph-org-reader-processor

The following sections describe the package.

Class MicrosoftGraphOrgReaderProcessorTransformersSurface

You can use this class to allow for manipulation of Microsoft Graph groups and users during ingestion.

Methods

The package has the following methods.

setGroupTransformer(groupTransformer: GroupTransformer): void

This method specifies the transformation of Microsoft Graph groups during ingestion.

Parameter	Type	Description
groupTransformer	GroupTransformer	

setOrganizationTransformer(organizationTransformer: OrganizationTransformer): void

This method specifies the transformation of Microsoft Graph organizations during ingestion.

Parameter	Type	Description
organizationTransformer	OrganizationTransformer	

setUserTransformer(userTransformer: UserTransformer): void

This method specifies the transformation of Microsoft Graph users during ingestion.

Parameter	Type	Description
`userTransformer`	`UserTransformer`	

Package `@vmware-tanzu/tdp-plugin-permission-backend`

The following sections describe the package.

Class `CustomPermissionPolicy`

Methods

The package has the following methods.

`handle(request: PolicyQuery): Promise<PolicyDecision>`

Parameter	Type	Description
`request`	`PolicyQuery`	

Class `PermissionPolicySurface`

You can use this class to define a `PermissionPolicy` for the Backstage application.

https://backstage.io/docs/permissions/writing-a-policy

Methods

The package has the following methods.

`set(permissionPolicy: PermissionPolicy)`: void

This method defines the `PermissionPolicy` for the Backstage application. This method can be invoked only once.

Parameter	Type	Description
`permissionPolicy`	`PermissionPolicy`	

Dependency version reference

When using any external dependencies with Tanzu Developer Portal, you must verify that the versions are compatible. The following are references for some external dependencies that you might want to use.

External Tanzu Developer Portal plug-ins compatibility

The following are Tanzu Developer Portal plug-ins that are not included by default. To use these with Configurator, you must choose a compatible version based on your version of Tanzu Application Platform.

Tanzu Application Platform v1.9.1 offers the following support:

Plug-in package name	Compatible npm version
`@vmware-tanzu/tdp-plugin-auth-backend`	2.0.0
`@vmware-tanzu/tdp-plugin-backstage-grafana`	2.0.0
`@vmware-tanzu/tdp-plugin-backstage-jira`	2.0.0
`@vmware-tanzu/tdp-plugin-backstage-sonarqube`	2.0.0
`@vmware-tanzu/tdp-plugin-backstage-sonarqube-backend`	2.0.0
`@vmware-tanzu/tdp-plugin-custom-logger`	2.0.0
`@vmware-tanzu/tdp-plugin-github-actions`	2.0.0
`@vmware-tanzu/tdp-plugin-home`	2.0.0
`@vmware-tanzu/tdp-plugin-ldap-backend`	2.0.0
`@vmware-tanzu/tdp-plugin-login`	2.0.0
`@vmware-tanzu/tdp-plugin-microsoft-graph-org-reader-processor`	2.0.0
`@vmware-tanzu/tdp-plugin-permission-backend`	2.0.0
`@vmware-tanzu/tdp-plugin-prometheus`	2.0.0
`@vmware-tanzu/tdp-plugin-rbac`	2.0.0
`@vmware-tanzu/tdp-plugin-rbac-backend`	2.0.0
`@vmware-tanzu/tdp-plugin-snyk`	2.0.0
`@vmware-tanzu/tdp-plugin-stack-overflow`	2.0.0
`@vmware-tanzu/tdp-plugin-techinsights`	2.0.0
`@vmware-tanzu/tdp-plugin-techinsights-backend`	2.0.1

Tanzu Developer Portal plug-in libraries compatibility

The following are libraries used to create Tanzu Developer Portal plug-ins.

When using these libraries, you must choose a compatible version based on your version of Tanzu Application Platform.

Tanzu Application Platform v1.9.1 offers the following support:

Library package name	Compatible npm version
`@vmware-tanzu/core-backend`	2.0.1
`@vmware-tanzu/core-common`	2.0.0
`@vmware-tanzu/core-frontend`	2.0.0

Backstage version compatibility

Tanzu Application Platform v1.9.1 is compatible with the following Backstage version. Developers must verify that a dependency used by Backstage is compatible with your current Tanzu Application Platform installation. When considering upgrading Tanzu Application Platform, read the relevant documentation to see if compatibility would change after upgrading.

Tanzu Application Platform version	Backstage version	Dependencies manifest
1.8.x	v1.20.3	Manifest file

Overview of Tanzu Developer Portal plug-ins

This topic gives you an overview of the different plug-in types that Tanzu Developer Portal supports. Some plug-ins are already integrated with Tanzu Developer Portal. Other plug-ins require you to use Configurator to integrate them.

Tanzu Developer Portal plug-ins

A Tanzu Developer Portal plug-in is a Backstage plug-in inside a wrapper. The wrapper makes it possible to dynamically integrate a Backstage plug-in into Tanzu Developer Portal. The wrapper defines integration points with the underlying Backstage instance to remove the need to manually update source code when adding a Backstage plug-in.

Tanzu Application Platform plug-ins

Tanzu Application Platform includes some pre-built Tanzu Developer plug-ins. These Tanzu Application Platform plug-ins are already integrated with Tanzu Developer Portal. You don't need to configure these plug-ins. To use a Tanzu Application Platform plug-in, you must install the relevant Tanzu Application Platform component.

Tanzu Application Platform has the following Tanzu Developer Portal plug-ins:

- Runtime Resources Visibility
- Application Live View
- Application Accelerator
- API Documentation
- Supply Chain Choreographer
- Security Analysis
- DORA Metrics

Backstage plug-ins

Backstage plug-ins are developed by Backstage and are in the `@backstage` namespace.

Community plug-ins

Community plug-ins are not developed by Backstage or VMware. These plug-ins are not in the `@backstage` namespace.

Validated plug-ins

Validated plug-ins are Backstage plug-ins or community plug-ins that VMware has validated for use with Tanzu Developer Portal. You don't need to create custom wrappers to integrate these plug-ins with Tanzu Developer Portal.

For more information, see the validated community plug-ins section.

External plug-ins

External plug-ins (also referred to as custom plug-ins) are plug-ins that are not in Tanzu Developer Portal Configurator.

These plug-ins are typically published to npmjs.org or a similar npm registry alternative. If you want to integrate an external plug-in that is not validated for use with Tanzu Developer Portal, you must write a custom wrapper for it.

Overview of Tanzu Developer Portal plug-ins

This topic gives you an overview of the different plug-in types that Tanzu Developer Portal supports. Some plug-ins are already integrated with Tanzu Developer Portal. Other plug-ins require you to use Configurator to integrate them.

Tanzu Developer Portal plug-ins

A Tanzu Developer Portal plug-in is a Backstage plug-in inside a wrapper. The wrapper makes it possible to dynamically integrate a Backstage plug-in into Tanzu Developer Portal. The wrapper defines integration points with the underlying Backstage instance to remove the need to manually update source code when adding a Backstage plug-in.

Tanzu Application Platform plug-ins

Tanzu Application Platform includes some pre-built Tanzu Developer plug-ins. These Tanzu Application Platform plug-ins are already integrated with Tanzu Developer Portal. You don't need to configure these plug-ins. To use a Tanzu Application Platform plug-in, you must install the relevant Tanzu Application Platform component.

Tanzu Application Platform has the following Tanzu Developer Portal plug-ins:

- Runtime Resources Visibility
- Application Live View
- Application Accelerator
- API Documentation
- Supply Chain Choreographer
- Security Analysis
- DORA Metrics

Backstage plug-ins

Backstage plug-ins are developed by Backstage and are in the `@backstage` namespace.

Community plug-ins

Community plug-ins are not developed by Backstage or VMware. These plug-ins are not in the `@backstage` namespace.

Validated plug-ins

Validated plug-ins are Backstage plug-ins or community plug-ins that VMware has validated for use with Tanzu Developer Portal. You don't need to create custom wrappers to integrate these plug-ins with Tanzu Developer Portal.

For more information, see the validated community plug-ins section.

External plug-ins

External plug-ins (also referred to as custom plug-ins) are plug-ins that are not in Tanzu Developer Portal Configurator.

These plug-ins are typically published to npmjs.org or a similar npm registry alternative. If you want to integrate an external plug-in that is not validated for use with Tanzu Developer Portal, you must write a custom wrapper for it.

Runtime resources visibility in Tanzu Developer Portal

This topic tells you about runtime resources visibility.

The Runtime Resources Visibility plug-in enables users to visualize their Kubernetes resources associated with their workloads.

Prerequisite

Do one of the following actions to access the Runtime Resources Visibility plug-in:

- Install the Tanzu Application Platform Full or View profile
- Install Tanzu Application Platform without using a profile and then install Tanzu Developer Portal separately
- Review the section If you have a metrics server

If you have a metrics server

By default, the Kubernetes API does not attempt to use any metrics servers on your clusters. To access metrics information for a cluster, set `skipMetricsLookup` to `false` for that cluster in the `kubernetes` section of `app-config.yaml`. Example:

```
tap_gui:
  # ... existing configuration
  app_config:
    # ... existing configuration
    kubernetes:
      clusterLocatorMethods:
        - type: 'config'
          clusters:
            - url: https://KUBERNETES-SERVICE-HOST:KUBERNETES-SERVICE-PORT
              name: host
              authProvider: serviceAccount
              serviceAccountToken: KUBERNETES-SERVICE-ACCOUNT-TOKEN
              skipTLSVerify: true
              skipMetricsLookup: false
```

Where:

- `KUBERNETES-SERVICE-HOST` and `KUBERNETES-SERVICE-PORT` are the URL and ports of your Kubernetes cluster. You can gather these through `kubectl cluster-info`.
- `KUBERNETES-SERVICE-ACCOUNT-TOKEN` is the token from your `tap-gui-token-id`.

You can retrieve this secret's ID by running:

```
kubectl get secrets -n tap-gui
```

and then running

```
kubectl describe secret tap-gui-token-ID
```

Where `ID` is the secret name from the first step.

> **Caution**
>
> If you enable metrics for a cluster but do not have a metrics server running on it, Tanzu Application Platform web interface users see an error notifying them that there is a problem connecting to the back end.

Visualize Workloads on Tanzu Developer Portal

To view your applications on Tanzu Developer Portal, use the following steps:

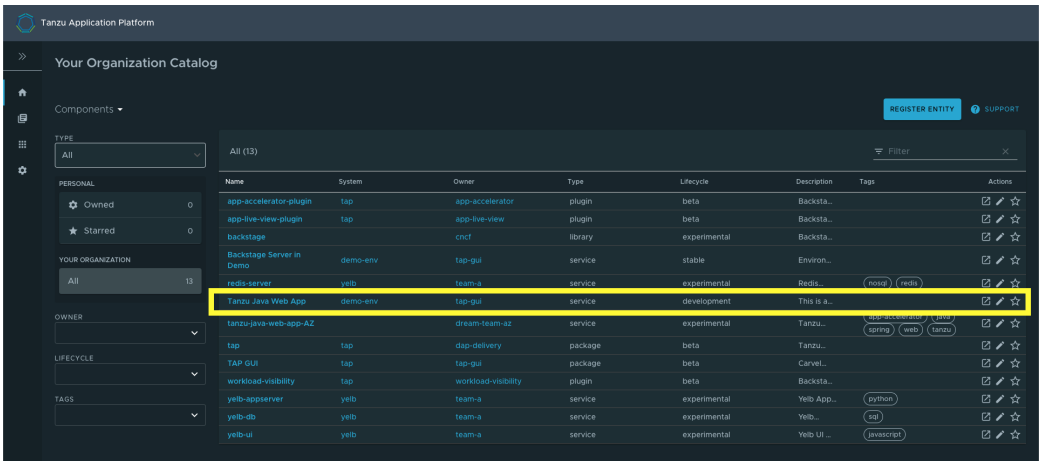
1. Deploy your first application on the Tanzu Application Platform
2. Add your application to Tanzu Developer Portal Software Catalog

Navigate to the **Runtime Resources Visibility** screen

You can view the list of running resources and the details of their status, type, namespace, cluster, and public URL if applicable for the resource type.

To view the list of your running resources:

1. Select your component from the Catalog index page.



2. Select the **Runtime Resources** tab.

Resources

Built-in Kubernetes resources in this view are:

- Services
- Deployments
- ReplicaSets
- Pods
- Jobs
- Cronjobs
- DaemonSets

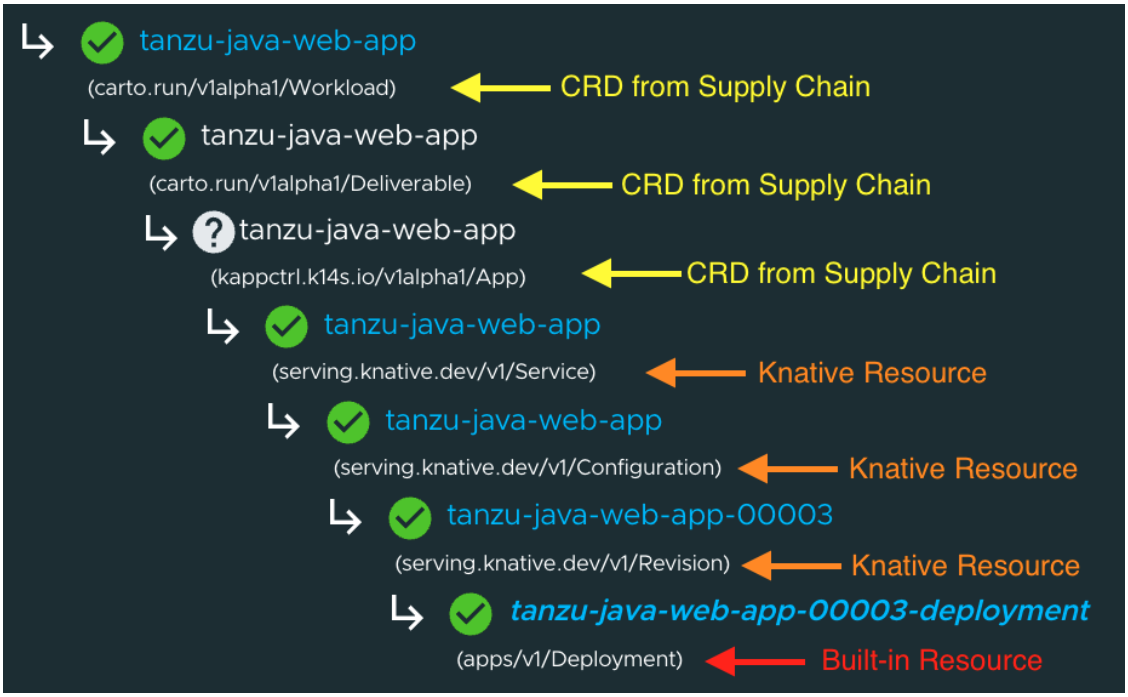
- ReplicaSets

The Runtime Resource Visibility plug-in also displays CRDs created with the Supply Chain, including:

- Cartographer Workloads
- Knative Services, Configurations, Revisions, and Routes

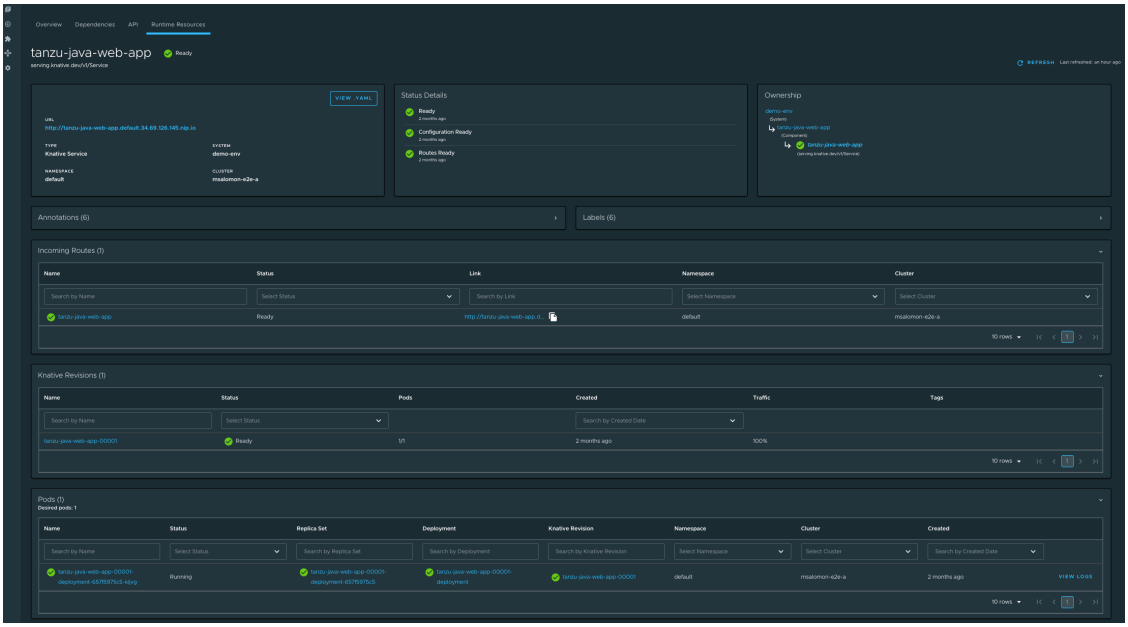
For more information, see Supply Chain Choreographer in Tanzu Developer Portal.

CRDs from Supply Chain are associated with Knative Resources, further down the chain, and built-in resources even further down the chain.



Resources details page

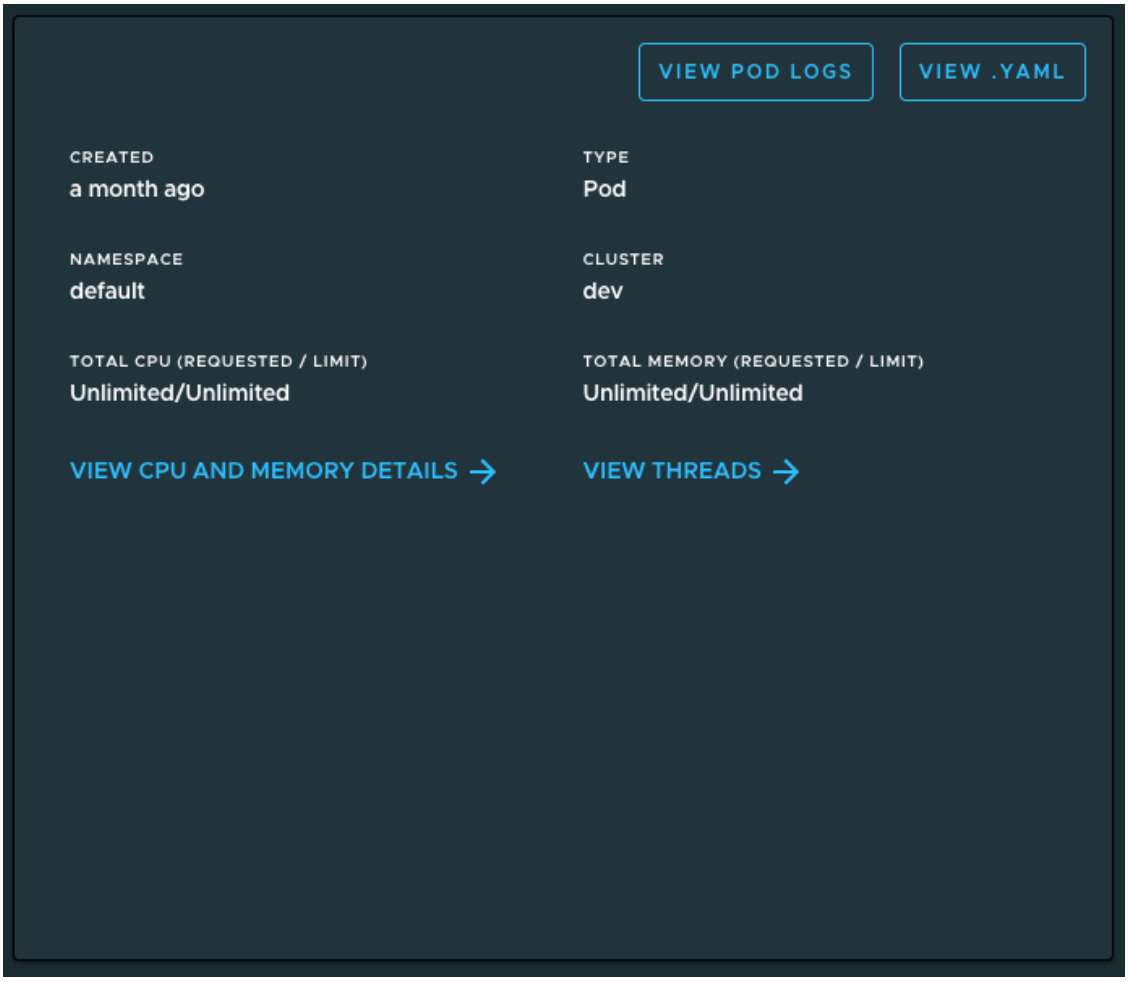
To get more information about a particular workload, select it from the table on the main **Runtime Resources** page to visit a page that provides details about the workload. These details include the workload status, ownership, and resource-specific information.



Overview card

All detail pages provide an overview card with information related to the selected resource. Most of the information feeds from the `metadata` attribute in each object. The following are some attributes that are displayed in the overview card:

- **View Pod Logs** button
- **View .YAML** button
- URL, which is for Knative and Kubernetes service detail pages
- Type
- System
- Namespace
- Cluster



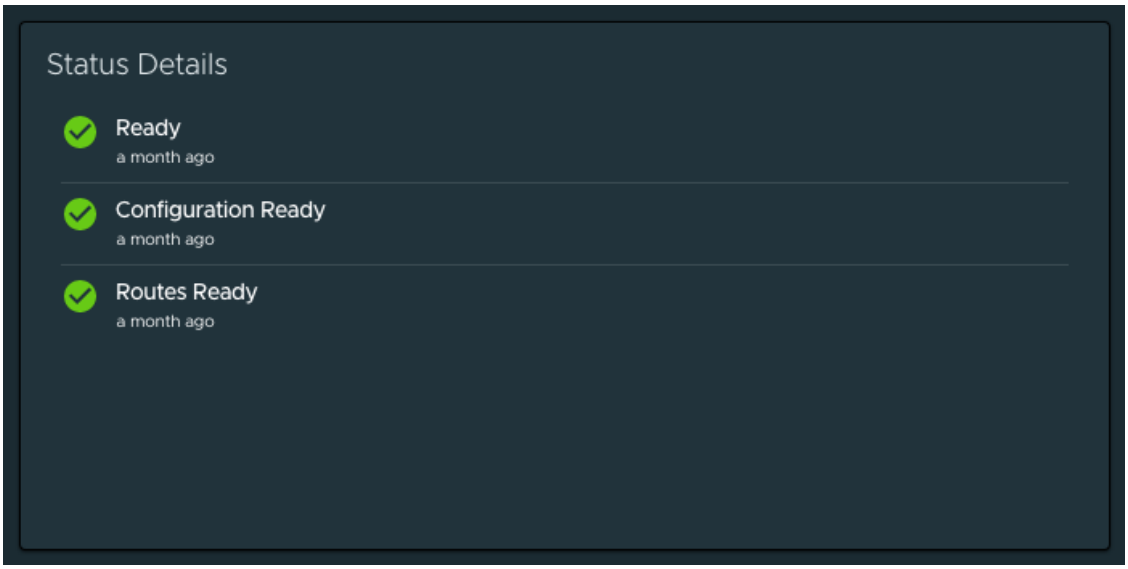
Note

The **VIEW CPU AND MEMORY DETAILS** and **VIEW THREADS** sections are only available for applications supporting Application Live View.

Status card

The status section displays all of the conditions in the resource's attribute `status.conditions`. Not all resources have conditions, and they can vary from one resource to the other.

For more information about object `spec` and `status`, see the Kubernetes documentation.



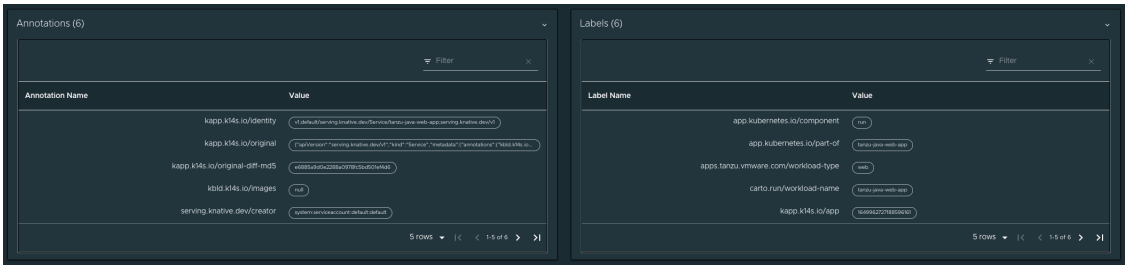
Ownership card

Depending on the resource that you are viewing, the ownership section displays all the resources specified in `metadata.ownerReferences`. You can use this section to navigate between resources.

For more information about owners and dependents, see the Kubernetes documentation.

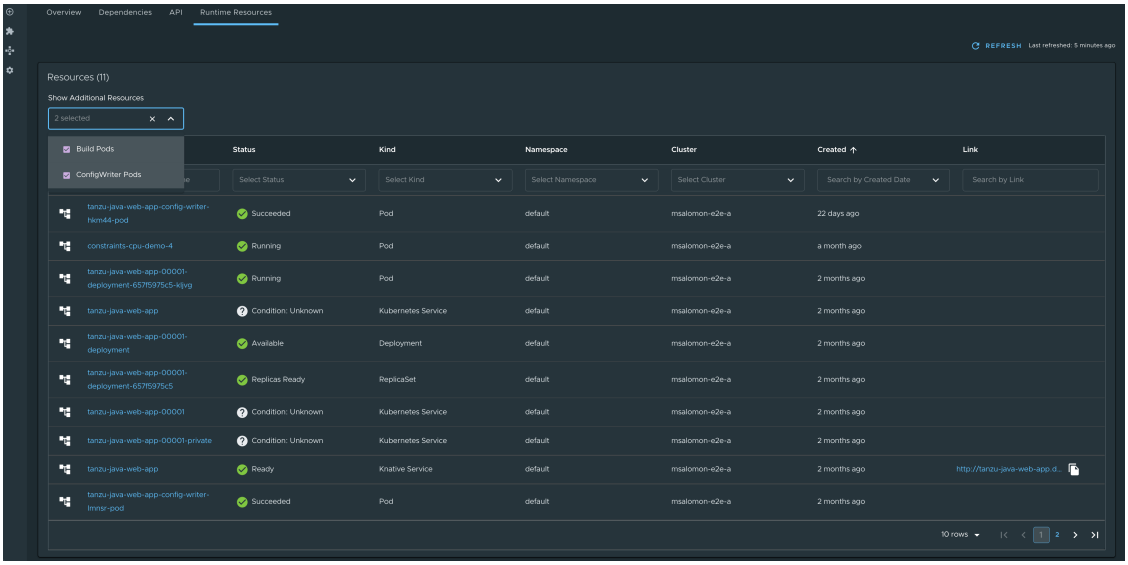
Annotations and Labels

The Annotations and Labels card displays information about `metadata.annotations` and `metadata.labels`.



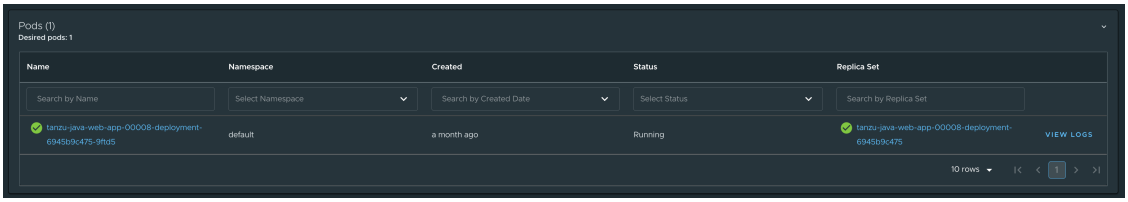
Selecting completed supply chain pods

Completed supply chain pods (build pods and ConfigWriter pods) are hidden by default in the index table. Users can choose to display them from the **Show Additional Resources** drop-down menu above the Resources index table. This drop-down menu is only visible if the resources include Build or ConfigWriter pods.



Navigating to the pod Details page

Users can see the pod table in each resource details page.



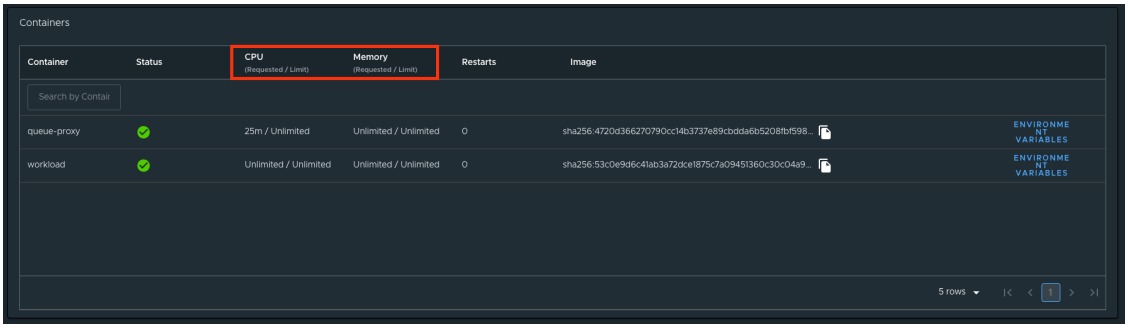
Overview of pod metrics

If you have a metrics server running on your cluster, the overview card displays realtime metrics for pods.

If you do not have a metrics server, the overview card displays the user-configured resource limits on the pod, defined in accordance with the Kubernetes documentation.

For applications built using Spring Boot, you can also monitor the actual real-time resource use using Screenshot of Application Live View for Spring Boot Applications in Tanzu Developer Portal..

Metrics and limits are also displayed for each container on a pod details page. If a particular container's current limit conflicts with a namespace-level LimitRange, a small warning indicator is displayed next to the container limit. Most conflicts are due to creating a container before applying a LimitRange.



Pods display the sum of the limits of all their containers. If a limit is not specified for a container, both the container and its pod are deemed to require unlimited resources.

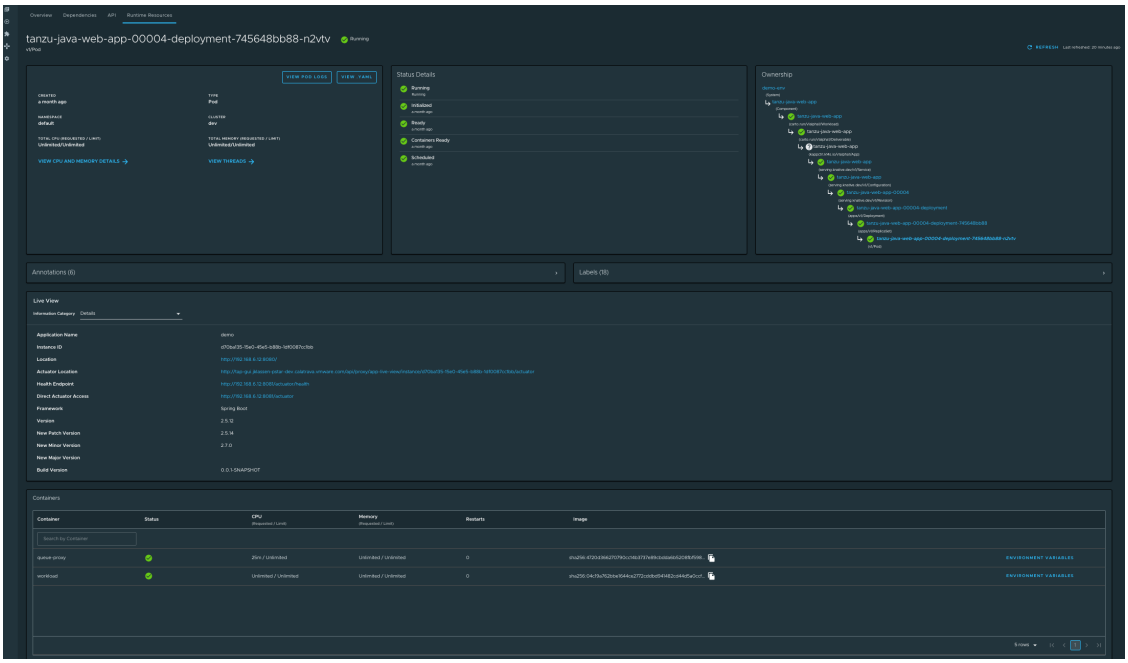
Namespace-level resource limits, such as default memory limits and default CPU limits, are not considered as part of these calculations.

For more information about default memory limits and default CPU limits see the Kubernetes documentation.

These limits apply only for Memory and CPU that a pod or container can use. Kubernetes manages these resource units by using a binary base, which is explained in the Kubernetes documentation.

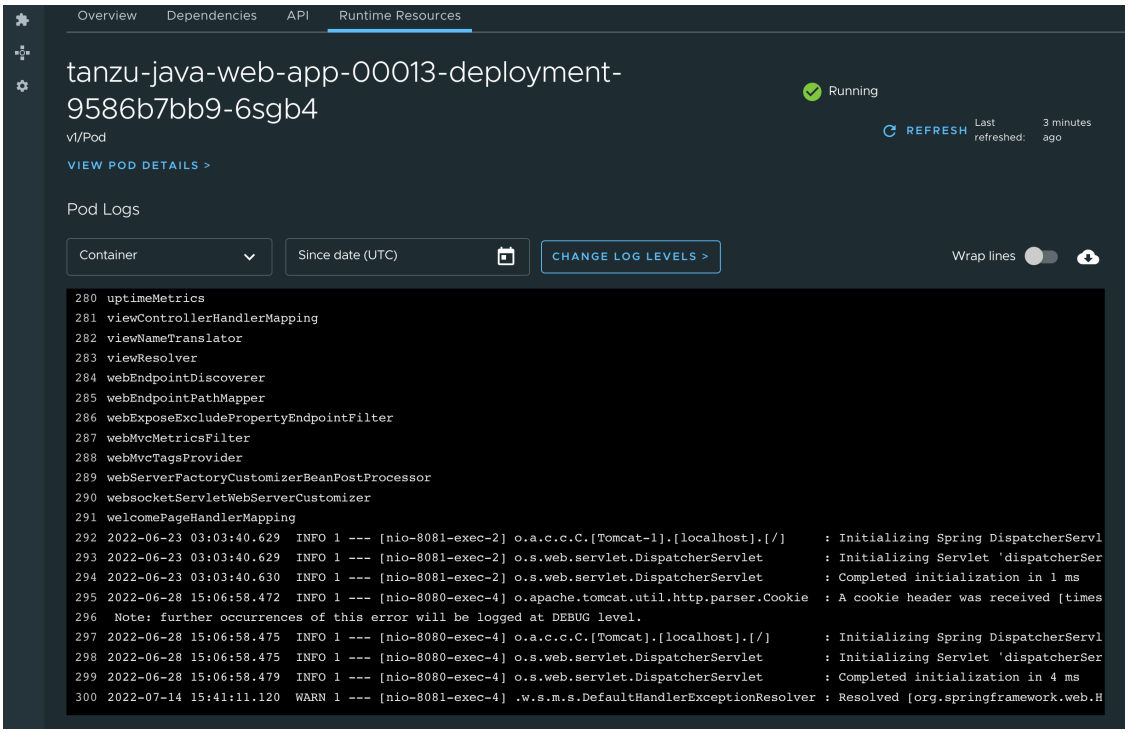
Navigating to Application Live View

To view additional information about your running applications, see the Application Live View section in the **Pod Details** page.



Viewing pod logs

To view logs for a pod, click **View Pod Logs** from the **Pod Details** page. By default, logs for the pod's first container are displayed, dating back to when the pod was created.



Pausing and resuming logs

Log entries are streamed in real time. New entries appear at the bottom of the log content area. Click or scroll the log content area to pause the log stream. Pausing the log stream enables you to focus on specific entries.

To resume the stream, click the **Follow Latest** button that appears after pausing.

Filtering by container

To display logs for a different container, select the container that you want from the **Container** drop-down menu.

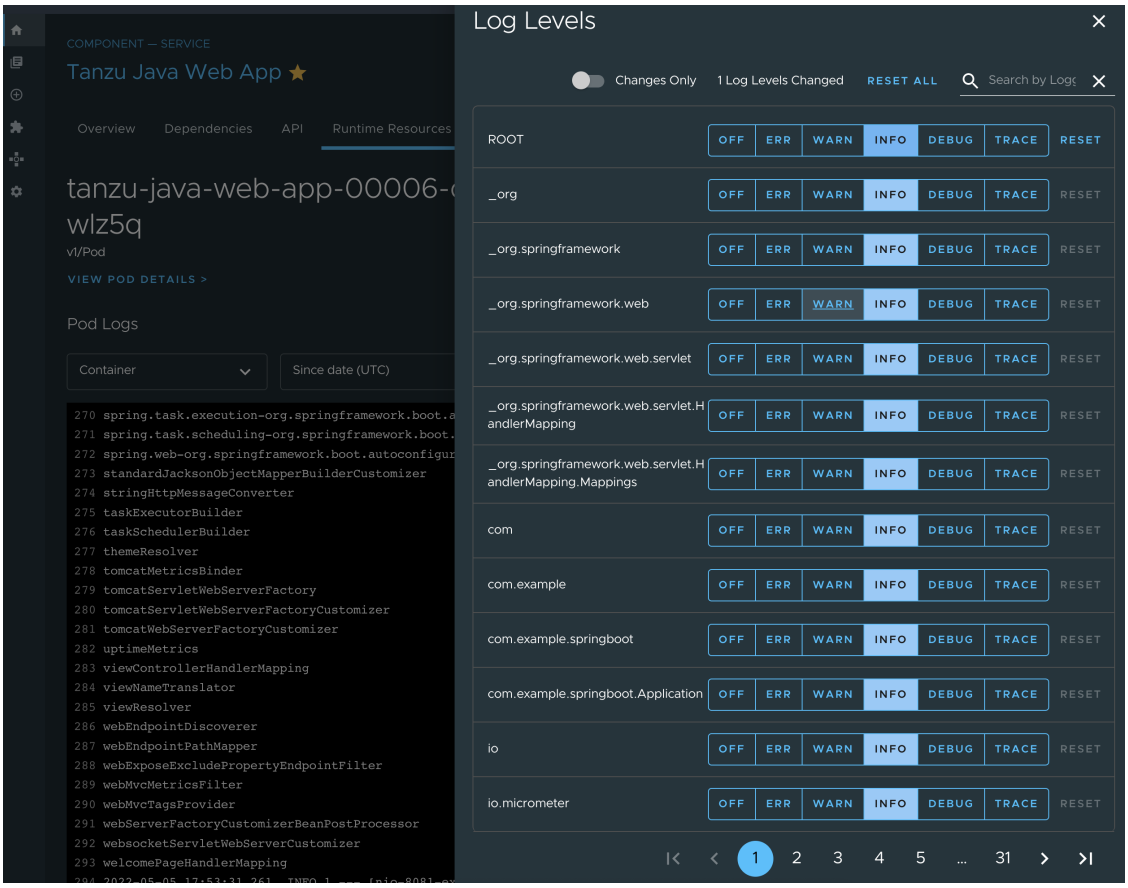
Filtering by date and time

To see logs since a specific date and time, select or type the UTC timestamp in the **Since date** field. If no logs are displayed, adjust the timestamp to an earlier time. If you do not select a timestamp, all logs produced since the pod was created are displayed.

For optimal performance, the pod logs page limits the total log entries displayed to the last 10,000, at most.

Changing log levels

If the pod is associated with an application that supports Application Live View, you can change the application's log levels by clicking the **Change Log Levels** button. You then see a panel that enables you to select levels for each logger associated with your application.



To change the levels for your application, select the desired level for each logger presented, and then click **X** in the upper-right corner of the panel, or press the Escape key, to close the panel.

Because adjusting log levels makes a real-time configuration change to your application, log-level adjustments are only reflected in log entries that your application produces after the change.

If no log entries for the expected levels appear, ensure that:

1. You adjusted the correct application loggers
2. You are viewing logs for the correct container and time frame
3. Your application is currently producing logs at the expected levels

Line wrapping

By default, log entries are not wrapped. To activate or deactivate line wrapping, click the **Wrap lines** toggle.

Downloading logs

To download current log content, click the **Download logs** button.

For optimal performance, the pod logs page limits the total log entries downloaded to the last 10,000, at most.

Connection interruptions

If the log stream connection is interrupted for any reason, such as a network error, a notification appears after the most recent log entry, and the page attempts to reconnect to the log stream. If reconnection fails, an error message displays at the top of the page, and you can click the **Refresh** button at the upper-right of the page to attempt to reconnect.

If you notice frequent disconnections at regular intervals, contact your administrator. Your administrator might need to update the back-end configuration for your installation to allow long-lived HTTP connections to log endpoints (endpoints starting with `BACKEND-HOST/api/k8s-logging/`).

Application Live View in Tanzu Developer Portal

This topic tells you about Application Live View in Tanzu Developer Portal.

Overview

The Application Live View features of Tanzu Application Platform include sophisticated components to give developers and operators a view into their running workloads on Kubernetes.

Application Live View shows an individual running process, for example, a Spring Boot application deployed as a workload resulting in a JVM process running inside of a pod. This is an important concept of Application Live View. Application Live View only recognizes running processes. If there is not a running process inside of a running pod, Application Live View does not show anything.

Under the hood, Application Live View uses the concept of actuators to gather data from those running processes. It visualizes them in a semantically meaningful way and allows users to interact with the inner workings of the running processes within limited boundaries.

The actuator data serves as the source of truth. Application Live View provides a live view of the data from inside of the running processes only. It does not store any of that data for further analysis or historical views.

This easy-to-use interface provides ways to troubleshoot, learn, and maintain an overview of certain aspects of the running processes. It gives a level of control to the users to change some parameters, such as environment properties, without a restart (where the Spring Boot application, for example, supports that).

Entry point to Application Live View plug-in

The Application Live View UI plug-in is part of Tanzu Developer Portal. To use the Application Live View plug-in:

1. Select the relevant component under the **Organization Catalog** in Tanzu Developer Portal.
2. Select the desired service under the **Runtime Resources** tab.
3. Select the desired pod from the **Pods** section under the **Runtime Resources** tab.
4. You can now see all the details, do some lightweight troubleshooting, and interact with the application within certain boundaries under the **Live View** section.

Application Live View in Tanzu Developer Portal

This topic tells you about Application Live View in Tanzu Developer Portal.

Overview

The Application Live View features of Tanzu Application Platform include sophisticated components to give developers and operators a view into their running workloads on Kubernetes.

Application Live View shows an individual running process, for example, a Spring Boot application deployed as a workload resulting in a JVM process running inside of a pod. This is an important concept of Application Live View. Application Live View only recognizes running processes. If there is not a running process inside of a running pod, Application Live View does not show anything.

Under the hood, Application Live View uses the concept of actuators to gather data from those running processes. It visualizes them in a semantically meaningful way and allows users to interact with the inner workings of the running processes within limited boundaries.

The actuator data serves as the source of truth. Application Live View provides a live view of the data from inside of the running processes only. It does not store any of that data for further analysis or historical views.

This easy-to-use interface provides ways to troubleshoot, learn, and maintain an overview of certain aspects of the running processes. It gives a level of control to the users to change some parameters, such as environment properties, without a restart (where the Spring Boot application, for example, supports that).

Entry point to Application Live View plug-in

The Application Live View UI plug-in is part of Tanzu Developer Portal. To use the Application Live View plug-in:

1. Select the relevant component under the **Organization Catalog** in Tanzu Developer Portal.
2. Select the desired service under the **Runtime Resources** tab.
3. Select the desired pod from the **Pods** section under the **Runtime Resources** tab.
4. You can now see all the details, do some lightweight troubleshooting, and interact with the application within certain boundaries under the **Live View** section.

Application Live View for Spring Boot Applications in Tanzu Developer Portal

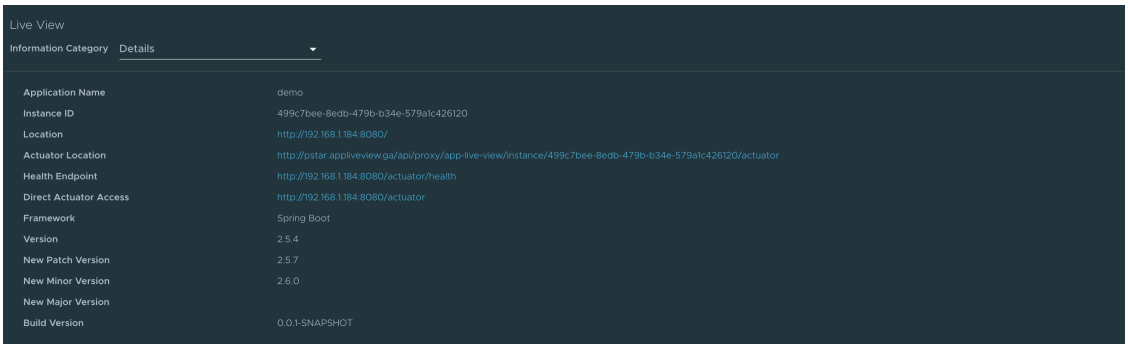
This topic tells you about the Application Live View pages for Spring Boot Applications in Tanzu Developer Portal.

Details page

This is the default page loaded in the **Live View** section. This page gives a tabular overview containing the following information:

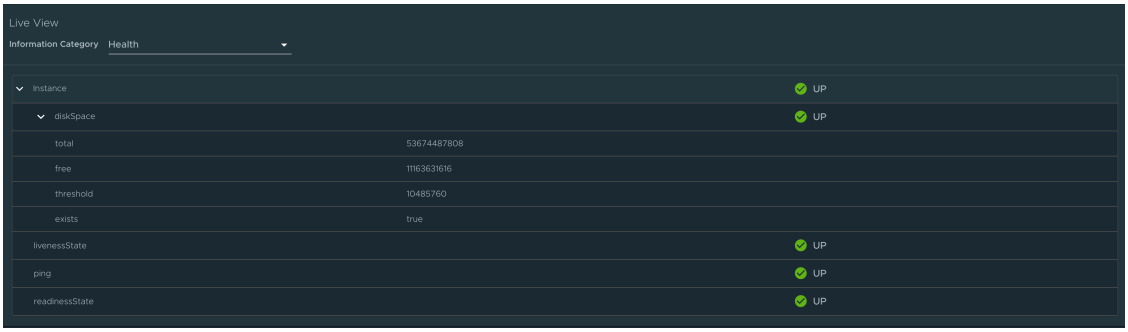
- application name
- instance ID
- location
- actuator location
- health endpoint
- direct actuator access
- framework
- version
- new patch version
- new major version
- build version

You can navigate between **Information Categories** by selecting from the drop-down menu on the top right corner of the page.



Health page

To go to the health page, select the **Health** option from the **Information Category** drop-down menu. The health page provides detailed information about the health of the application. It lists all the components that make up the health of the application such as readiness, liveness, and disk space. It displays the status and details associated with each component.



Environment page

To go to the **Environment** page, select the **Environment** option from the **Information Category** drop-down menu. The Environment page contains details of the applications' environment. It contains properties including, but not limited to, system properties, environment variables, and configuration properties (such as application.properties) in a Spring Boot application.

The page includes the following capabilities for `viewing` configured environment properties:

- The UI has a search feature that enables you to search for a property or values.
- Each property has a search icon at the right corner which helps you quickly see all the occurrences of a specific property key without manually typing in the search box. Clicking the search button locates the property name.
- The **Refresh Scope** button on the top right corner of the page probes the application to refresh all the environment properties.

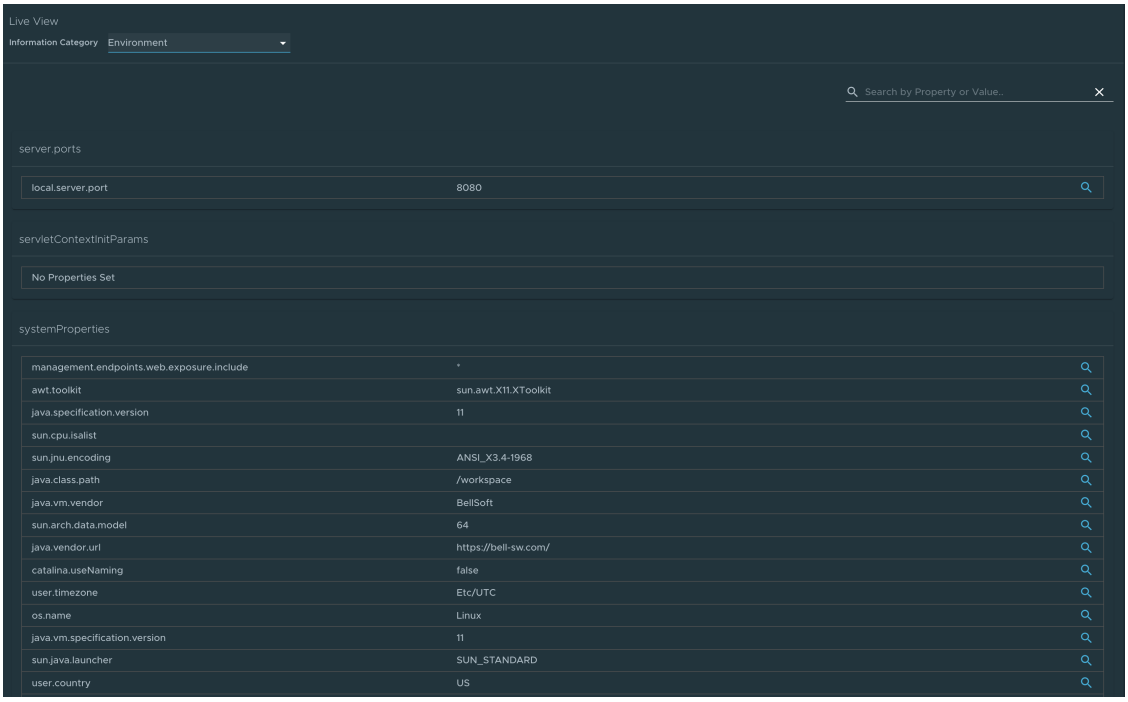
The page also includes the following capabilities for `editing` configured environment properties:

- The UI allows you to edit environment properties and see the live changes in the application. These edits are temporary and go away if the underlying pod is restarted.
- For each configured environment property, you can edit its value by clicking on the **Override** button in the same row. After the value is saved, you can view the message that the property was overridden from the initial value. The updated property is visible in the **Applied Overrides** section at the top of the page. The **Reset** button in the same row resets the environment property to the initial state.
- You can edit or remove the overridden environment variables in the **Applied Overrides** section.

- The **Applied Overrides** section also enables you to add new environment properties to the application.

Note

`management.endpoint.env.post.enabled=true` must be set in the application config properties of the application and a corresponding, editable environment must be present in the application.



Log Levels page

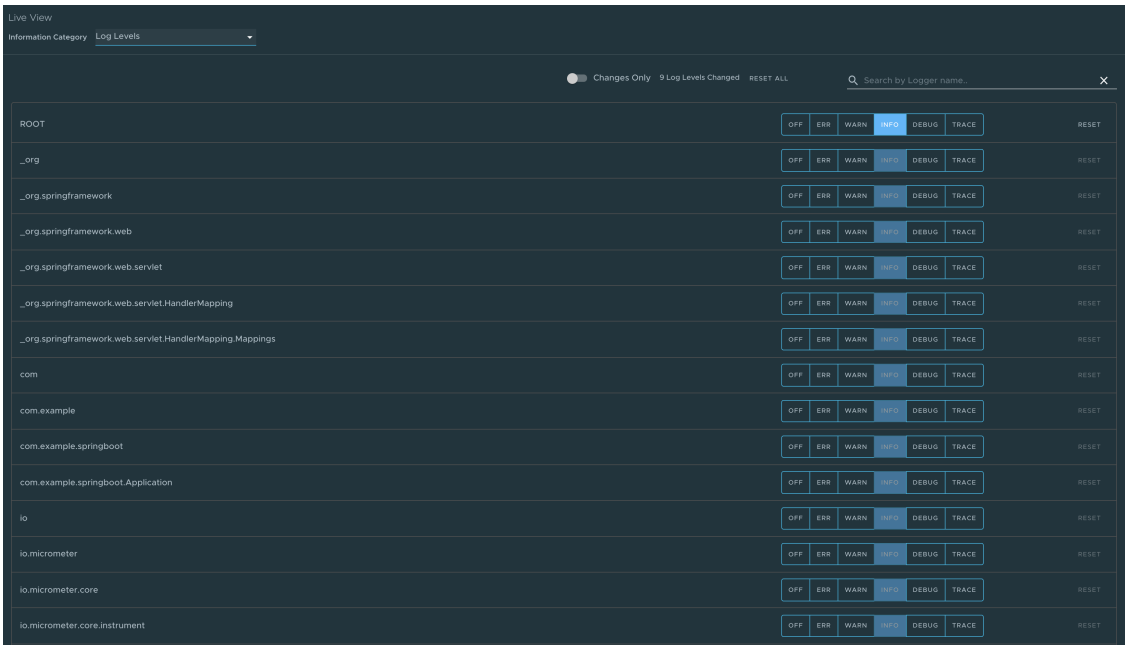
To go to the **Log Levels** page, select the **Log Levels** option from the **Information Category** drop-down menu. The log levels page provides access to the application's loggers and the configuration of their levels.

You can configure the log levels such as INFO, DEBUG, and TRACE in real time from the UI. You can search for a package and edit its respective log level. You can configure the log levels at a specific class and package. They can deactivate all the log levels by modifying the log level of root logger to OFF.

The toggle **Changes Only** displays the changed log levels. Use the search feature to search by logger name. The **Reset** resets the log levels to the original state. The **Reset All** on top right corner of the page resets all the loggers to default state.

Note

Use the UI to change the log levels and see the live changes on the application. These changes are temporary and go away if the underlying pod is restarted.

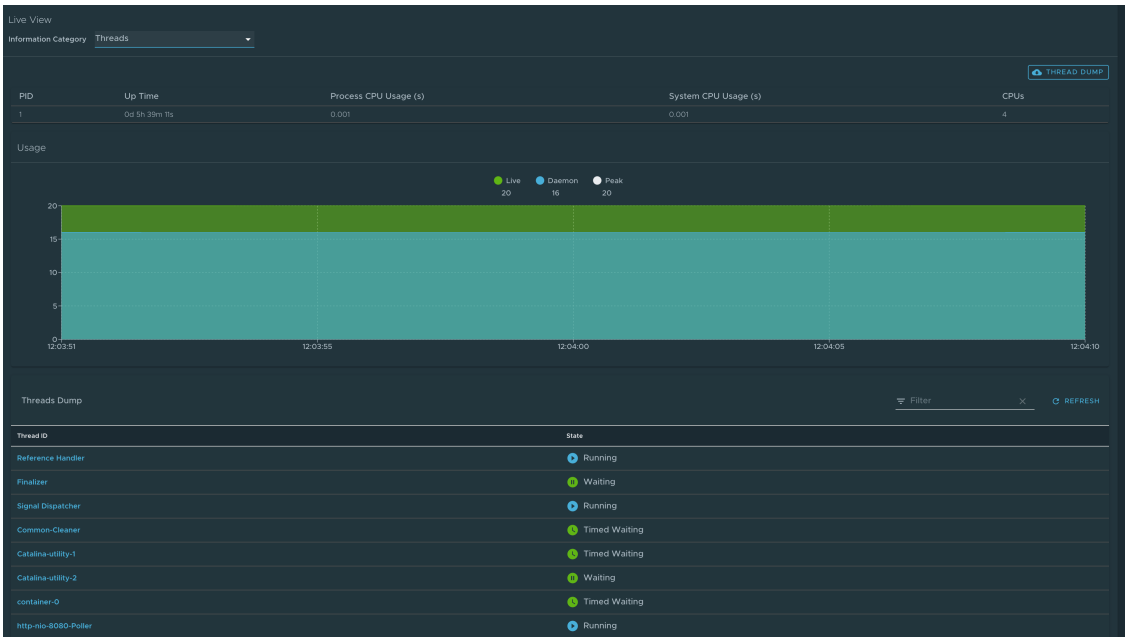


Threads page

To go to the **Threads** page, select the **Threads** option from the **Information Category** drop-down menu.

This page displays all details related to Java Virtual Machine (JVM) threads and running processes of the application. This tracks live threads and daemon threads real-time. It is a snapshot of different thread states. Navigating to a thread state displays all the information about a particular thread and its stack trace.

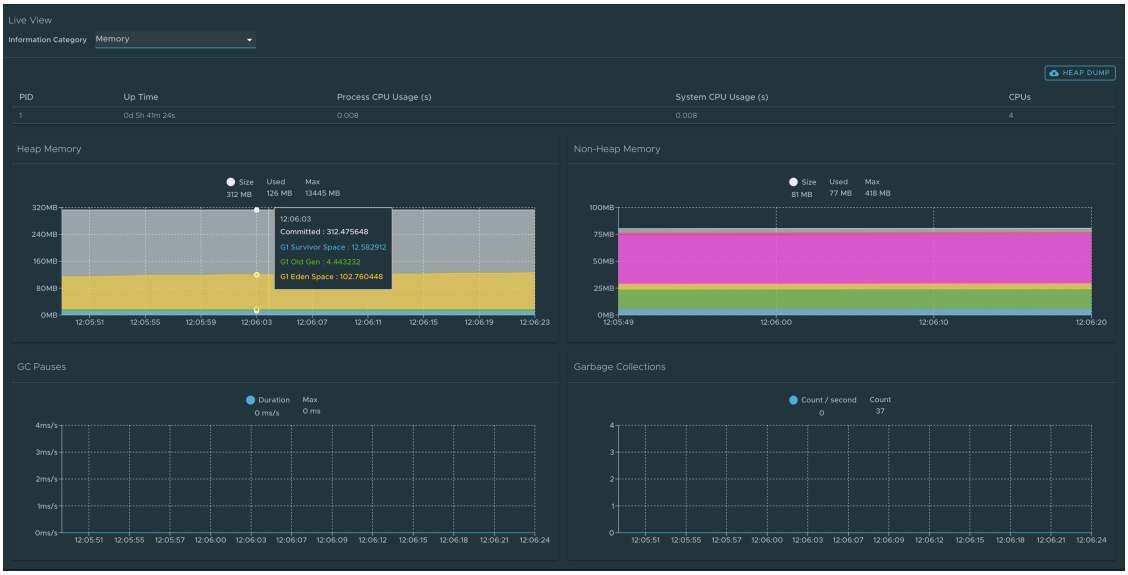
Use the search feature to search for threads by thread ID or state. The refresh icon refreshes to the latest state of the threads. You can view more thread details by clicking on the Thread ID. The page also has a feature to download thread dump data for analysis purposes.



Memory page

To go to the **Memory** page, select the **Memory** option from the **Information Category** drop-down menu.

- The memory page highlights the memory use inside of the JVM. It displays a graphical representation of the different memory regions within heap and non-heap memory. This visualizes data from inside of the JVM (in case of Spring Boot apps running on a JVM) and therefore provides memory insights into the application in contrast to “outside” information about the Kubernetes pod level.
- The real-time graphs displays a stacked overview of the different spaces in memory with the total memory used and total memory size. The page contains graphs to display the GC pauses and GC events.
- The **Heap Dump** at the top-right corner enables you to download heap dump data.



Note

This graphical visualization happens in real time and shows real-time data only. As mentioned at the top, the Application Live View features do not store any information. That means the graphs visualize the data over time only for as long as you stay on that page.

Request Mappings page

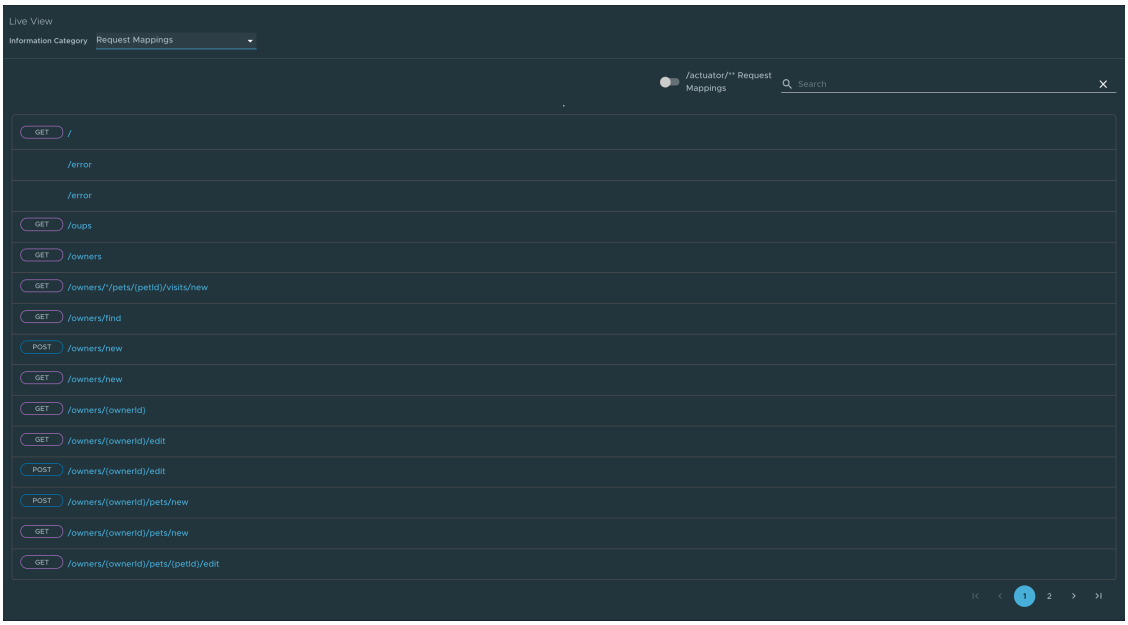
To go to the Request Mappings page, select the **Request Mappings** option from the **Information Category** drop-down menu.

This page provides information about the application’s request mappings. For each mapping, it displays the request handler method. You can view more details of the request mapping, such as the header metadata of the application.

When you click on the request mapping, a side panel appears. This panel contains information about the mapping-media types `Produces` and `Consumes`. The panel also displays the `Handler` class for the request. Use the search feature to search for the request mapping or the method. The toggle **/actuator/** Request Mappings** displays the actuator related mappings of the application.

Note

When application actuator endpoint is exposed on `management.server.port`, the application does not return any actuator request mappings data in the context. The application displays a message when the actuator toggle is enabled.



HTTP Requests page

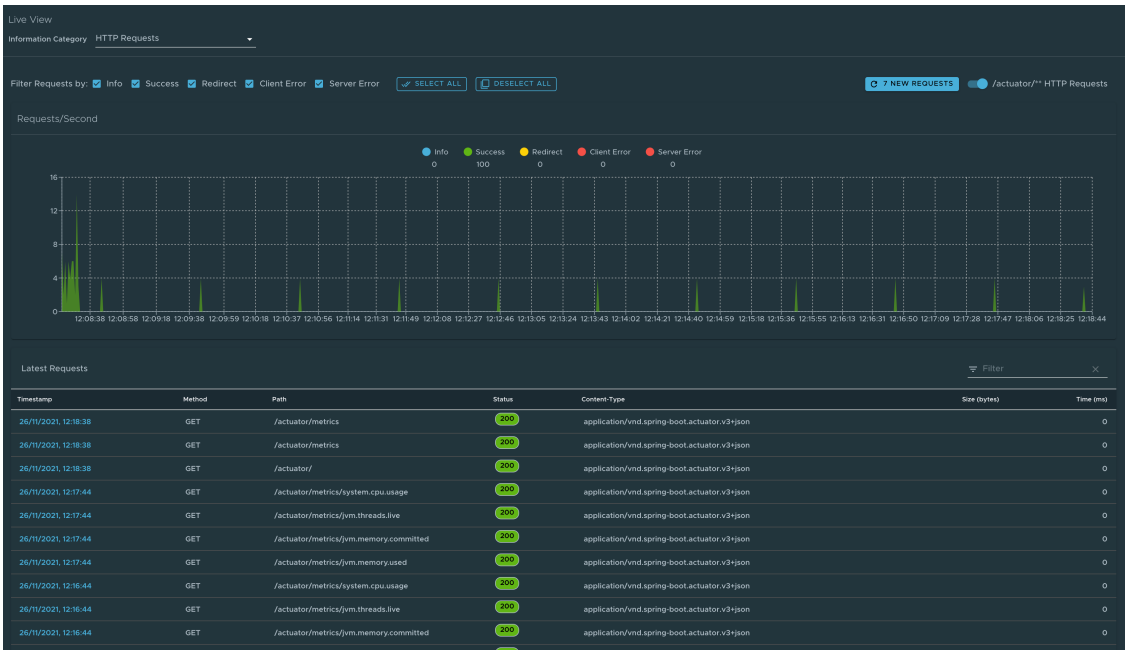
To go to the HTTP Requests page, click **HTTP Requests** from the **Information Category** drop-down menu. The HTTP Requests page provides information about HTTP request-response exchanges to the application.

The graph visualizes the requests per second indicating the response status of all the requests. You can filter the response statuses, which include info, success, redirects, client-errors, and server-errors. The trace data is captured in detail in a tabular format with metrics such as timestamp, method, path, status, content-type, length, time.

The search feature on the table filters the traces based on the search field value. You can view more details of the request, such as method, headers, and response of the application by clicking on the timestamp. The refresh icon above the graph loads the latest traces of the application. The toggle **/actuator/**** on the top right corner of the page displays the actuator related traces of the application.

Note

When application actuator endpoint is exposed on management.server.port, no actuator HTTP Traces data is returned for the application. In this case, a message is displayed when the actuator toggle is enabled.

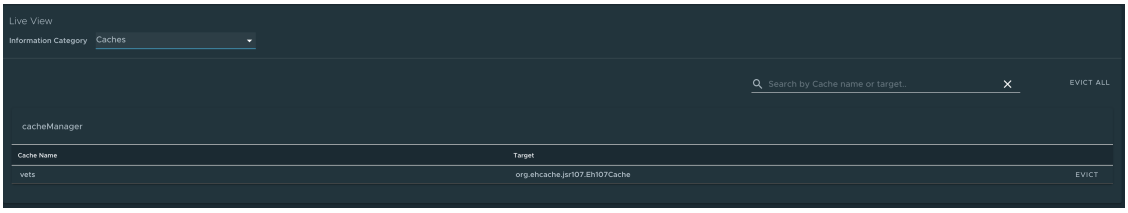


Caches page

To go to the **Caches** page, select the **Caches** option from the **Information Category** drop-down menu.

The Caches page provides access to the application's caches. It gives the details of the cache managers associated with the application including the fully qualified name of the native cache.

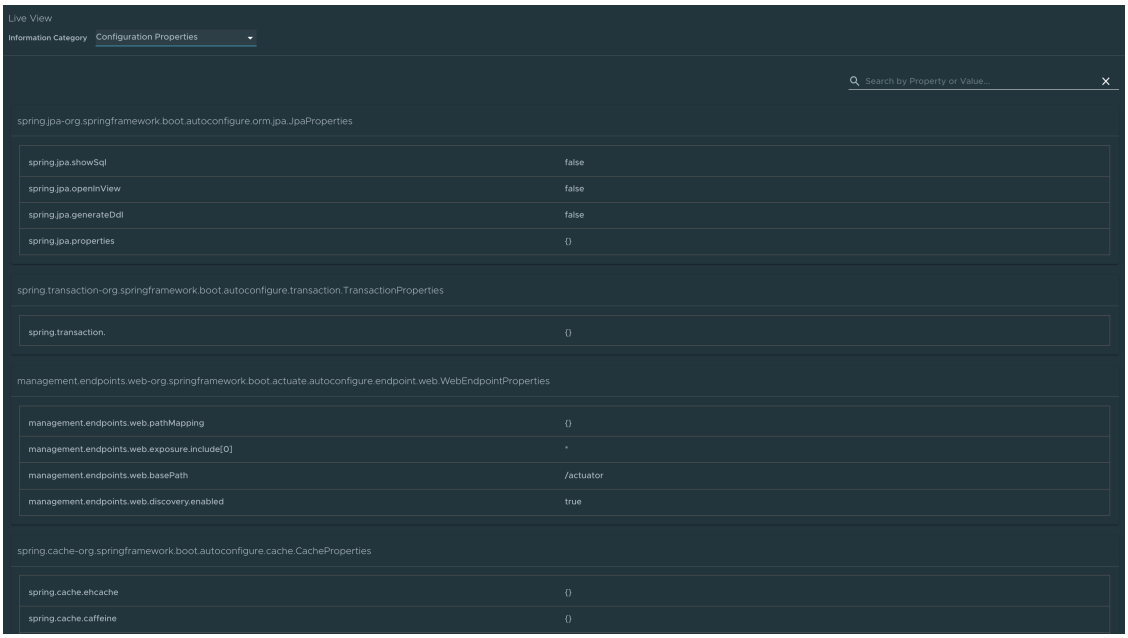
Use the search feature in the Caches Page to search for a specific cache/cache manager. You can clear individual caches by clicking **Evict**. You can clear all the caches completely by clicking **Evict All**. If there are no cache managers for the application, the message `No cache managers available for the application` is displayed.



Configuration Properties page

To go to the **Configuration Properties** page, select the **Configuration Properties** option from the **Information Category** drop-down menu.

The configuration properties page provides information about the configuration properties of the application. In case of Spring Boot, it displays application's `@ConfigurationProperties` beans. It gives a snapshot of all the beans and their associated configuration properties. Use the search feature to search for a property's key/value or the bean name.

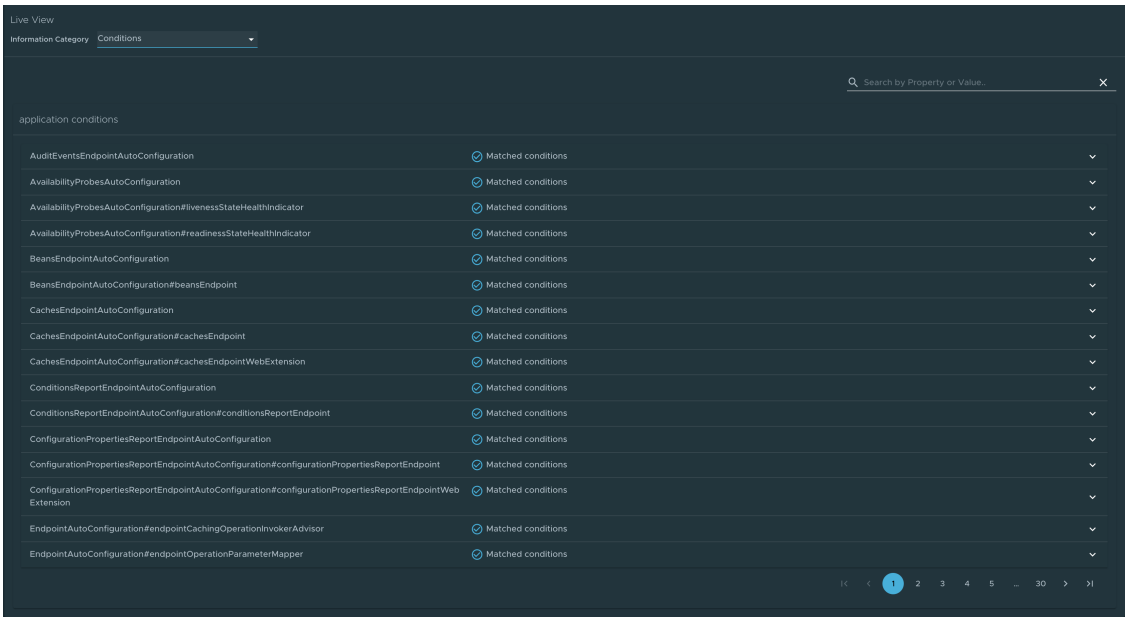


Conditions page

To go to the **Conditions** page, select the **Conditions** option from the **Information Category** drop-down menu. The conditions evaluation report provides information about the evaluation of conditions on configuration and auto-configuration classes.

In the case of Spring Boot, this gives you a view of all the beans configured in the application. When you click on the bean name, the conditions and the reason for the conditional match is displayed.

In the case of non-configured beans, it shows both the matched and unmatched conditions of the bean if any. In addition to this, it also displays names of unconditional auto configuration classes if any. You can use the search feature to filter out the beans and the conditions.

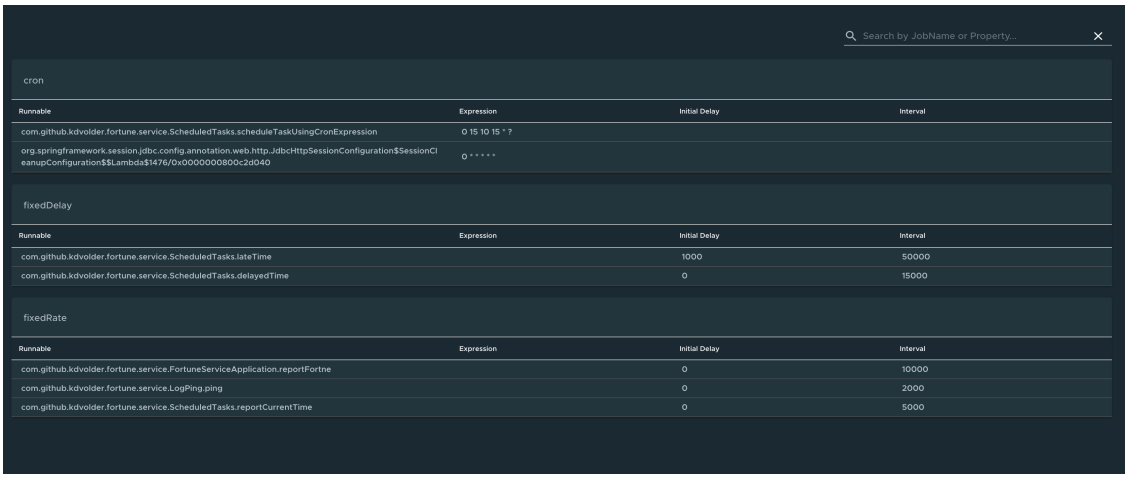


Scheduled Tasks page

To go to the **Scheduled Tasks** page, select the **Scheduled Tasks** option from the **Information Category** drop-down menu.

The scheduled tasks page provides information about the application's scheduled tasks. It includes cron tasks, fixed delay tasks and fixed rate tasks, custom tasks and the properties associated with them.

You can search for a particular property or a task in the search bar to retrieve the task or property details.



Beans page

To go to the **Beans** page, select the **Beans** option from the **Information Category** drop-down menu. The beans page provides information about a list of all application beans and its dependencies. It displays the information about the bean type, dependencies, and its resource. You can search by the bean name or its corresponding fields.

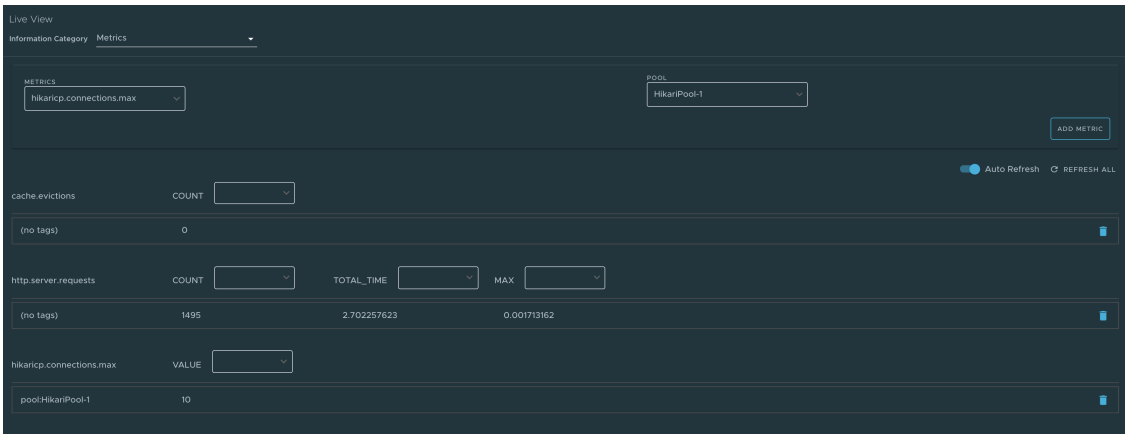
Metrics page

To go to the **Metrics** page, select the **Metrics** option from the **Information Category** drop-down menu.

The metrics page provides access to application metrics information. You can choose from the list of various metrics available for the application, such as `jvm.memory.used`, `jvm.memory.max`, `http.server.request`, and so on.

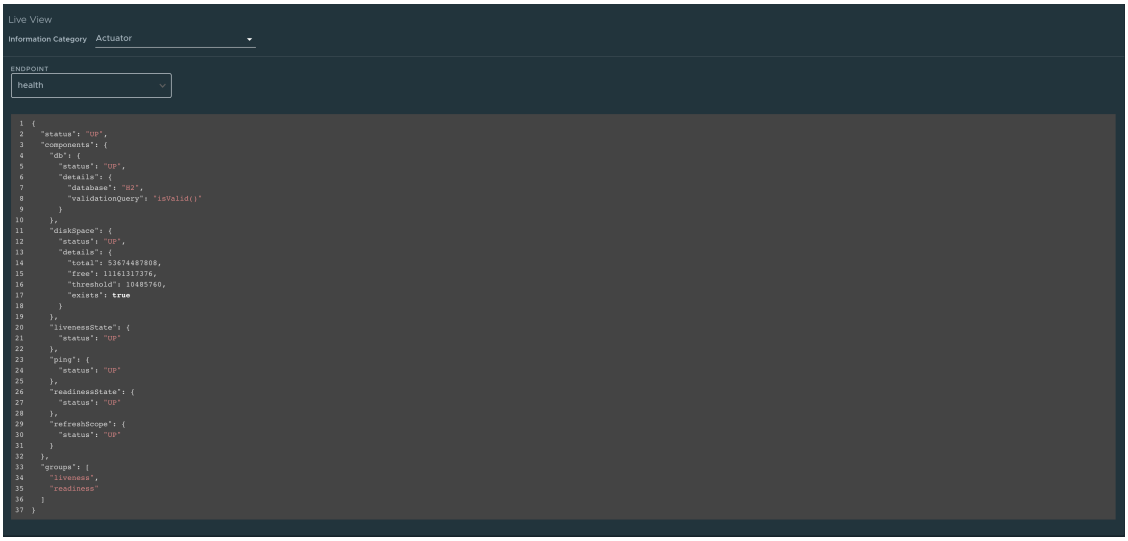
After the metric is chosen, you can view the associated tags. You can choose the value of each tag based on filtering criteria. Clicking **Add Metric** adds the metric to the page which is refreshed every 5 seconds by default.

You can pause the auto refresh feature by deactivating the **Auto Refresh** toggle. You can refresh the metrics manually by clicking **Refresh All**. The format of the metric value can be changed according to your needs. They can delete a particular metric by clicking the minus symbol in the same row.



Actuator page

To go to the **Actuator** page, select the **Actuator** option from the **Information Category** drop-down menu. The actuator page provides a tree view of the actuator data. You can choose from a list of actuator endpoints and parse through the raw actuator data.



Troubleshooting

You might run into cases where a workload running on your cluster does not appear in the Application Live View overview, the detail pages do not load any information while running, or similar issues. If you encounter issues, see Troubleshooting in the Application Live View documentation.

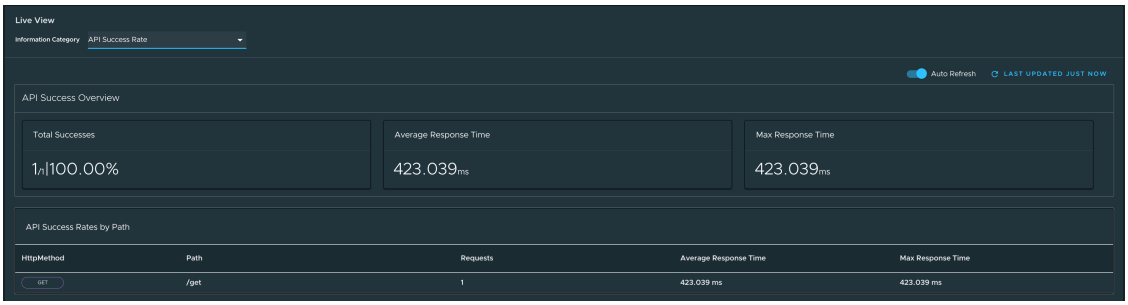
Application Live View for Spring Cloud Gateway applications in Tanzu Developer Portal

This topic tells you about the Application Live View pages for Spring Cloud Gateway applications in Tanzu Developer Portal.

API Success Rate page

To access to the API Success Rate page, select the **API Success Rate** option from the **Information Category** drop-down menu.

The API success rate page displays the total successes, average response time, and maximum response time for the gateway routes. It also displays the details of each successful route path.



API Overview page

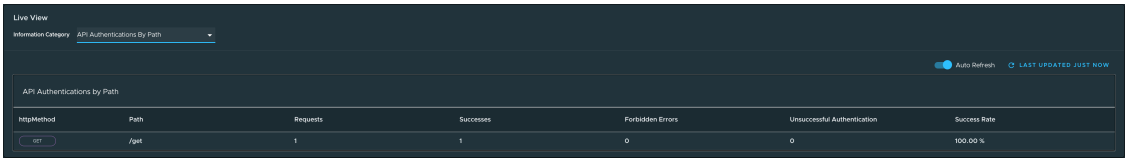
To access the API Overview page, select the **API Overview** option from the **Information Category** drop-down menu.

The API Overview page provides route count, number of successes, errors, and the rate-limited requests. It also provides an **auto refresh** feature to get the updated results. These metrics are depicted in a line graph.

API Authentications By Path page

To access the API Authentications By Path page, select the **API Authentications By Path** option from the **Information Category** drop-down menu.

The API Authentications By Path page displays the total requests, number of successes, and forbidden and unsuccessful authentications grouped by the HTTP method and gateway route path. The page also displays the success rate for each route.



Note

In addition to the preceding three pages, the Spring Boot actuator pages are also displayed.

Troubleshooting

You might run into cases where a workload running on your cluster does not appear in the Application Live View overview, or the detail pages do not load any information while running, or other similar issues. For more information about such issues, see Troubleshooting in the Application Live View documentation.

Application Live View for Steeltoe applications in Tanzu Developer Portal

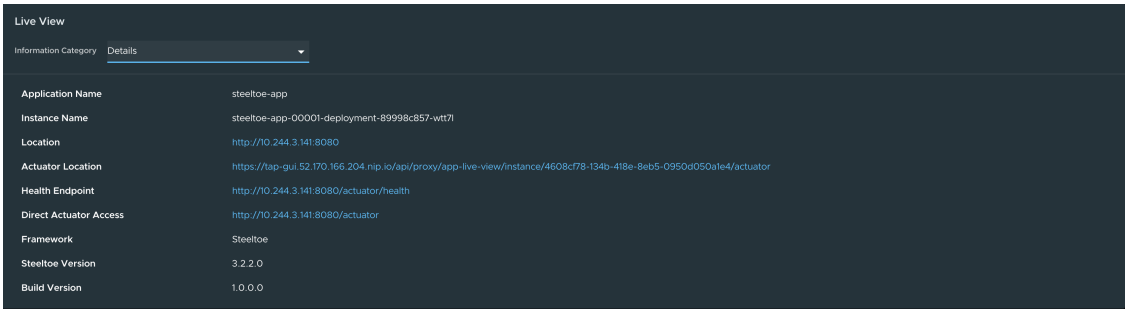
This topic tells you about the Application Live View pages for Steeltoe applications in Tanzu Developer Portal.

Details page

This is the default page loaded in the **Live View** section. This page gives a tabular overview containing the following information:

- Application name
- Instance ID
- Location
- Actuator location
- Health endpoint
- Direct actuator access
- Framework
- Version
- New patch version
- New major version
- Build version

You can navigate between **Information Categories** by selecting from the drop-down menu on the top right corner of the page.



Health page

To access the health page, select the **Health** option from the **Information Category** drop-down menu.

The health page provides detailed information about the health of the application. It lists all the components that make up the health of the application, such as readiness, liveness, and disk space. It displays the status and details associated with each component.

Environment page

To access the **Environment** page, select the **Environment** option from the **Information Category** drop-down menu.

The Environment page contains details of the applications' environment. It contains properties including, but not limited to, system properties, environment variables, and configuration properties (such as `appsettings.json`) in a Steeltoe application.

The page includes the following capabilities for `viewing` configured environment properties:

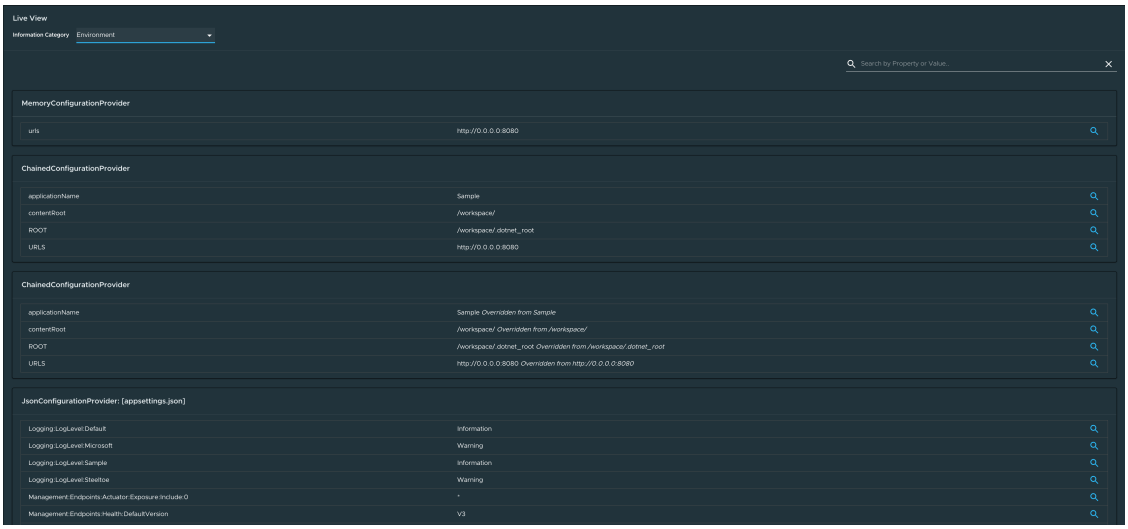
- The UI has a search feature that enables you to search for a property or values.
- Each property has a search icon at the right corner which helps you quickly see all the occurrences of a specific property key without manually typing in the search box. Clicking the search button locates the property name.
- The **Refresh Scope** button on the top right corner of the page probes the application to refresh all the environment properties.

The page also includes the following capabilities for `editing` configured environment properties:

- The UI allows you to edit environment properties and see the live changes in the application. These edits are temporary and go away if the underlying pod is restarted.
- For each of the configured environment properties, you can edit its value by clicking on the **Override** button in the same row. After the value is saved, you can view the message that the property was overridden from the initial value. Also, the updated property is visible in the **Applied Overrides** section at the top of the page. The **Reset** button in the same row resets the environment property to the initial state.
- You can also edit or remove the overridden environment variables in the **Applied Overrides** section.
- The **Applied Overrides** section also enables you to add new environment properties to the application.

Note

The `management.endpoint.env.post.enabled=true` must be set in the application config properties of the application, and a corresponding editable environment must be present in the application.



Log Levels page

To go to the **Log Levels** page, select the **Log Levels** option from the **Information Category** drop-down menu. The **Log Levels** page provides access to the application's loggers and the configuration of the levels.

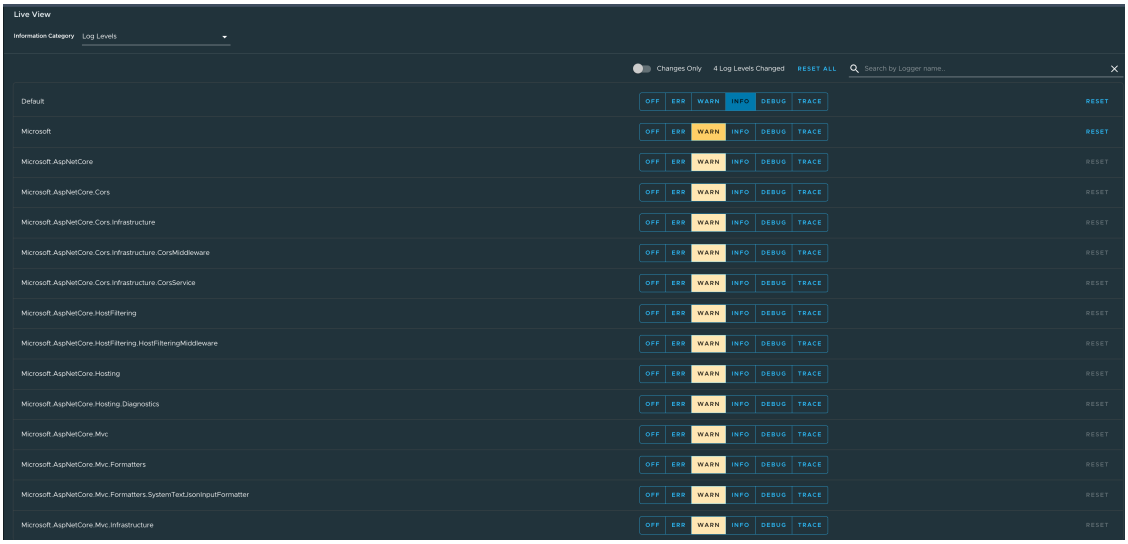
You can:

- Configure log levels, such as **INFO**, **DEBUG**, and **TRACE**, in real time from the UI
- Search for a package and edit its respective log level
- Configure the log levels at a specific class and package
- Deactivate all the log levels by changing the log level of root logger to **OFF**

Use the **Changes Only** toggle to display the changed log levels. Use the search feature to search by logger name. Click **Reset All** to reset all the loggers to the default state.

Note

The UI allows you to change the log levels and see the live changes on the application. These changes are temporary and go away if the underlying pod is restarted.

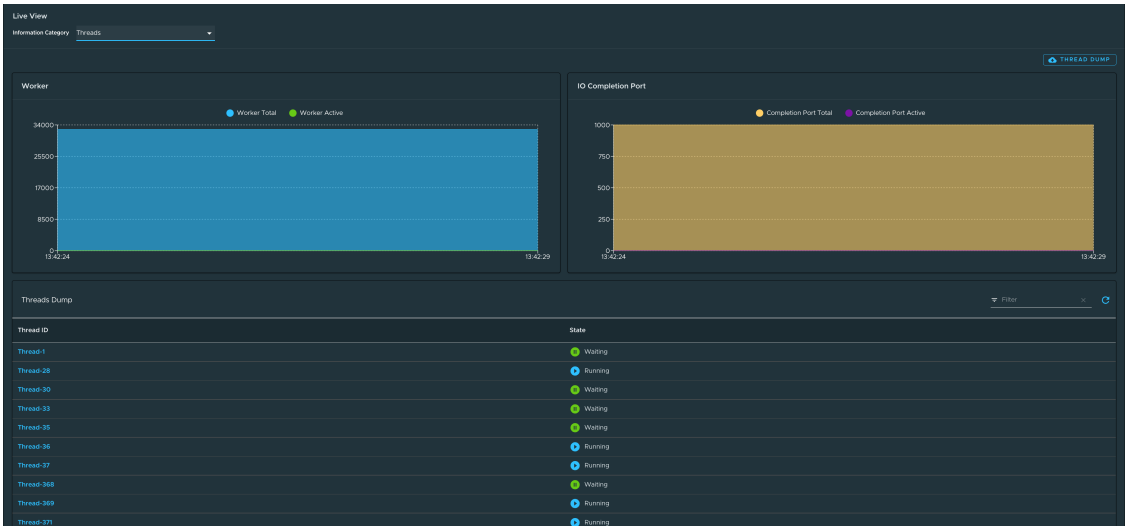


Threads page

To access the **Threads** page, select the **Threads** option from the **Information Category** drop-down menu.

This page displays all details related to CLR threads and running processes of the application. This tracks worker threads and completion port threads in real time. Navigating to a thread state displays all the information about a particular thread and its stack trace.

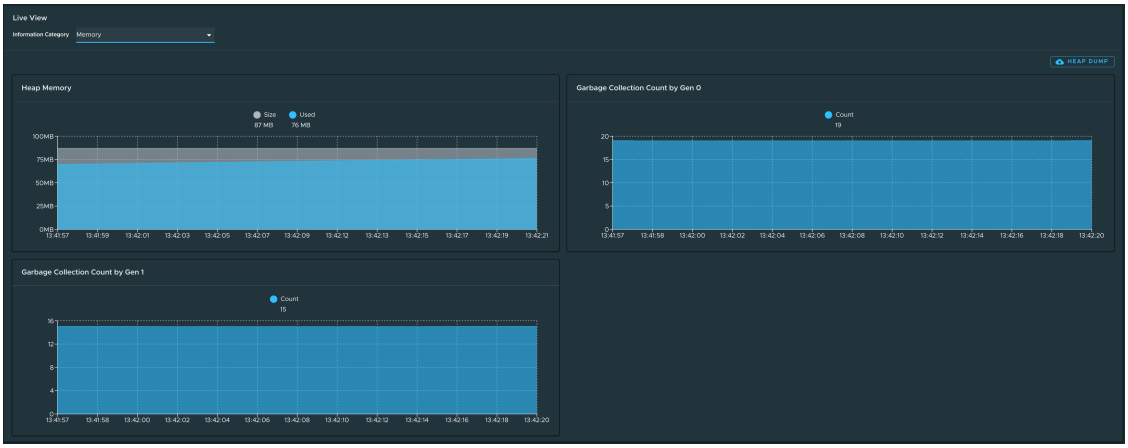
- The refresh icon refreshes to the latest state of the threads.
- To view more thread details, click the thread ID.
- The page has a feature to download the thread dump for analysis.
- The page has a feature to view the CPU stats for a Steeltoe application.



Memory page

To access the **Memory** page, select the **Memory** option from the **Information Category** drop-down menu.

This page displays all details related to used and committed memory of the application. This also displays the garbage collection count by generation (gen0/gen1). The page also has a feature to download the heap dump for analysis. The page also has a feature to view the CPU stats for a Steeltoe application

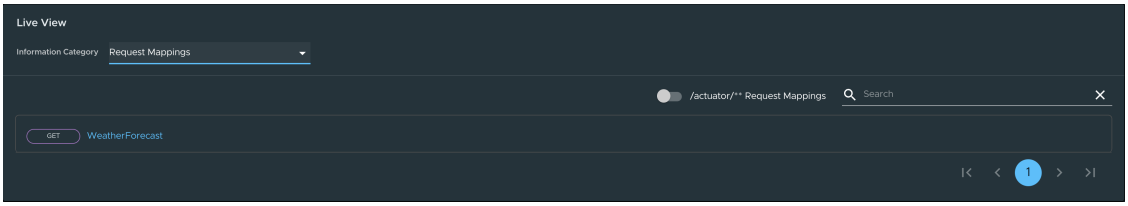


Request Mappings page

To access the **Request Mappings** page, select the **Request Mappings** option from the **Information Category** drop-down menu.

This page provides information about the application's request mappings. For each mapping, the page displays the request handler method. You can view more details of the request mapping, such as the header metadata of the application.

When you click on the request mapping, a side panel appears. This panel contains information about the mapping-media types `Produces` and `Consumes`. The panel also displays the `Handler` class for the request. The search feature enables you to search for the request mapping or the method. The toggle **/actuator/** Request Mappings** displays the actuator-related mappings of the application.



HTTP Requests page

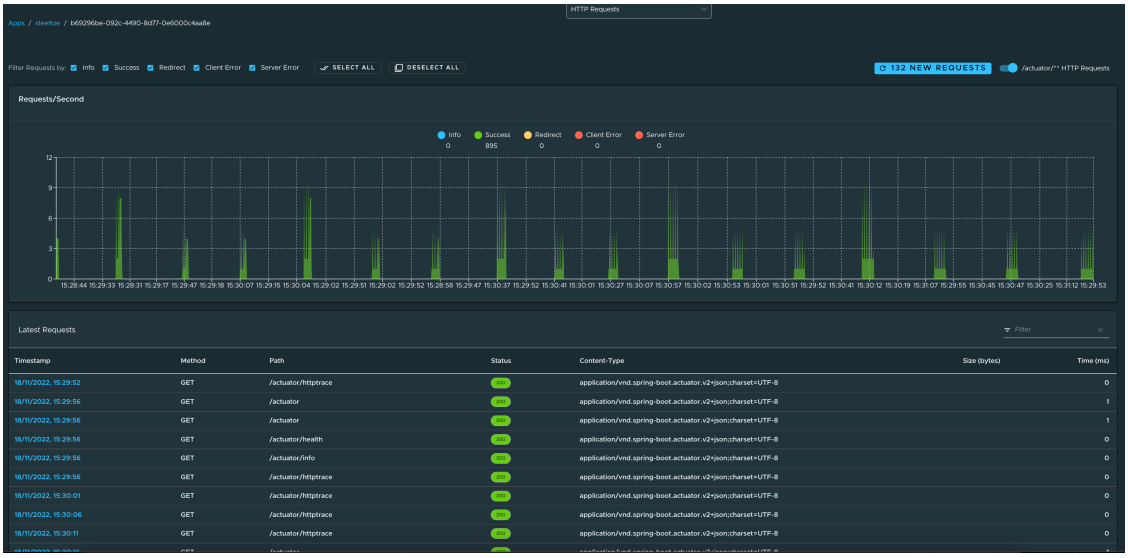
To access the **HTTP Requests** page, select the **HTTP Requests** option from the **Information Category** drop-down menu.

The **HTTP Requests** page provides information about HTTP request-response exchanges to the application.

The graph visualizes the requests per second, which indicates the response status of all the requests. You can filter by the response statuses, which include **info**, **success**, **redirects**, **client-errors**, and **server-errors**. The trace data is captured in detail in a tabular format with metrics, such as **timestamp**, **method**, **path**, **status**, **content-type**, **length**, and **time**.

The search feature on the table filters the traces based on the search text box value. By clicking on the timestamp, you can view more details of the request, such as method, headers, and the response of the application.

The refresh icon above the graph loads the latest traces of the application. The toggle **/actuator/**** on the top-right corner of the page displays the actuator-related traces of the application.



Metrics page

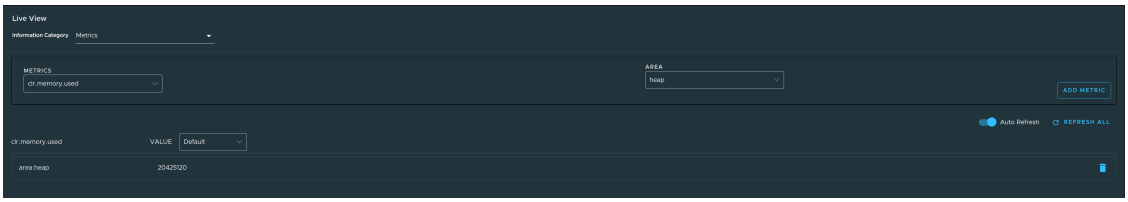
To access the **Metrics** page, select the **Metrics** option from the **Information Category** drop-down menu.

The metrics page provides access to application metrics information. You can choose from the list of various metrics available for the application, such as `clr.memory.used`, `System.Runtime.gc-committed`, `clr.threadpool.active`, and so on.

After you choose the metric, you can view the associated tags. You can choose the value of each of the tags based on filtering criteria. Click **Add Metric** to add the metric to the page. The page is refreshed every 5 seconds by default.

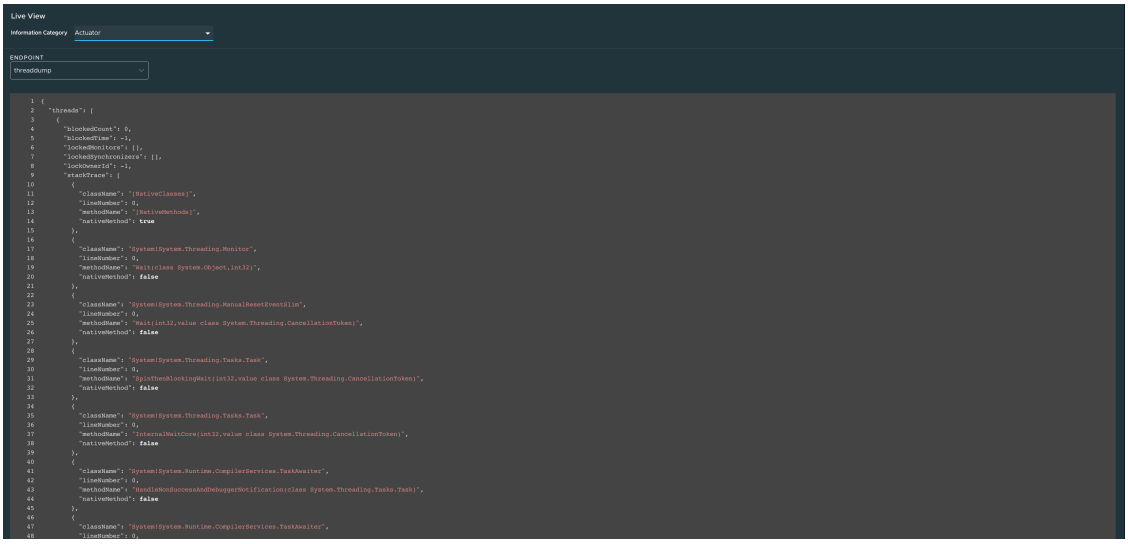
The UI on the **Metrics** page includes features that enable you to:

- Pause the auto refresh feature by deactivating the **Auto Refresh** toggle.
- Refresh the metrics manually by clicking **Refresh All**.
- Change the format of the metric value according to your needs.
- Delete a particular metric by clicking the minus-sign button in the relevant row.



Actuator page

To access the **Actuator** page, select the **Actuator** option from the **Information Category** drop-down menu. The actuator page provides a tree view of the actuator data. You can choose from a list of actuator endpoints and parse through the raw actuator data.



Troubleshooting

You might run into cases where a workload running on your cluster does not appear in the Application Live View overview, or the Details pages do not load any information while running, or other similar issues. For help with troubleshooting common issues, see Troubleshooting.

Application Accelerator in Tanzu Developer Portal

This topic tells you how to use Application Accelerator in Tanzu Developer Portal.

Overview

Application Accelerator for VMware Tanzu helps you bootstrap developing and deploying your applications in a discoverable and repeatable way.

Enterprise architects author and publish accelerator projects that provide developers and operators with ready-made, enterprise-conforming code and configurations. You can then use Application Accelerator to create new projects based on those accelerator projects.

The Application Accelerator UI enables you to discover available accelerators, configure them, and generate new projects to download.

Access Application Accelerator

To open the Application Accelerator UI plug-in and select an accelerator:

1. Within Tanzu Application Platform, click **Create** in the left navigation pane to open the **Accelerators** page.

   Here you can view accelerators already registered with the system. Developers can add new accelerators by registering them with Kubernetes.

2. Every accelerator has a title and short description. Click **VIEW REPOSITORY** to view an accelerator definition. This opens the accelerator's Git repository in a new browser tab.

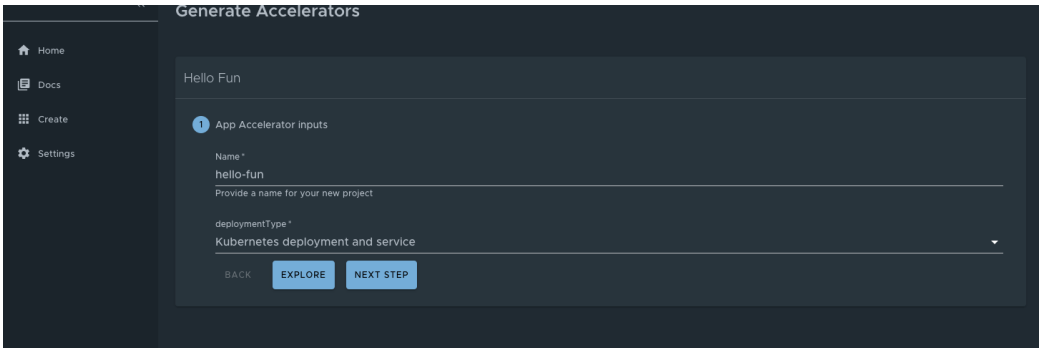
3. Search and filter based on text and tags associated with the accelerators to find the accelerator representing the project you want to create.

4. Click **CHOOSE** for the accelerator you want. This opens the **Generate Accelerators** page.

Configure project generation

To configure how projects are generated:

1. On the **Generate Accelerators** page, add any configuration values needed to generate the project. The application architect defined these values in `accelerator.yaml` in the accelerator definition. Filling some text boxes can cause other text boxes to appear. Fill them all in.

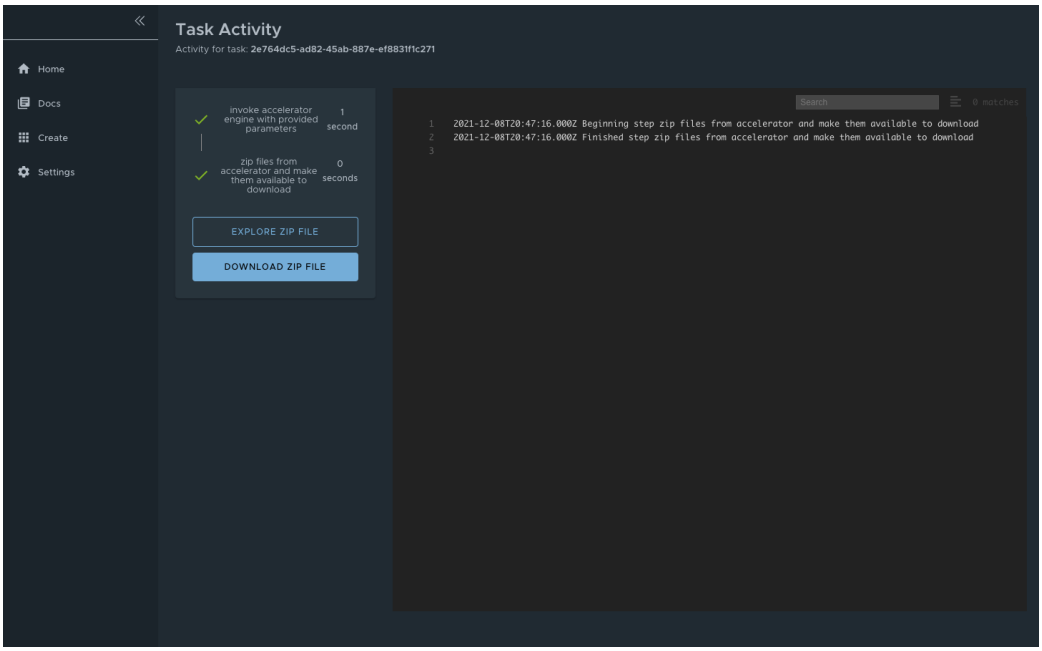


2. Click **EXPLORE** to open the **Explore Project** page and view the project before it is generated.
3. After configuring your project, click **NEXT STEP** to see the project summary page.
4. Review the values you specified for the configurable options.
5. Click **BACK** to make more changes, if necessary. Otherwise, proceed to create the project.

Create the project

To create the project:

1. Click **Create** to start generating your project. See the progress on the **Task Activity** page. A detailed log is displayed on the right.

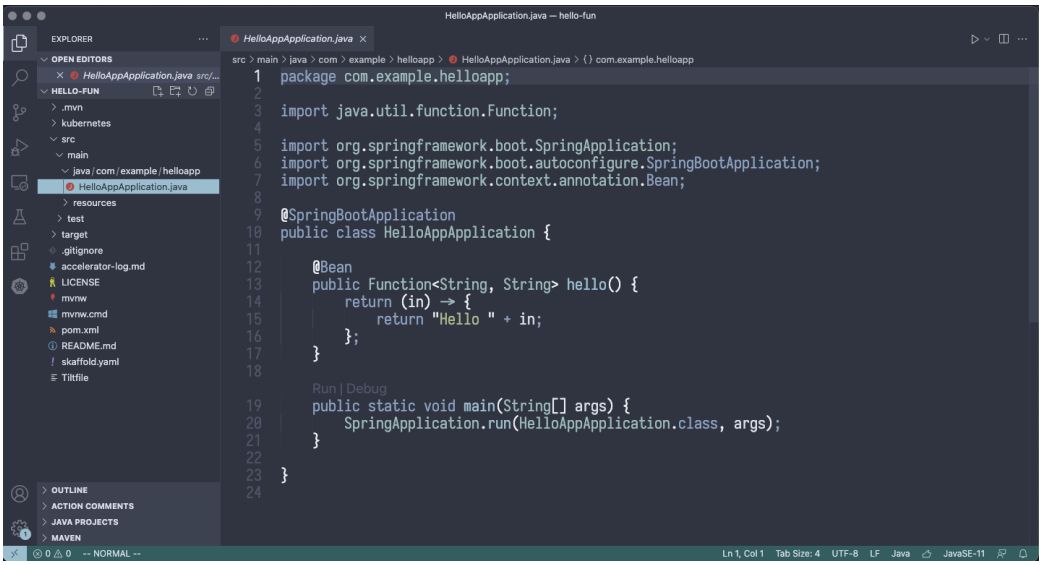


2. After the project is generated, click **EXPLORE ZIP FILE** to open the **Explore Project** page to verify configuration.
3. Click **DOWNLOAD ZIP FILE** to download the project in a ZIP file.

Develop your code

To develop your code:

1. Expand the ZIP file.
2. Open the project in your integrated development environment (IDE).



Next steps

To learn more about Application Accelerator for VMware Tanzu, see the Application Accelerator documentation.

Application Accelerator in Tanzu Developer Portal

This topic tells you how to use Application Accelerator in Tanzu Developer Portal.

Overview

Application Accelerator for VMware Tanzu helps you bootstrap developing and deploying your applications in a discoverable and repeatable way.

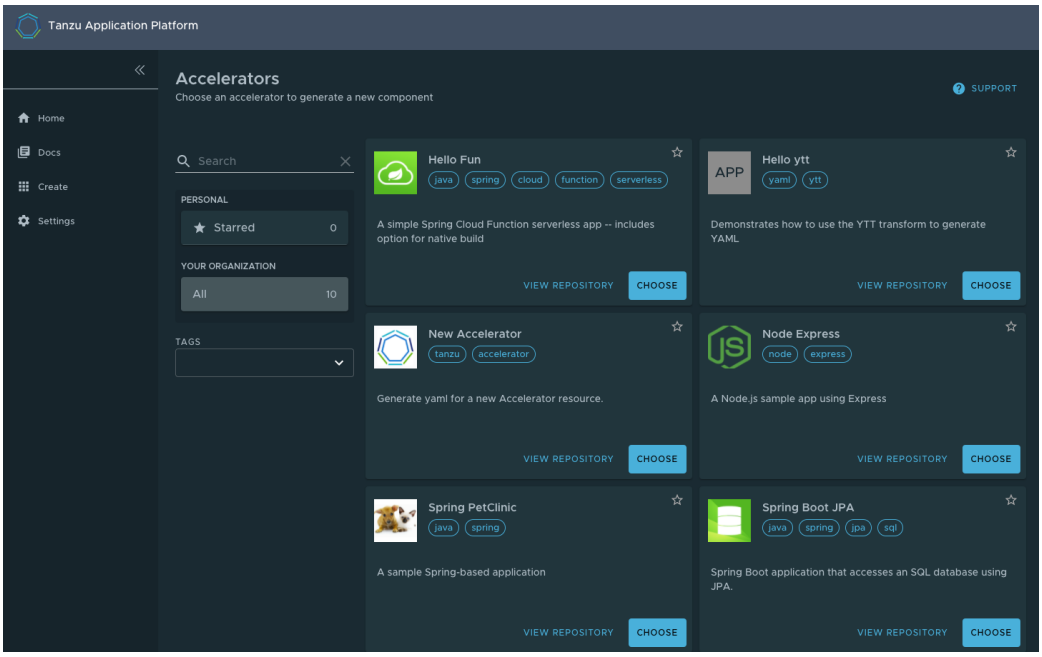
Enterprise architects author and publish accelerator projects that provide developers and operators with ready-made, enterprise-conforming code and configurations. You can then use Application Accelerator to create new projects based on those accelerator projects.

The Application Accelerator UI enables you to discover available accelerators, configure them, and generate new projects to download.

Access Application Accelerator

To open the Application Accelerator UI plug-in and select an accelerator:

1. Within Tanzu Application Platform, click **Create** in the left navigation pane to open the **Accelerators** page.



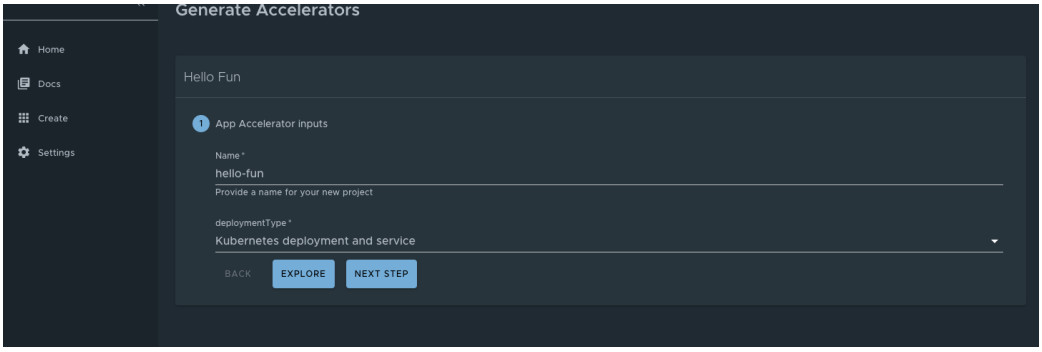
Here you can view accelerators already registered with the system. Developers can add new accelerators by registering them with Kubernetes.

2. Every accelerator has a title and short description. Click **VIEW REPOSITORY** to view an accelerator definition. This opens the accelerator's Git repository in a new browser tab.
3. Search and filter based on text and tags associated with the accelerators to find the accelerator representing the project you want to create.
4. Click **CHOOSE** for the accelerator you want. This opens the **Generate Accelerators** page.

Configure project generation

To configure how projects are generated:

1. On the **Generate Accelerators** page, add any configuration values needed to generate the project. The application architect defined these values in `accelerator.yaml` in the accelerator definition. Filling some text boxes can cause other text boxes to appear. Fill them all in.



2. Click **EXPLORE** to open the **Explore Project** page and view the project before it is generated.
3. After configuring your project, click **NEXT STEP** to see the project summary page.
4. Review the values you specified for the configurable options.
5. Click **BACK** to make more changes, if necessary. Otherwise, proceed to create the project.

Create the project

To create the project:

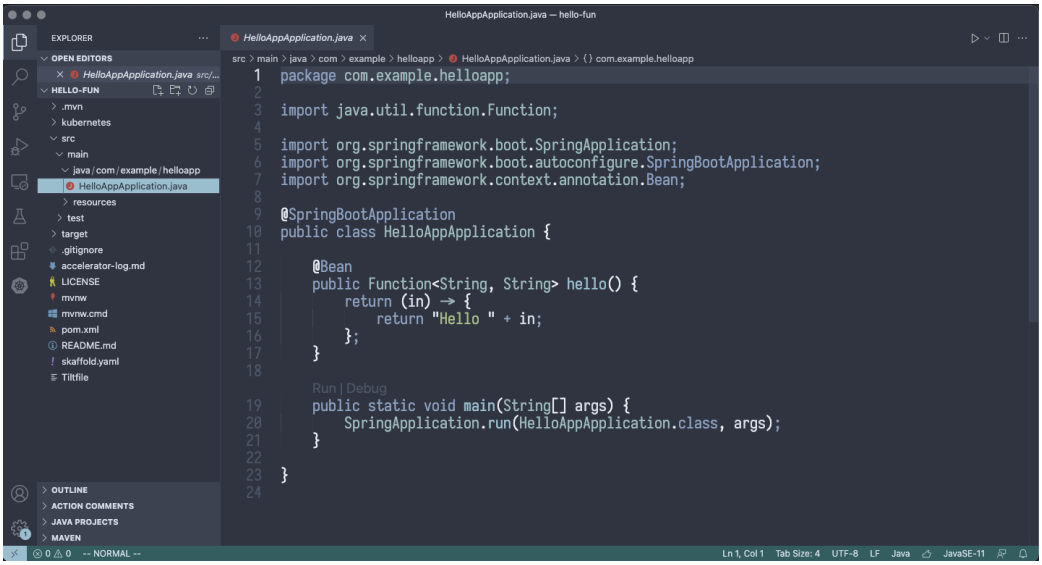
2. After the project is generated, click **EXPLORE ZIP FILE** to open the **Explore Project** page to verify configuration.
3. Click **DOWNLOAD ZIP FILE** to download the project in a ZIP file.

Develop your code

To develop your code:

1. Expand the ZIP file.
2. Open the project in your integrated development environment (IDE).



Next steps

To learn more about Application Accelerator for VMware Tanzu, see the Application Accelerator documentation.

Install Application Accelerator

This topic tells you how to install Application Accelerator from the Tanzu Application Platform (commonly known as TAP) package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install Application Accelerator. For more information about profiles, see About Tanzu Application Platform components and profiles.

Prerequisites

Before installing Application Accelerator:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- Install Flux SourceController on the cluster. See Install Flux CD Source Controller.
- Install Source Controller on the cluster. See Install Source Controller.

Install

To install Application Accelerator:

1. List version information for the package by running:

   ```
   tanzu package available list accelerator.apps.tanzu.vmware.com --namespace tap-install
   ```

   For example:

   ```
   $ tanzu package available list accelerator.apps.tanzu.vmware.com --namespace tap-install

   - Retrieving package versions for accelerator.apps.tanzu.vmware.com...
     NAME                                VERSION  RELEASED-AT
     accelerator.apps.tanzu.vmware.com  1.4.0    2022-12-08 12:00:00 -0500 EST
   ```

2. (Optional) View the changes you can make to the default installation settings by running:

   ```
   tanzu package available get accelerator.apps.tanzu.vmware.com/VERSION-NUMBER \
     --values-schema \
     --namespace tap-install
   ```

   Where `VERSION-NUMBER` is the version of the Application Accelerator package listed earlier.

   For example:

   ```
   $ tanzu package available get accelerator.apps.tanzu.vmware.com/1.4.0 \
       --values-schema \
       --namespace tap-install
   ```

For more information about values schema options, see the properties listed in Configure properties and resource use later.

3. Create a file named `app-accelerator-values.yaml` using the following example code:

```
server:
  service_type: "LoadBalancer"
  watched_namespace: "accelerator-system"
samples:
  include: true
```

4. Edit the values in your `app-accelerator-values.yaml` if needed, or leave the default values. You can add values you want from Configure properties and resource use.

5. Install the package by running:

```
tanzu package install app-accelerator \
  --package accelerator.apps.tanzu.vmware.com \
  --version VERSION-NUMBER \
  --namespace tap-install \
  --values-file app-accelerator-values.yaml
```

Where `VERSION-NUMBER` is the version of the Application Accelerator package listed earlier.

For example:

```
$ tanzu package install app-accelerator \
    --package accelerator.apps.tanzu.vmware.com \
    --version 1.4.0 \
    --namespace tap-install \
    --values-file app-accelerator-values.yaml

- Installing package 'accelerator.apps.tanzu.vmware.com'
| Getting package metadata for 'accelerator.apps.tanzu.vmware.com'
| Creating service account 'app-accelerator-tap-install-sa'
| Creating cluster admin role 'app-accelerator-tap-install-cluster-role'
| Creating cluster role binding 'app-accelerator-tap-install-cluster-rolebindin
g'
| Creating secret 'app-accelerator-tap-install-values'
- Creating package resource
- Package install status: Reconciling

 Added installed package 'app-accelerator' in namespace 'tap-install'
```

6. Verify the package install by running:

```
tanzu package installed get app-accelerator -n tap-install
```

For example:

```
$ tanzu package installed get app-accelerator -n tap-install

| Retrieving installation details for cc...
NAME:                    app-accelerator
PACKAGE-NAME:            accelerator.apps.tanzu.vmware.com
PACKAGE-VERSION:         1.4.0
STATUS:                  Reconcile succeeded
CONDITIONS:              [{ReconcileSucceeded True  }]
USEFUL-ERROR-MESSAGE:
```

Verify that `STATUS` is `Reconcile succeeded`.

7. To see the IP address for the Application Accelerator API when the `server.service_type` is set to `LoadBalancer`, run:

   ```
   kubectl get service -n accelerator-system
   ```

   This lists an external IP address for use with the `--server-url` Tanzu CLI flag for the Accelerator plug-in `generate` & `generate-from-local` command.

For how to troubleshoot installation issues, see Troubleshoot Application Accelerator.

Configure properties and resource use

When you install the Application Accelerator, you can configure the following optional properties from within your `app-accelerator-values.yaml` configuration file:

Property	Default	Description
`registry.secret_ref`	`registry.tanzu.vmware.com`	The secret used for accessing the registry where the App-Accelerator images are located
`server.service_type`	`ClusterIP`	The service type for the acc-ui-server service including LoadBalancer, NodePort, or ClusterIP
`server.watched_namespace`	`accelerator-system`	The namespace the server watches for accelerator resources
`server.engine_invocation_url`	`http://acc-engine.accelerator-system.svc.cluster.local/invocations`	The URL to use for invoking the accelerator engine
`engine.service_type`	`ClusterIP`	The service type for the acc-engine service including LoadBalancer, NodePort, or ClusterIP
`engine.max_direct_memory_size`	`32M`	The maximum size for the Java -XX:MaxDirectMemorySize setting
`samples.include`	`True`	Option to include the bundled sample Accelerators in the installation
`ingress.include`	`False`	Option to include the ingress configuration in the installation
`ingress.enable_tls`	`False`	Option to include TLS for the ingress configuration
`domain`	`tap.example.com`	Top-level domain to use for ingress configuration, default is `shared.ingress_domain`
`tls.secret_name`	`tls`	The name of the secret
`tls.namespace`	`tanzu-system-ingress`	The namespace for the secret
`telemetry.retain_invocation_events_for_no_days`	`30`	The number of days to retain recorded invocation events resources
`telemetry.record_invocation_events`	`true`	The system records each engine invocation when generating files for an accelerator?
`git_credentials.secret_name`	`git-credentials`	The name to use for the secret storing Git credentials for accelerators
`git_credentials.username`	`null`	The user name to use in secret storing Git credentials for accelerators
`git_credentials.password`	`null`	The password to use in secret storing Git credentials for accelerators

Property	Default	Description
`git_credentials.ca_file`	`null`	The CA certificate data to use in secret storing Git credentials for accelerators
`managed_resources.enable`	`false`	Whether to enable the App used to control managed accelerator resources
`managed_resources.git.url`	none	Required if managed_resources are enabled. Git repository URL containing manifests for managed accelerator resources
`managed_resources.git.ref`	`origin/main`	Required if managed_resources are enabled. Git ref to use for repository containing manifests for managed accelerator resources
`managed_resources.git.sub_path`	`null`	Git subPath to use for repository containing manifests for managed accelerator resources
`managed_resources.git.secret_ref`	`git-credentials`	Secret name to use for repository containing manifests for managed accelerator resources

VMware recommends that you do not override the default setting for `registry.secret_ref`, `server.engine_invocation_url`, or `engine.service_type`. These properties are only used to configure non-standard installations.

The following table is the resource use configurations for the components of Application Accelerator.

Component	Resource requests	Resource limits
acc-controller	CPU: 100m memory: 20Mi	CPU: 100m memory: 30Mi
acc-server	CPU: 100m memory:20Mi	CPU: 100m memory: 30Mi
acc-engine	CPU: 500m memory: 1Gi	CPU: 500m memory: 2Gi

Create an Application Accelerator Git repository during project creation

This topic tells you how to enable and use GitHub repository creation in the Application Accelerator plug-in of Tanzu Developer Portal.

Overview

The Application Accelerator plug-in uses the Backstage GitHub provider integration and the authentication mechanism to retrieve an access token. Then it can interact with the provider API to create GitHub repositories.

Supported Providers

The supported Git providers are GitHub and GitLab.

Note

To create a repository in a self-hosted GitLab, you must add a custom GitLab integration in `tap-values.yaml` as described in the Full Profile sample.

Configure

The following steps describe an example configuration that uses GitHub:

1. Create an **OAuth App** in GitHub based on the configuration described in this Backstage documentation. GitHub Apps are not supported. For more information about creating an OAuth App in GitHub, see the GitHub documentation.

   These values appear in your `app-config.yaml` or `app-config.local.yaml` for local development. For example:

   ```
   auth:
    environment: development
    providers:
      github:
        development:
          clientId: GITHUB-CLIENT-ID
          clientSecret: GITHUB-CLIENT-SECRET
   ```

2. Add a GitHub integration in your `app-config.yaml` configuration. For example:

   ```
   app_config:
    integrations:
      github:
        - host: github.com
   ```

   For more information, see the Backstage documentation.

(Optional) Deactivate Git repository creation

As of Tanzu Application Platform v1.5, you can deactivate Git repository creation by setting the property `customize.features.accelerators.gitRepoCreation` to `false` in `tap-values.yaml`. This also deactivates Git repository creation in the Application Accelerator extension for VS Code.

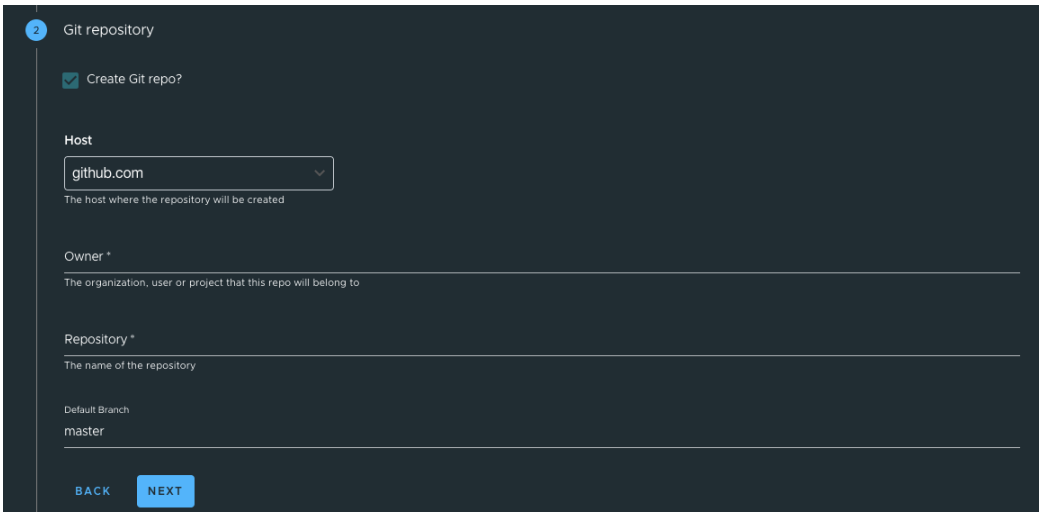
See the following example configuration for deactivating Git repository creation:

```
app_config:
  customize:
    features:
      accelerators:
        gitRepoCreation: false
```

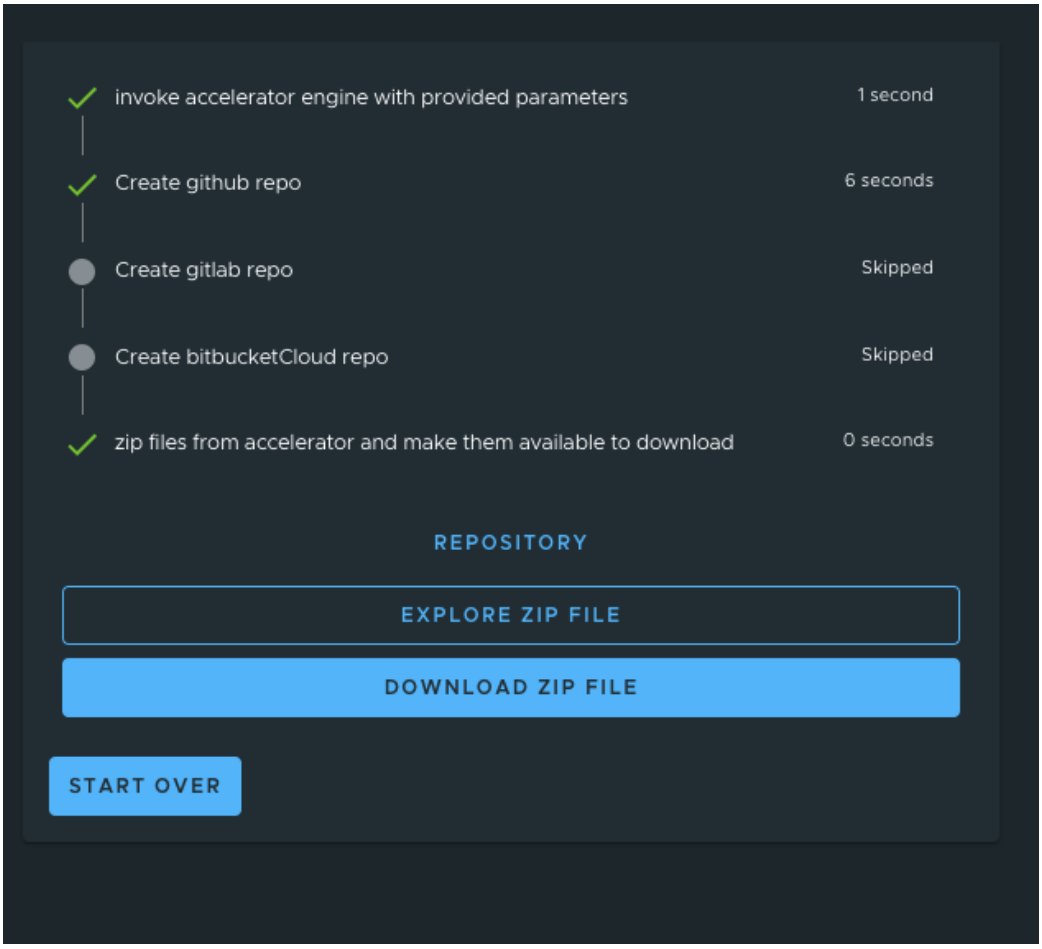
Create a Project

To create a project:

1. Go to Tanzu Developer Portal, access the Accelerators section, and then select an accelerator. The accelerator form now has a second step named **Git repository**.
2. Fill in the accelerator options and click **Next**.
3. Select the **Create Git repo?** check box.
4. Fill in the **Owner**, **Repository**, and **Default Branch** text boxes.



5. After entering the repository name, a dialog box appears that requests GitHub credentials. Log in and then click **Next**.
6. Click **GENERATE ACCELERATOR**. A link to the repository location appears.



API documentation plug-in in Tanzu Developer Portal

This topic gives you an overview of the API documentation plug-in of Tanzu Developer Portal. For more information, see Get started with the API documentation plug-in.

Overview

The API documentation plug-in provides a standalone list of APIs that can be connected to components and systems of the Tanzu Developer Portal software catalog.

Each API entity can reflect the components that provide that API and the list of components that are consumers of that API. Also, an API entity can be associated with systems and appear on the system diagram. To show this dependency, make the `spec.providesApis:` and `spec.consumesApis:` sections of the component definition files reference the name of the API entity.

Here's a sample of how you can add `providesApis` and `consumesApis` to an existing component's catalog definition, linking them together.

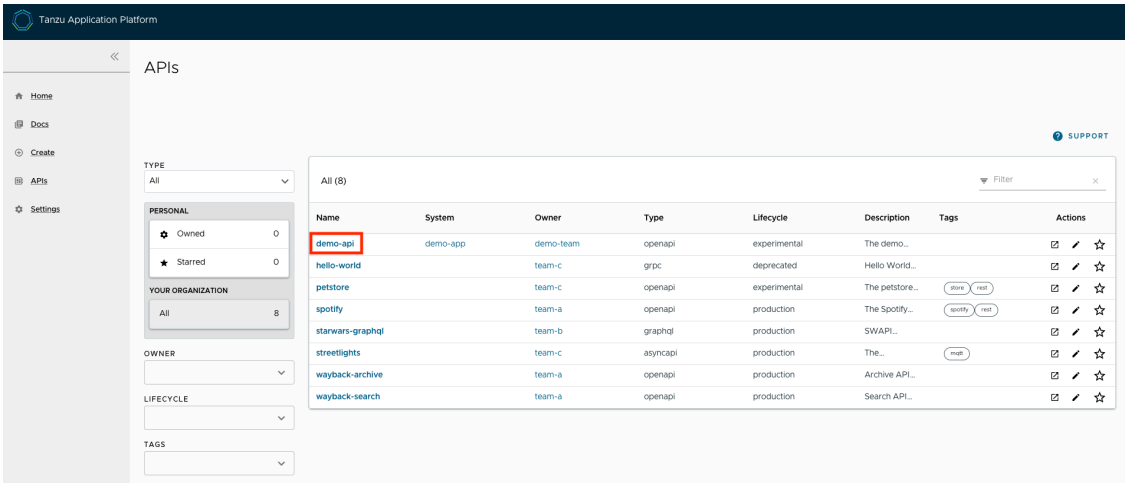
```
apiVersion: backstage.io/v1alpha1
kind: Component
metadata:
  name: example-component
  description: Example Component
spec:
  type: service
  lifecycle: experimental
  owner: team-a
  system: example-system
  providesApis: # list of APIs provided by the Component
    - example-api-1
  consumesApis: # list of APIs consumed by the Component
    - example-api-2
```

For more information about the structure of the definition file for an API entity, see the Backstage Kind: API documentation. For more information about the API documentation plug-in, see the Backstage API documentation in GitHub.

Use the API documentation plug-in

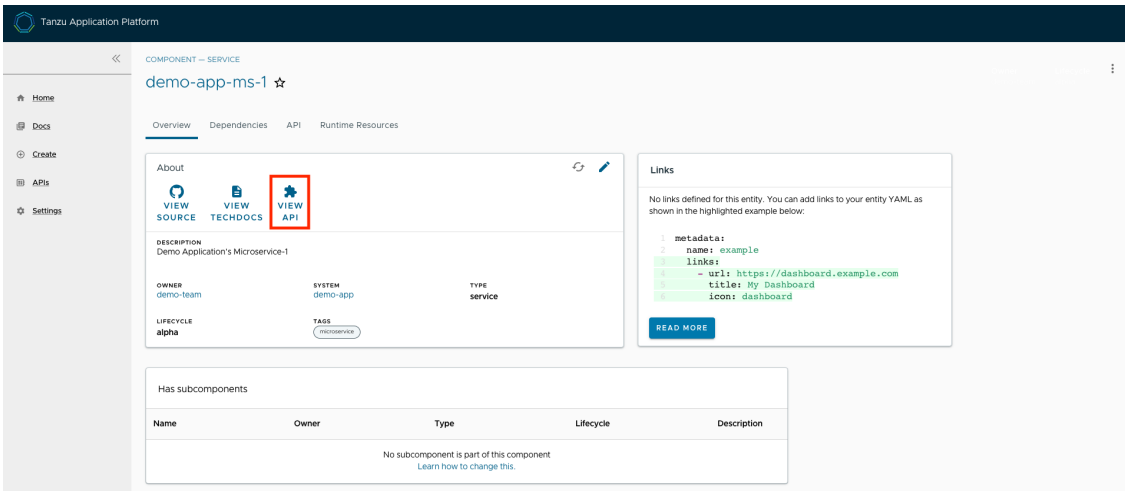
The API documentation plug-in is part of Tanzu Developer Portal.

The first way to use the API documentation plug-in is API-first. Click **APIs** in the left navigation pane of Tanzu Developer Portal. This opens the **API catalog page**.

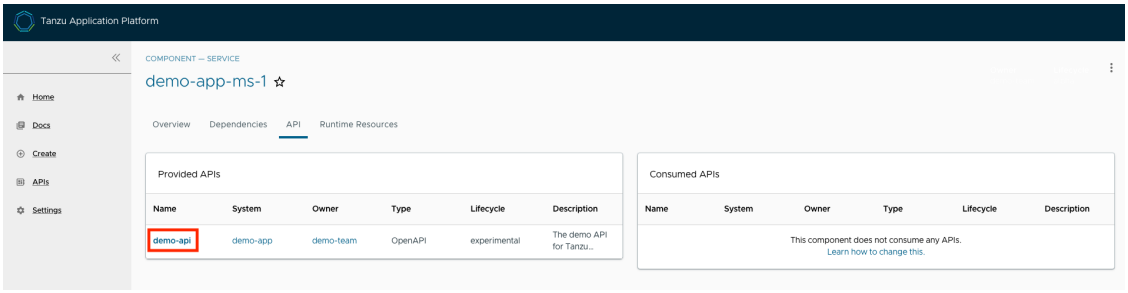


On that page, you can view all the APIs already registered in the catalog regardless of whether they are associated with components or systems.

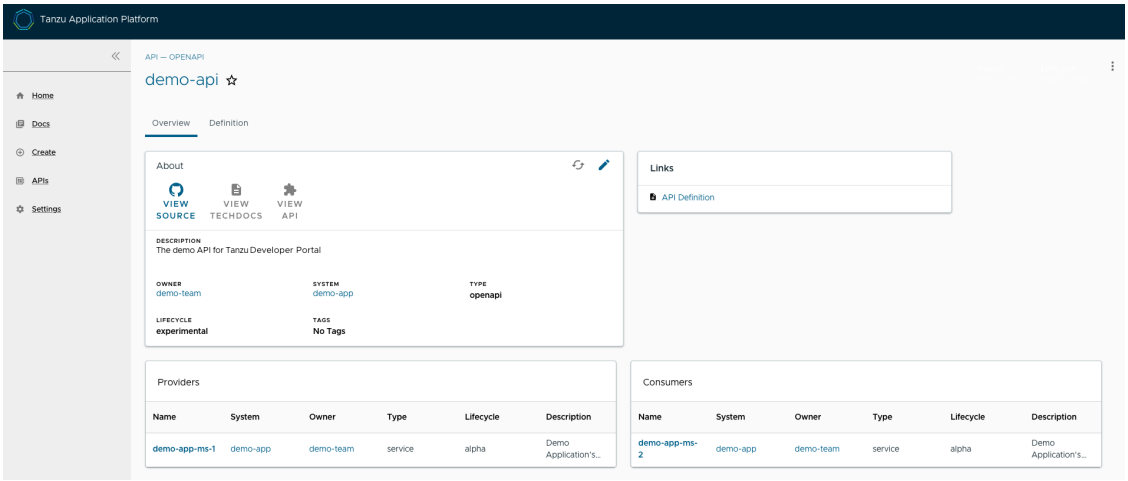
The second way to use the API documentation plug-in is to use components and systems of the software catalog, listed on the home page of Tanzu Developer Portal. If there is an API entity associated with the selected component or system, the **VIEW API** icon is active.



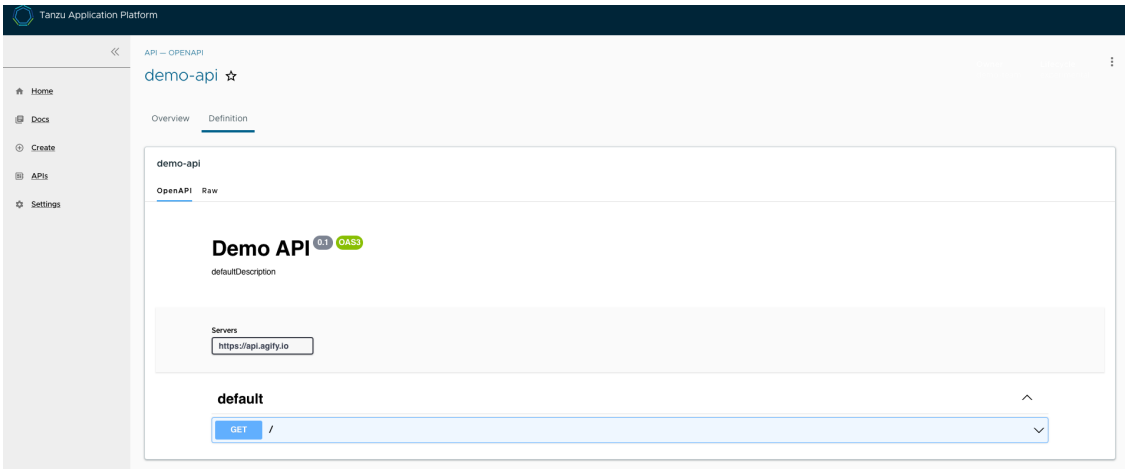
The **VIEW API** tab displays which APIs are being consumed by a component and which APIs are being provided by the component.



Clicking on the API itself takes you to the catalog entry for the API, which the Kind type listed in the upper-left corner denotes. Every API entity has a title and short description, including a reference to the team that owns the definition of that API and the software catalog objects that are connected to it.



Select the **Definition** tab on the top of the API page to see the definition of that API in human-readable and machine-readable format.



The API documentation plug-in supports the following API formats:

- OpenAPI 2 & 3
- AsyncAPI
- GraphQL
- Plain (to support any other format)

Create a new API entry

You can create a new API entry manually or automatically.

Manually create a new API entry

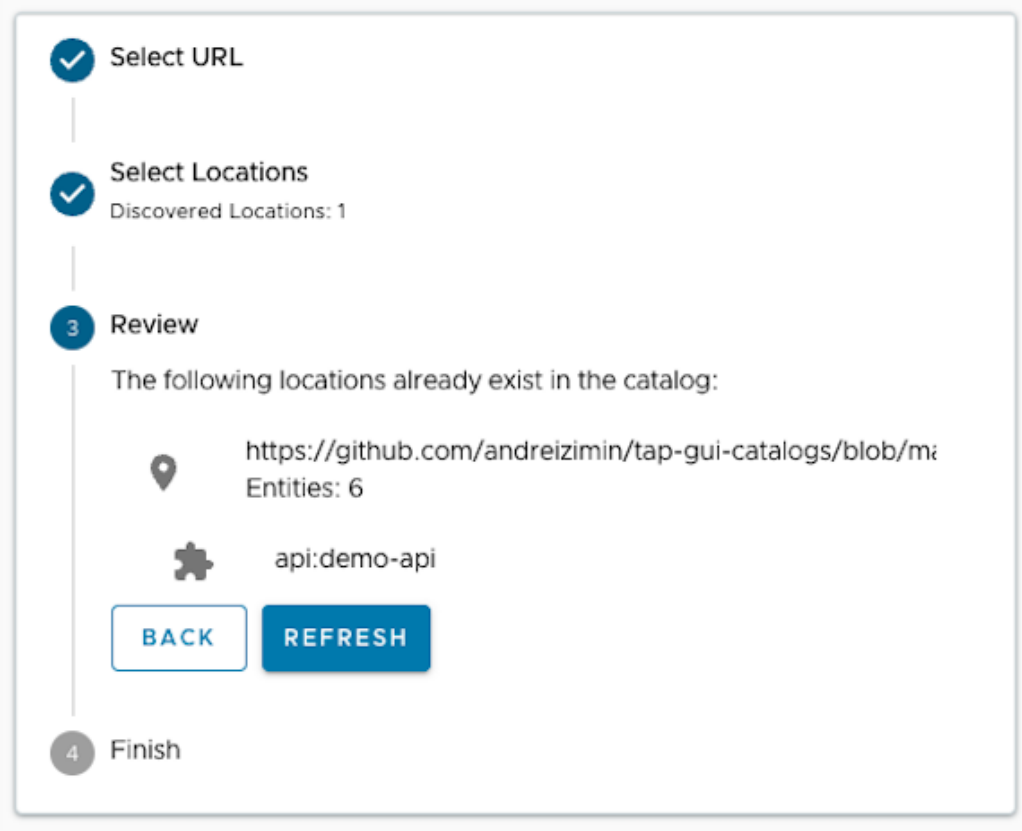
Manually creating a new API entity is similar to registering any other software catalog entity. To manually create a new API entity:

1. Click the **Home** button on the left navigation pane to access the home page of Tanzu Developer Portal.
2. Click **REGISTER ENTITY**.
3. **Register an existing component** prompts you to type a repository URL. Paste the link to the `catalog-info.yaml` file of your choice that contains the definition of your API entity. For example, you can copy the following YAML content and save it as `catalog-info.yaml` on a Git repository of your choice.

```
apiVersion: backstage.io/v1alpha1
kind: API
metadata:
name: demo-api
description: The demo API for Tanzu Developer Portal
links:
  - url: https://api.agify.io
    title: API Definition
    icon: docs
spec:
type: openapi
lifecycle: experimental
owner: demo-team
system: demo-app # Or specify system name of your choice
definition: |
  openapi: 3.0.1
  info:
    title: defaultTitle
    description: defaultDescription
```

```
  version: '0.1'
servers:
  - url: https://api.agify.io
paths:
  /:
    get:
      description: Auto generated using Swagger Inspector
      parameters:
        - name: name
          in: query
          schema:
            type: string
          example: type_any_name
      responses:
        '200':
          description: Auto generated using Swagger Inspector
          content:
            application/json; charset=utf-8:
              schema:
                type: string
              examples: {}
```

4. Click **ANALYZE** and then review the catalog entities to be added.



5. Click **IMPORT**.
6. Click **APIs** on the left navigation pane to view entries on the **API** page.

Automatically create a new API entry

Tanzu Application Platform v1.3 introduced a feature called **API Auto Registration** that can automatically register your APIs. For more information, see API Auto Registration.

API documentation plug-in in Tanzu Developer Portal

This topic gives you an overview of the API documentation plug-in of Tanzu Developer Portal. For more information, see Get started with the API documentation plug-in.

Overview

The API documentation plug-in provides a standalone list of APIs that can be connected to components and systems of the Tanzu Developer Portal software catalog.

Each API entity can reflect the components that provide that API and the list of components that are consumers of that API. Also, an API entity can be associated with systems and appear on the system diagram. To show this dependency, make the `spec.providesApis:` and `spec.consumesApis:` sections of the component definition files reference the name of the API entity.

Here's a sample of how you can add `providesApis` and `consumesApis` to an existing component's catalog definition, linking them together.

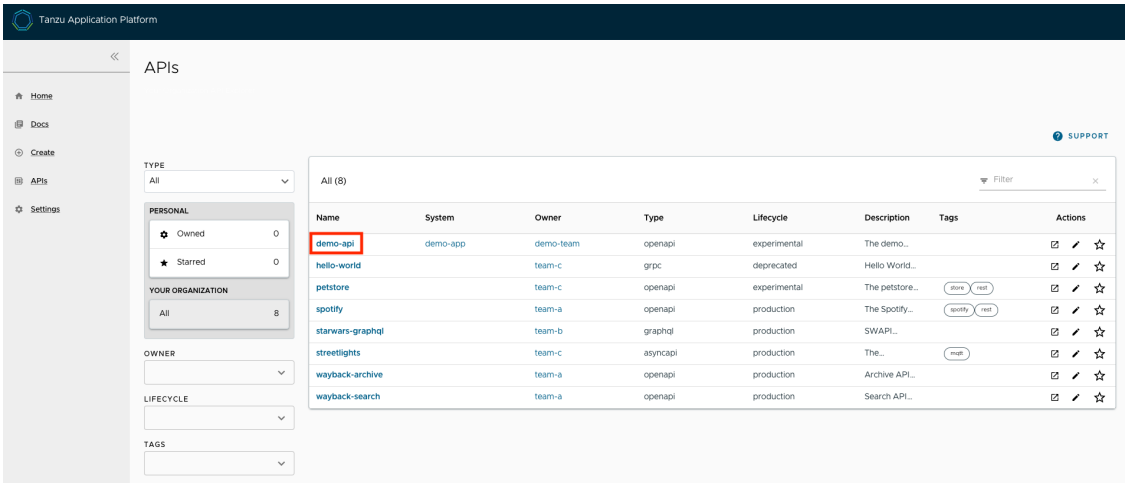
```
apiVersion: backstage.io/v1alpha1
kind: Component
metadata:
  name: example-component
  description: Example Component
spec:
  type: service
  lifecycle: experimental
  owner: team-a
  system: example-system
  providesApis: # list of APIs provided by the Component
    - example-api-1
  consumesApis: # list of APIs consumed by the Component
    - example-api-2
```

For more information about the structure of the definition file for an API entity, see the Backstage Kind: API documentation. For more information about the API documentation plug-in, see the Backstage API documentation in GitHub.

Use the API documentation plug-in

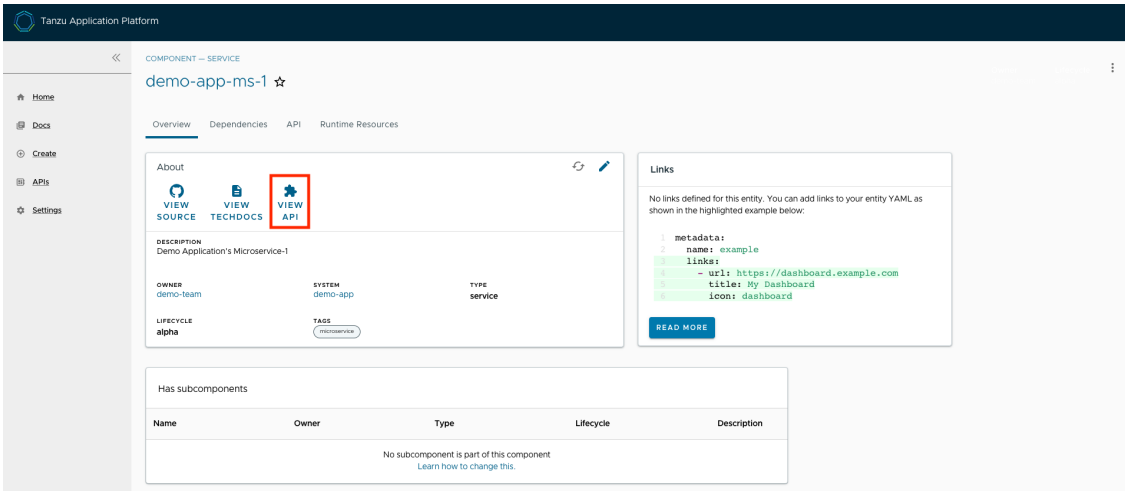
The API documentation plug-in is part of Tanzu Developer Portal.

The first way to use the API documentation plug-in is API-first. Click **APIs** in the left navigation pane of Tanzu Developer Portal. This opens the **API catalog page**.

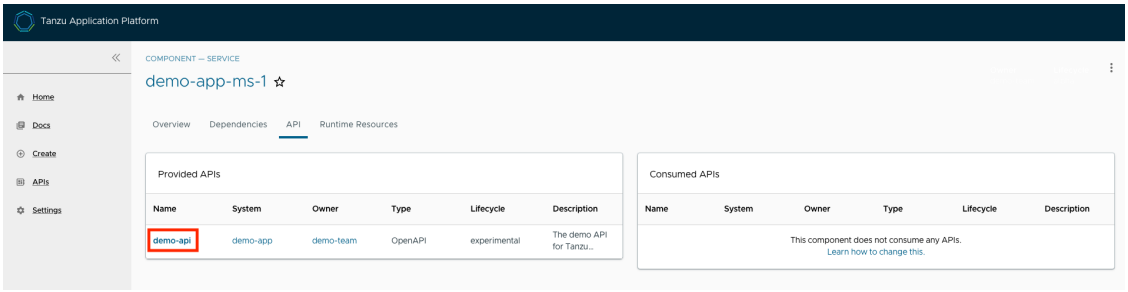


On that page, you can view all the APIs already registered in the catalog regardless of whether they are associated with components or systems.

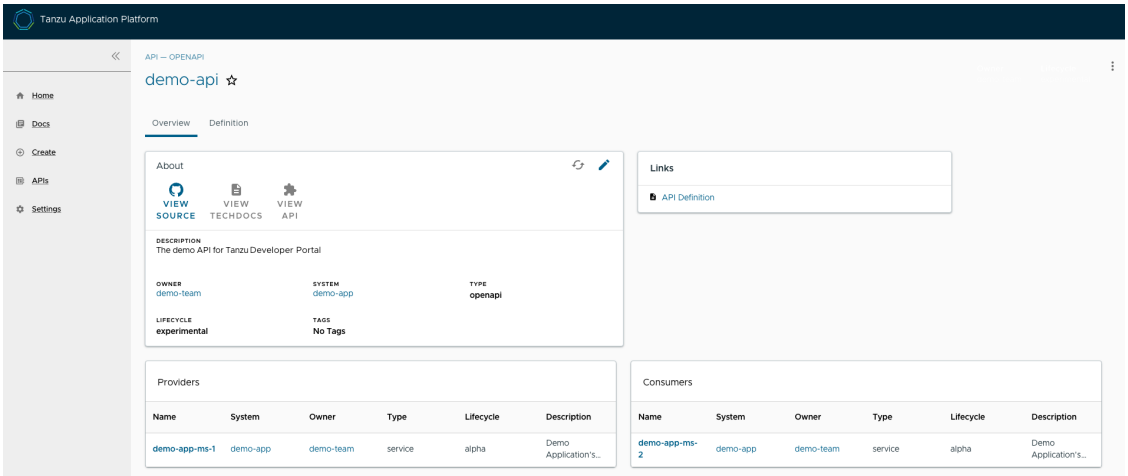
The second way to use the API documentation plug-in is to use components and systems of the software catalog, listed on the home page of Tanzu Developer Portal. If there is an API entity associated with the selected component or system, the **VIEW API** icon is active.



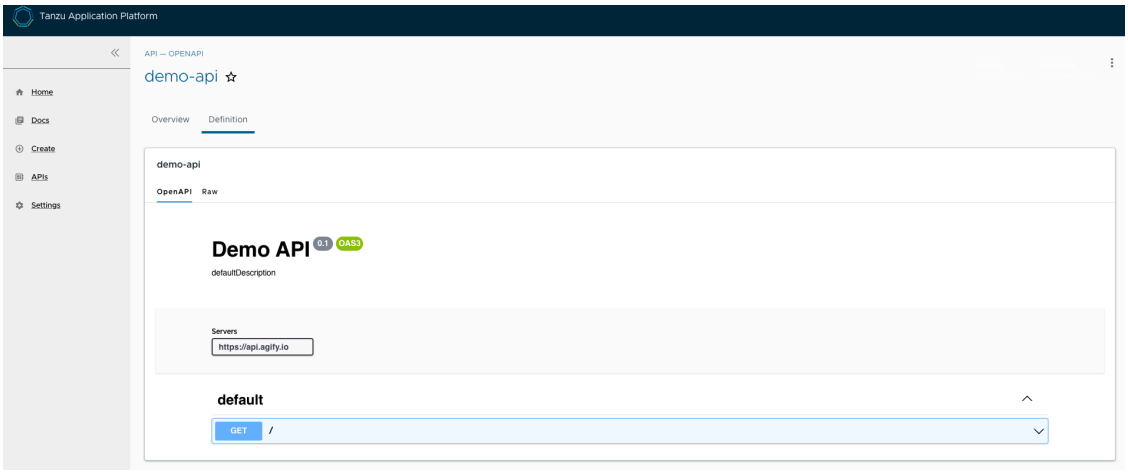
The **VIEW API** tab displays which APIs are being consumed by a component and which APIs are being provided by the component.



Clicking on the API itself takes you to the catalog entry for the API, which the Kind type listed in the upper-left corner denotes. Every API entity has a title and short description, including a reference to the team that owns the definition of that API and the software catalog objects that are connected to it.



Select the **Definition** tab on the top of the API page to see the definition of that API in human-readable and machine-readable format.



The API documentation plug-in supports the following API formats:

- OpenAPI 2 & 3
- AsyncAPI
- GraphQL
- Plain (to support any other format)

Create a new API entry

You can create a new API entry manually or automatically.

Manually create a new API entry

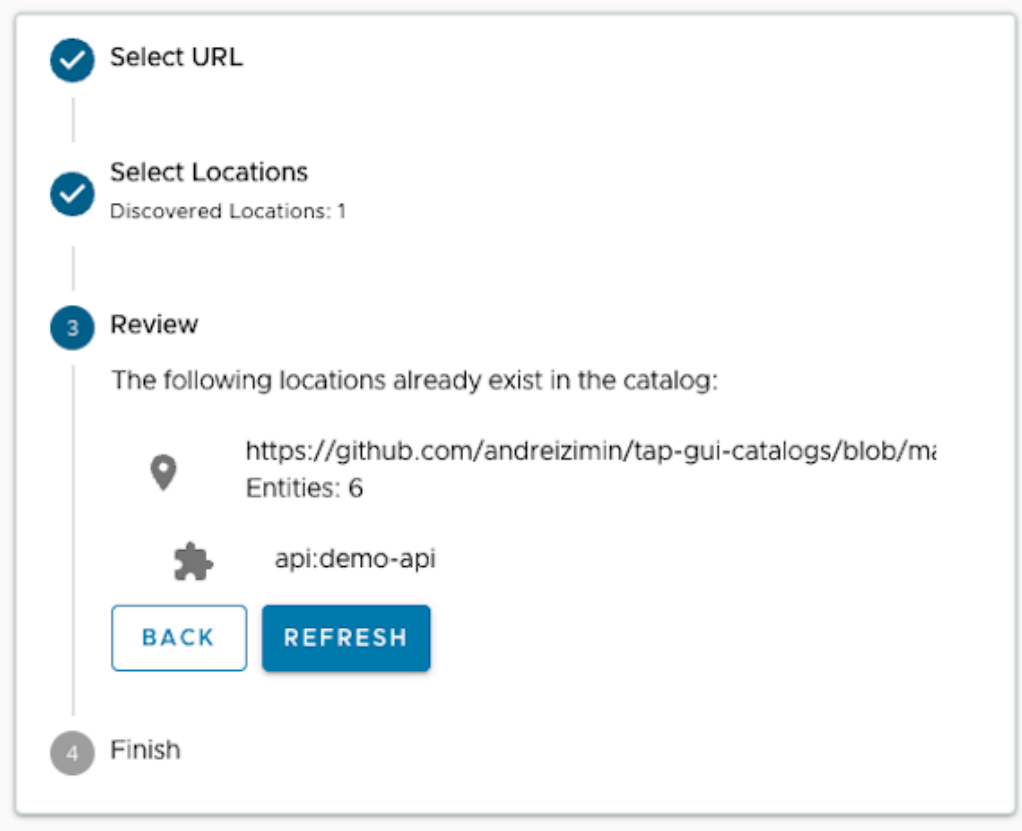
Manually creating a new API entity is similar to registering any other software catalog entity. To manually create a new API entity:

1. Click the **Home** button on the left navigation pane to access the home page of Tanzu Developer Portal.
2. Click **REGISTER ENTITY**.
3. **Register an existing component** prompts you to type a repository URL. Paste the link to the `catalog-info.yaml` file of your choice that contains the definition of your API entity. For example, you can copy the following YAML content and save it as `catalog-info.yaml` on a Git repository of your choice.

```
apiVersion: backstage.io/v1alpha1
kind: API
metadata:
name: demo-api
description: The demo API for Tanzu Developer Portal
links:
  - url: https://api.agify.io
    title: API Definition
    icon: docs
spec:
type: openapi
lifecycle: experimental
owner: demo-team
system: demo-app # Or specify system name of your choice
definition: |
  openapi: 3.0.1
  info:
    title: defaultTitle
    description: defaultDescription
```

```
  version: '0.1'
servers:
  - url: https://api.agify.io
paths:
  /:
    get:
      description: Auto generated using Swagger Inspector
      parameters:
        - name: name
          in: query
          schema:
            type: string
          example: type_any_name
      responses:
        '200':
          description: Auto generated using Swagger Inspector
          content:
            application/json; charset=utf-8:
              schema:
                type: string
              examples: {}
```

4. Click **ANALYZE** and then review the catalog entities to be added.



5. Click **IMPORT**.
6. Click **APIs** on the left navigation pane to view entries on the **API** page.

Automatically create a new API entry

Tanzu Application Platform v1.3 introduced a feature called **API Auto Registration** that can automatically register your APIs. For more information, see API Auto Registration.

Get started with the API documentation plug-in

This topic tells you how to get started with the API documentation plug-in in Tanzu Developer Portal.

API entries

This section describes API entities, how to add them, and how to update them.

About API entities

The list of API entities is visible on the left side navigation pane of Tanzu Developer Portal. It is also visible on the Overview page of specific components on the home page. APIs are a definition of the interface between components.

Their definition is provided in raw machine-readable and human-readable formats. For more information, see the API plug-in documentation.

Add a demo API entity to the Tanzu Developer Portal software catalog

To add a demo API entity and its related Catalog objects, follow the steps used for registering any other software catalog entity:

1. Go to the Home page of Tanzu Developer Portal by clicking **Home** on the left-side navigation pane.
2. Click **REGISTER ENTITY**.
3. In the repository URL text box, type the link to the `catalog-info.yaml` file of your choice or use the following sample definition.
4. Save this code block as `catalog-info.yaml`.
5. Upload it to the Git repository of your choice and copy the link to `catalog-info.yaml`. This demo setup includes a domain named `demo-domain` with a single system named `demo-system`. This systems consists of two microservices (`demo-app-ms-1` and `demo-app-ms-1`) and one API named `demo-api` that `demo-app-ms-1` provides and that `demo-app-ms-2` consumes.

```
apiVersion: backstage.io/v1alpha1
kind: Domain
metadata:
  name: demo-domain
  description: Demo Domain for Tanzu Application Platform
  annotations:
    'backstage.io/techdocs-ref': dir:.
spec:
  owner: demo-team

---

apiVersion: backstage.io/v1alpha1
kind: Component
metadata:
  name: demo-app-ms-1
  description: Demo Application's Microservice-1
  tags:
    - microservice
  annotations:
    'backstage.io/kubernetes-label-selector': 'app.kubernetes.io/part-of=demo-a
pp-ms-1'
    'backstage.io/techdocs-ref': dir:.
spec:
  type: service
```

```
  providesApis:
   - demo-api
  lifecycle: alpha
  owner: demo-team
  system: demo-app

---

apiVersion: backstage.io/v1alpha1
kind: Component
metadata:
  name: demo-app-ms-2
  description: Demo Application's Microservice-2
  tags:
    - microservice
  annotations:
    'backstage.io/kubernetes-label-selector': 'app.kubernetes.io/part-of=demo-a
pp-ms-2'
    'backstage.io/techdocs-ref': dir:.
spec:
  type: service
  consumesApis:
   - demo-api
  lifecycle: alpha
  owner: demo-team
  system: demo-app

---

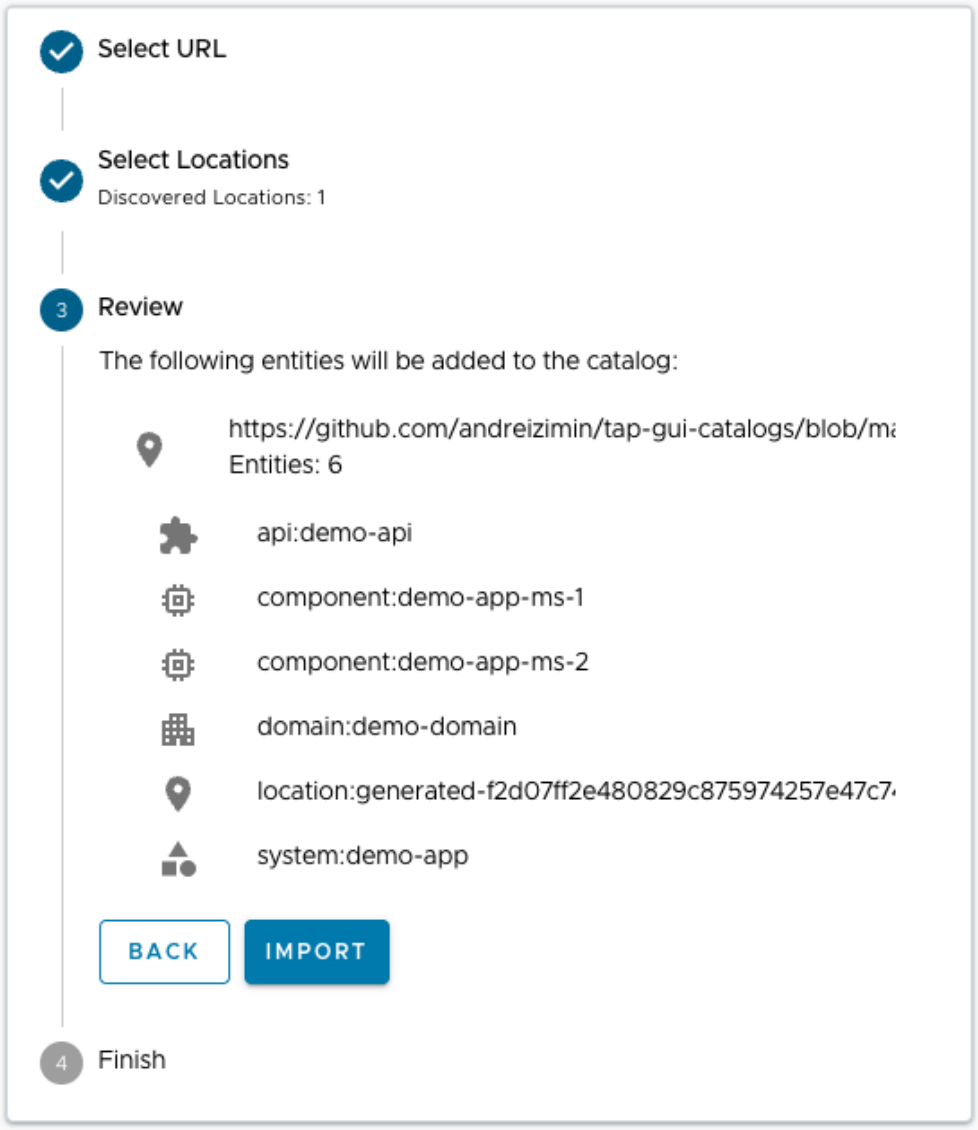
apiVersion: backstage.io/v1alpha1
kind: System
metadata:
  name: demo-app
  description: Demo Application for Tanzu Application Platform
  annotations:
    'backstage.io/techdocs-ref': dir:.
spec:
  owner: demo-team
  domain: demo-domain

---

apiVersion: backstage.io/v1alpha1
kind: API
metadata:
  name: demo-api
  description: The demo API for Tanzu Developer Portal
  links:
    - url: https://api.agify.io
      title: API Definition
      icon: docs
spec:
  type: openapi
  lifecycle: experimental
  owner: demo-team
  system: demo-app # Or specify system name of your choice
  definition: |
    openapi: 3.0.1
    info:
      title: Demo API
      description: defaultDescription
      version: '0.1'
    servers:
      - url: https://api.agify.io
    paths:
      /:
```

```
    get:
      description: Auto generated using Swagger Inspector
      parameters:
        - name: name
          in: query
          schema:
            type: string
          example: type_any_name
      responses:
        '200':
          description: Auto generated using Swagger Inspector
          content:
            application/json; charset=utf-8:
              schema:
                type: string
              examples: {}
```

6. Paste the link to `catalog-info.yaml` and click **ANALYZE**.
7. Review the catalog entities and click **IMPORT**.



8. Go to the **API** page by clicking **APIs** on the left side navigation pane. The catalog changes and entries are visible for further inspection. If you select the system **demo-app**, the diagram appears as follows:

Update your demo API entry

To update your demo API entry, click **demo-api** in the list of available APIs in your software catalog and click the **Edit** icon on the Overview page.

It opens the source `catalog-info.yaml` file that you can edit. For example, you can change the `spec.paths.parameters.example` from `type_any_name` to `Tanzu` and then save your changes.

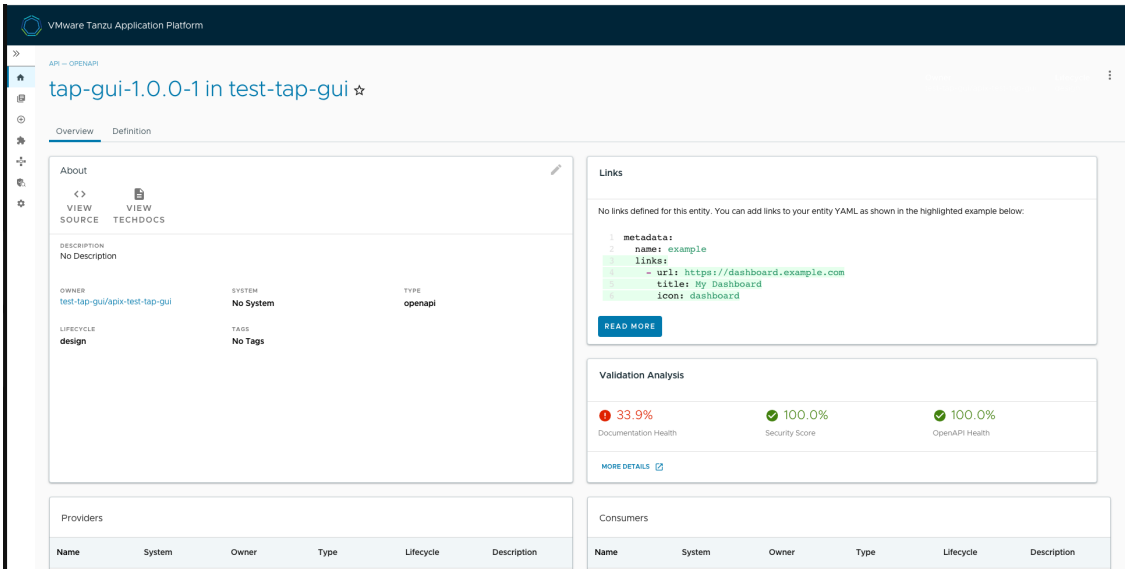
After making any edits, Tanzu Developer Portal re-renders the API entry with the next refresh cycle.

Validation Analysis of API specifications

This section describes the Validation Analysis card, the data format needed to populate the card, and how to get automatic scores for your OpenAPI entities.

About the Validation Analysis card

When viewing entities of the kind `API` on the Overview tab, you see the Validation Analysis card that displays the health of an API through various scoring parameters.



To display the health scores, an API entity must contain the following metadata structure:

```
apiVersion: backstage.io/v1alpha1
kind: API
metadata:
  name: NAME
  description: DESCRIPTION
  apiscores:
    scores:
    - id: documentationReport
      label: "Documentation Health"
      value: 34.375
      valueType: percentage
      status: failed
    - id: securityReport
      label: "Security Score"
      value: 70.0
      valueType: percentage
      status: warning
    - id: openApiHealthReport
      label: "OpenAPI Health"
      value: 89.0625
      valueType: percentage
      status: passed
    scoreDetailsURL:  VALIDATION-REPORT-URL-FOR-MORE-DETAILS
# Other API Entity parameters
```

If an API entity follows this schema, the Validation Analysis card displays helpful information about the API.

```
    - id:        # Unique ID
      label:     # Descriptive label displayed as a title over the numerical value
      value:     # Any number value
      valueType: # One of the types (percentage or other). Displays the % symbol or di
splays nothing.
      status:    # One of the statuses (passed, warning, or failed). Displays the numb
er in green, yellow, or red.
```

DORA metrics in Tanzu Developer Portal

This topic tells you about viewing DevOps Research and Assessment (DORA) metrics in Tanzu Developer Portal.

Overview

DORA is a research program for studying the capabilities that drive software delivery and operations performance. DORA helps teams apply these capabilities to improve organizational performance. For more information about DORA, see the DORA website.

DORA metrics are a set of key performance indicators (KPIs) that DORA has developed to measure the effectiveness of an organization's DevOps practices. These metrics help organizations to assess their software development and delivery processes and identify areas for improvement.

Collecting DORA metrics can be challenging because it involves:

- Gathering data from various sources and tools
- Ensuring data accuracy and consistency
- Dealing with organizational and cultural resistance to measurement and improvement

Tanzu Application Platform is uniquely positioned to provide DORA metrics through its integrated supply chain. This supply chain offers end-to-end visibility and control over the entire development

and deployment process, enabling comprehensive measurement and optimization of DevOps practices.

DORA metrics

DORA metrics include:

- Deployment Frequency, which measures how often code changes are deployed to an environment. High deployment frequency is often associated with a mature DevOps culture.
- Lead Time for Changes, which measures the time it takes to go from code committed to code successfully running in an environment. Shortening this lead time is often a goal of DevOps practices.
- Change Failure Rate, which measures the rate at which changes to the production environment cause failures or incidents. Lower failure rates indicate a reliable software delivery process.
- Mean Time to Recovery (MTTR), which measures how quickly an organization can recover from incidents or outages in production. A lower MTTR suggests that an organization resolves issues quickly.

Supported DORA metrics

This table shows supported DORA metrics in the Tanzu Application Platform v1.9.1 DORA plug-in. Support for more metrics is planned for later DORA plug-in versions.

DORA metric	Tanzu Application Platform v1.9.1 DORA plug-in support
Deployment Frequency	Yes
Lead Time for Changes	Yes
Change Failure Rate	No
Mean Time to Recovery	No

Use the DORA plug-in

To use the DORA plug-in:

1. Select the component you want to view DORA metrics for.
2. Click the **DORA** tab in the navigation list.

DORA metric calculation

By default, DORA metrics are calculated from the average number of deployments to all environments in the last 7 days. Two filtering options are available from drop-down menus:

- By date range, based on a predefined set of choices
- By environment, based on the location labels configured by a platform engineer

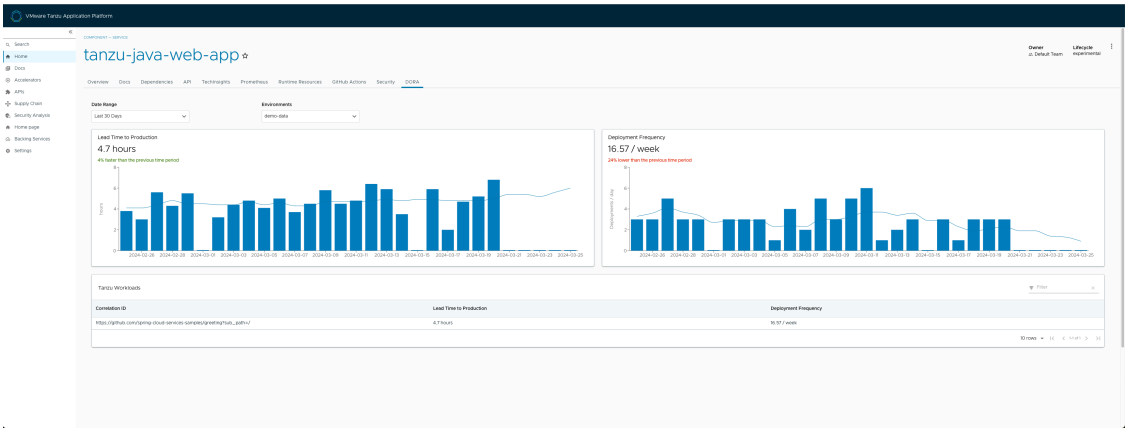
For more information about location configuration, see Configure Artifact Metadata Repository.

DORA graphs display trends of Lead Time and Deployment Frequency metrics over time.

The Lead Time graph displays in bars the daily average time taken for a code change to go from a commit to a running container. The trend line illustrates the average lead time for deployments made in the last 7 days.

The Deployment Frequency graph displays the frequency of code changes deployed to production, depicted in daily bars and a corresponding 7-day moving average trend line.

Tanzu workloads have a correlation ID that groups all the artifacts together.



Security Analysis in Tanzu Developer Portal

This topic tells you about the Security Analysis plug-in in Tanzu Developer Portal.

Overview

The Security Analysis plug-in summarizes vulnerability data across all workloads running in Tanzu Application Platform, enabling faster identification and remediation of CVEs.

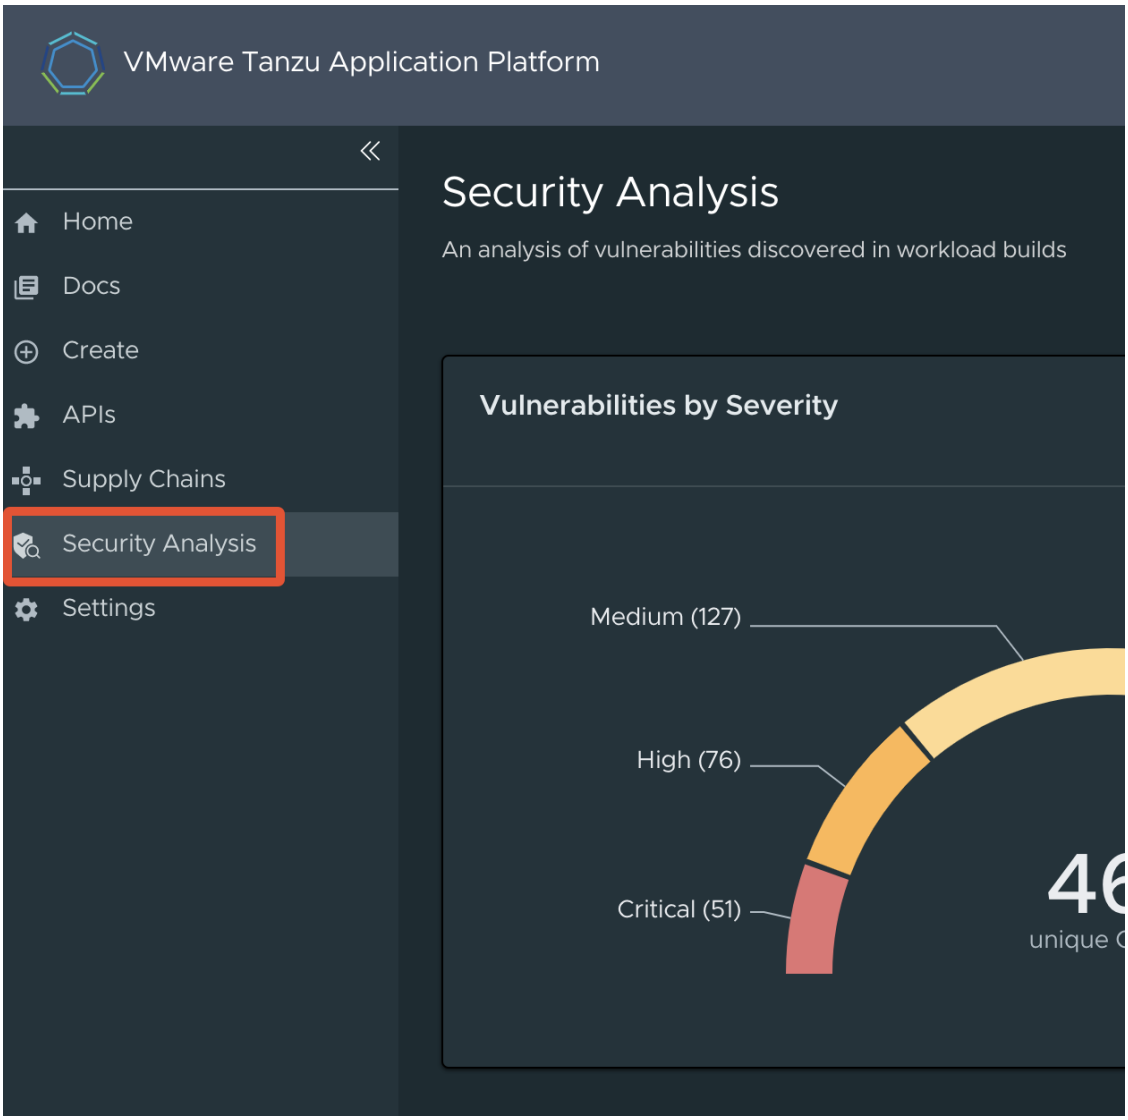
Installing and configuring

The Security Analysis plug-in is installed by default. It is tightly coupled with the Supply Chain Choreographer plug-in. After installing and configuring the Supply Chain Choreographer GUI plug-in, there is no additional configuration needed for the Security Analysis plug-in.

The Security Analysis plug-in is part of the Tanzu Application Platform Full and View profiles.

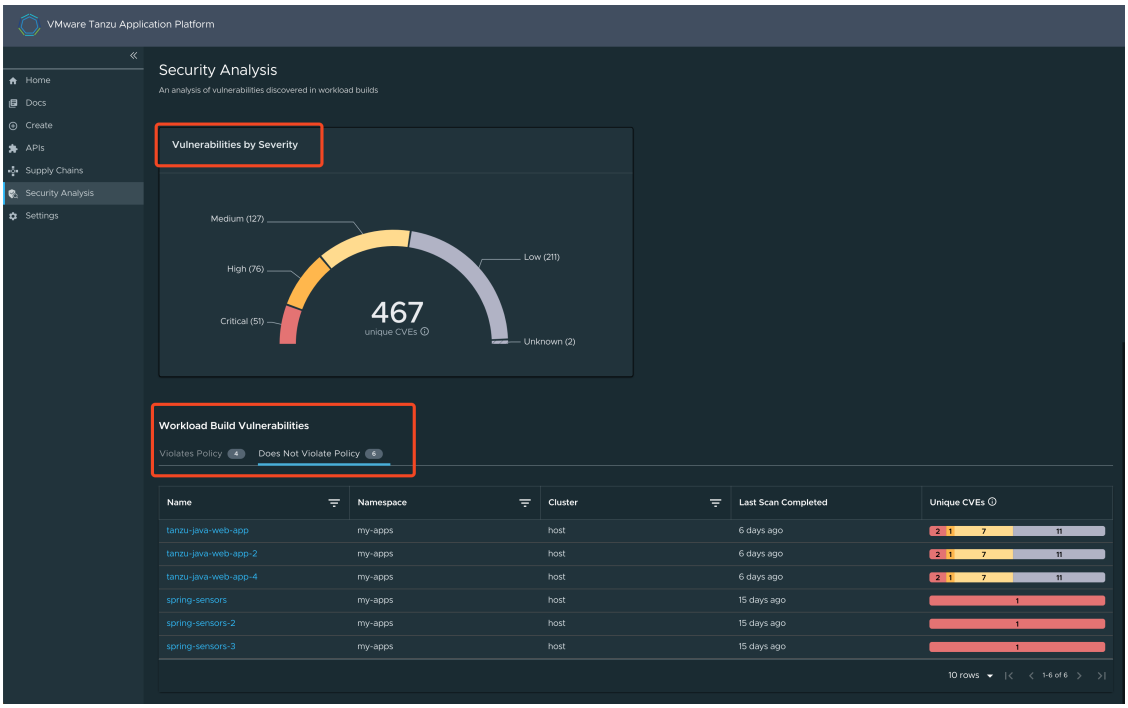
Accessing the plug-in

The Security Analysis plug-in is always accessible from the left navigation pane. Click the **Security Analysis** button to open the **Security Analysis** dashboard.



Viewing vulnerability data

The **Security Analysis** dashboard provides a summary of all vulnerabilities across all clusters for single-cluster and multicluster deployments.



The **Vulnerabilities by Severity** widget quickly counts the number of critical, high, medium, low, and unknown severity CVEs, based on the CVSS severity rating of each CVE.

It includes a sum of all workloads' source and image scan vulnerabilities. For example, if CVE-123 exists in the latest source scans and image scans of Workload ABC and Workload DEF, it is counted four times.

Note

The sum includes any CVEs on the allowlist (ignoreCVEs).

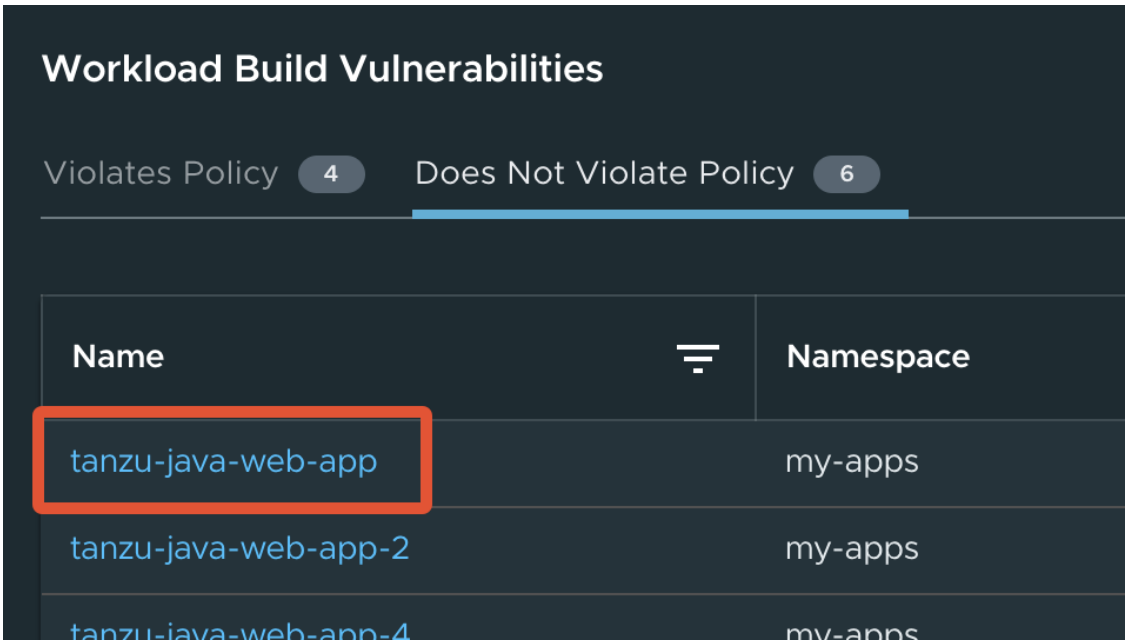
The **Workload Build Vulnerabilities** tables, with the **Violates Policy** tab and **Does Not Violate** tab, separate workloads based on the scan policy. For more information, see Enforce compliance policy using Open Policy Agent The Unique CVEs column uses the same sum logic as described earlier, but for individual workloads.

The sum of a workload's CVEs might not match the Supply Chain Choreographer's Vulnerability Scan Results. The data on this dashboard is based on `kubectl describe` for `SourceScan` and `ImageScan`. The data on the Supply Chain Choreographer's Vulnerability Scan Results is based on Metadata Store data.

Only vulnerability scans associated with a Cartographer workload appear. Use tanzu insight to view results for non-workload scan results.

Viewing CVE and package details

The Security Analysis plug-in has a **CVE** page and a **Package** page. These are accessed by clicking on a workload name, which opens the Supply Chain Choregrapher plug-in. Clicking on the CVE or Package name opens the **CVE** or **Package** page, respectively.



The **CVE** page contains basic information about the vulnerability and includes a table with all affected packages and versions.

The **Package** page contains basic information about a package and includes a table with all CVEs and the affected package versions.

Supply Chain Choreographer in Tanzu Developer Portal

This topic tells you about Supply Chain Choreographer in Tanzu Developer Portal.

Overview

The Supply Chain Choreographer (SCC) plug-in enables you to visualize the execution of a workload by using any of the installed Out-of-the-Box supply chains. For more information about the Out-of-the-Box (OOTB) supply chains that are available in Tanzu Application Platform, see Supply Chain Choreographer for Tanzu.

Prerequisites

To use Supply Chain Choreographer in Tanzu Developer Portal you must have:

- One of the following installed on your cluster:
  - Tanzu Application Platform Full profile
  - Tanzu Application Platform View profile
  - Tanzu Developer Portal package and a metadata store package
- One of the following installed on the target cluster where you want to deploy your workload:
  - Tanzu Application Platform Run profile
  - Tanzu Application Platform Full profile

For more information, see Overview of multicluster Tanzu Application Platform

Enable CVE scan results

To see CVE scan results within Tanzu Developer Portal, connect Tanzu Developer Portal to the Tanzu Application Platform component Supply Chain Security Tools - Store (SCST - Store).

Automatically connect Tanzu Developer Portal to SCST - Store

Tanzu Developer Portal has automation for enabling connection between Tanzu Developer Portal and SCST - Store. This automation is active by default and requires no configuration.

Important

There is a known issue with the automatic configuration breaking the SBOM download feature introduced in Tanzu Application Platform v1.6. To fix this issue, edit `tap-values.yaml` as described in Troubleshooting.

To deactivate this automation, add the following block to the Tanzu Developer Portal section within `tap-values.yaml`:

```
# ...
tap_gui:
  # ...
  metadataStoreAutoconfiguration: false
```

This file change creates a service account for the connection with privileges scoped only to Metadata Store. In addition, it mounts the token of the service account into the Tanzu Developer Portal pod and produces for you the `app_config` section necessary for Tanzu Developer Portal to communicate with SCST - Store.

Troubleshooting

For debugging the automation, or for verifying that the automation is active, you must know which resources are created. The following commands display the different Kubernetes resources that are created when `tap_gui.metadataStoreAutoconfiguration` is set to `true`:

```
$ kubectl -n tap-gui get serviceaccount metadata-store
NAME             SECRETS   AGE
metadata-store   1         AGE-VALUE
```

```
$ kubectl -n tap-gui get secret metadata-store-access-token
NAME                          TYPE                                  DATA   AGE
metadata-store-access-token   kubernetes.io/service-account-token   3      AGE-VALUE
```

```
$ kubectl -n tap-gui get clusterrole metadata-store-reader
NAME                     CREATED AT
metadata-store-reader    CREATED-AT-TIME
```

```
$ kubectl -n tap-gui get clusterrolebinding read-metadata-store
NAME                   ROLE                                  AGE
read-metadata-store    ClusterRole/metadata-store-reader     AGE-VALUE
```

There is another condition that impacts whether the automation creates the necessary service account. If your configuration includes a `/metadata-store` block, the automation doesn't create the Kubernetes resources for use in `autoconfiguration` and the automation doesn't overwrite the proxy block that you provide. To use the automation, you must delete the block at `tap_gui.app_config.proxy["/metadata-store"]`.

For example, a `tap-values.yaml` file with the following content does not create additional Kubernetes resources as described earlier:

```
# ...
tap_gui:
  # ...
  app_config:
    # ...
    proxy:
      '/metadata-store':
        target: SOMETHING
```

Manually connect Tanzu Developer Portal to the Metadata Store

To manually enable CVE scan results:

1. Obtain the read-write token, which is created by default when installing Tanzu Application Platform. Alternatively, create an additional read-write service account.
2. Add this proxy configuration to the `tap-gui:` section of `tap-values.yaml`:

   ```
   tap_gui:
     app_config:
       proxy:
         /metadata-store:
           target: https://metadata-store-app.metadata-store:8443/api/v1
           changeOrigin: true
           secure: false
           allowedHeaders: ['Accept', 'Report-Type-Format']
           headers:
             Authorization: "Bearer ACCESS-TOKEN"
             X-Custom-Source: project-star
   ```

   Where `ACCESS-TOKEN` is the token you obtained after creating a read-write service account.

Important

The `Authorization` value must start with the word `Bearer`.

Enable GitOps Pull Request Flow

Set up for GitOps and pull requests to enable the supply chain box-and-line diagram to show **Approve a Request** in the **Config Writer** stage details view when the **Config Writer** stage is clicked. For more information, see GitOps vs. RegistryOps.

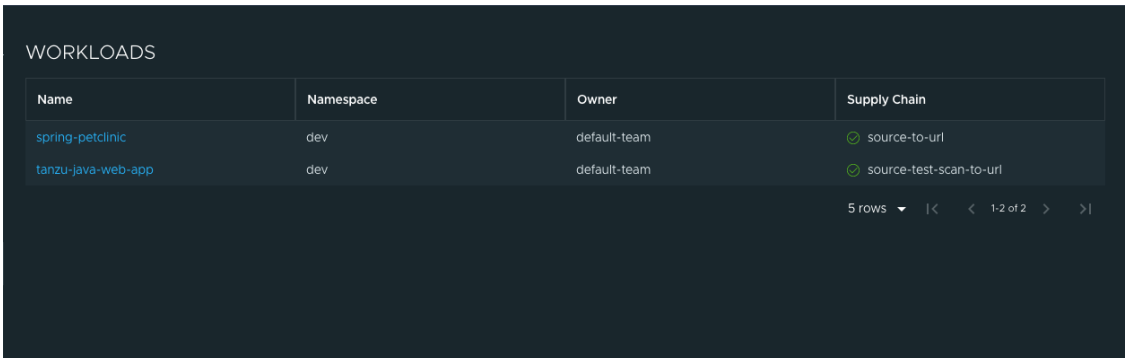
Supply Chain Visibility

Before using the Supply Chain Visibility (SCC) plug-in to visualize a workload, you must create a workload.

The workload must have the `app.kubernetes.io/part-of` label specified, whether you manually create the workload or use one supplied with the OOTB supply chains.

Use the left sidebar navigation to access your workload and visualize it in the supply chain that is installed on your cluster.

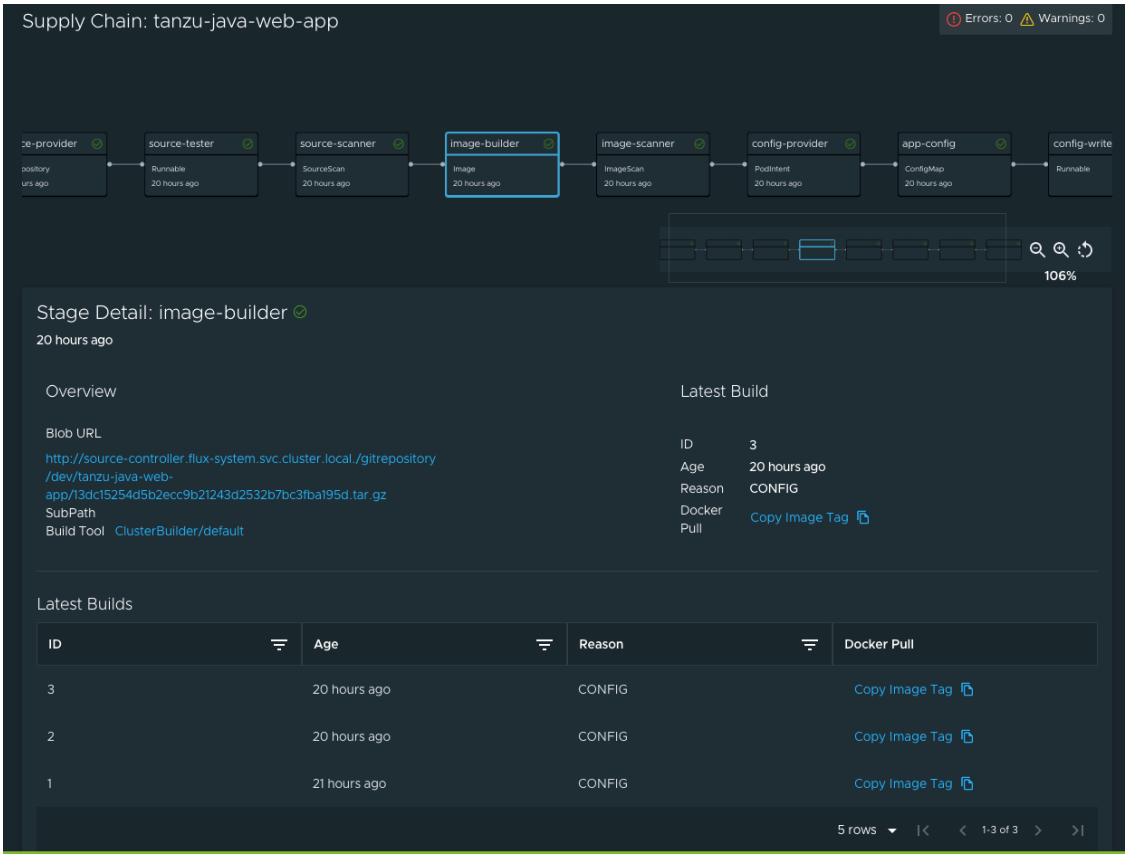
The example workload described in this topic is named `tanzu-java-web-app`.



Click **tanzu-java-web-app** in the **WORKLOADS** table to navigate to the visualization of the supply chain.

There are two sections within this view:

- The box-and-line diagram at the top shows all the configured custom resource definitions (CRDs) that this supply chain uses, and any artifacts that the supply chain's execution outputs
- The **Stage Detail** section at the bottom shows source data for each part of the supply chain that you select in the diagram view



When a workload is deployed to a cluster that has the `deliverable` package installed, a new section appears in the supply chain that shows **Pull Config** boxes and **Delivery** boxes.

When you have a `Pull Request` configured in your environment, access the merge request from the supply chain by clicking **APPROVE A REQUEST**. This button is displayed after you click **Config Writer** in the supply chain diagram.

View Vulnerability Scan Results

Click the **Source Scan** stage or **Image Scan** stage to view vulnerability source scans and image scans for workload builds. The data is from Supply Chain Security Tools - Store.

CVE issues represent any vulnerabilities associated with a package or version found in the source code or image, including vulnerabilities from past scans.

Note

For example, the `log4shell` package is found in image ABC on 1 January without any CVEs. On 15 January, the log4j CVE issue is found while scanning image DEF. If a user returns to the **Image Scan** stage for image ABC, the log4j CVE issue appears and is associated with the `log4shell` package.

Triage vulnerabilities (alpha)

This feature enables you to store analysis data for each of the vulnerabilities found in the scan.

Caution

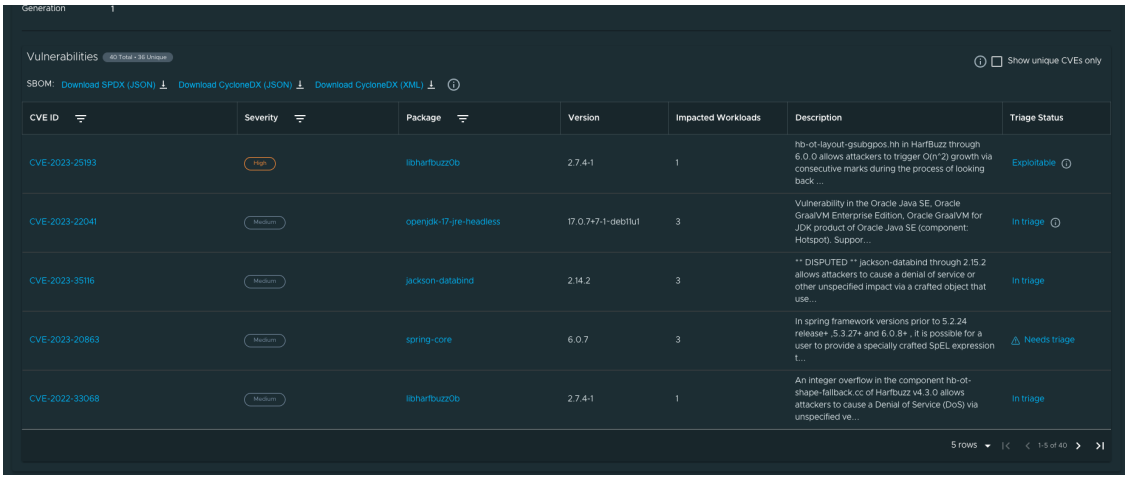
The capability to triage scan results in Tanzu Developer Portal is in the alpha stage, which means that it is still in early development and is subject to change at any point. You might encounter unexpected behavior from it.

The feature is turned off by default in Tanzu Developer Portal. To enable the feature, add the following YAML to your configuration section within the `tap-values.yaml` file:

```
# tap-values.yaml

tap_gui:
  app_config:
    customize:
      features:
        supplyChain:
          enableTriageUI: true
```

When you select a scan stage, the system shows a table with vulnerabilities and a **Triage Status** column where you can see the latest status stored for each vulnerability.



The triage panel enables you to select a status, justification, and resolutions from a set of options, and has a text box to add extra details for the analysis. After you submit this information, the status is updated on the table and the latest analysis is visible the next time you open the panel.

Needs triage is the default status for all vulnerabilities. After you submit an analysis, the status changes and the information button next to the status shows you the stored vulnerability analysis.

Support for CRDs

Tanzu Developer Portal v1.7.0 and later introduced support for CRDs. The following example illustrates the creation of a basic custom resource definition (CRD), which is used as part of a supply chain and its visualization in the workload:

To define and use a CRD in a supply chain:

1. Define the CRD.
2. Set CRD permissions.
3. Define the supply chain.
4. Define the `ClusterTemplate`.
5. Create the workload.
6. Visualize the workload.

Define the CRD

To define a CRD:

1. Create a new YAML file with the name `NAME-crd.yaml`. For example, `rockets-crd.yaml`.
2. Add the following basic structure to the YAML file:

   ```
   apiVersion: apiextensions.k8s.io/v1
   kind: CustomResourceDefinition
   metadata:
    name: ...
   spec: ...
   ```

   At its most basic, a CRD must have `apiVersion`, `kind`, `metadata`, and `spec`.

   The `apiVersion` for a CRD must always be `apiextensions.k8s.io/v1` and the `kind` must be `CustomResourceDefinition`.

3. Add values for `group` and `name`. The value for `group` is usually expressed in a domain URL format, such as `company.com`, and the `name` value can be anything.

The following example uses `spaceagency.com` for the `group` and `rockets` for the `name`.

```
apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
metadata:
  name: rockets.spaceagency.com
spec:
  group: spaceagency.com
  scope: Namespaced
  names:
    plural: rockets
    singular: rocket
    kind: Rocket
    shortNames:
      - roc
```

Ensure that the name used in `metadata.name` follows the format `PLURAL-NAME.GROUP`. In this example it is `rockets.spaceagency.com`.

4. Add properties in the `spec` section under a list called `versions`. Make each version an object with a `name` and a `schema` for the version, so that the CRD looks like the following example:

```
apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
metadata: ...
spec:
  ...
  versions:
  - name: v1
    served: true
    storage: true
    schema:
      openAPIV3Schema:
        type: object
        properties:
          spec:
            type: object
            properties:
              type:
                type: string
              fuel:
                type: string
              payloadCapacity:
                type: string
```

The `versions` property also has mandatory `served` and `storage` properties. For more information about `served` and `storage`, and CRDs in general, see the Kubernetes documentation.

For this example the `schema` is an `openAPIV3Schema` object. For more information, see the OpenAPI Specification in GitHub.

The `openAPIV3Schema` object lists the attributes that the instances will have and their types. In this example there are 3 attributes (`type`, `fuel`, and `payloadCapacity`), and all of them are strings.

5. Verify that your CRD looks like this finished example:

```
apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
metadata:
  name: rockets.spaceagency.com
spec:
  group: spaceagency.com
```

```
  scope: Namespaced
  names:
    plural: rockets
    singular: rocket
    kind: Rocket
    shortNames:
      - roc
  versions:
  - name: v1
    served: true
    storage: true
    schema:
      openAPIV3Schema:
        type: object
        properties:
          spec:
            type: object
            properties:
              type:
                type: string
              fuel:
                type: string
              payloadCapacity:
                type: string
```

(Optional) Add custom data to display in the SCC UI

You can display custom data in the SCC plug-in UI by using the Printer Column feature. For more information, see the Kubernetes documentation.

Note

You must have a service account with permissions to view the CRD, which is where printer column data is maintained. When using a service account without this permission, you don't see any printer column data and you don't see any warning that the data is missing.

A printer column is a list that is specified as part of a `version` object. Each list item specifies the following for printing:

- A column name
- The type of the value
- A JSON path, relative to the CRD itself, that shows where to get the value

The following example has 3 printer columns for displaying the `.spec.type`, `.spec.fuel`, and `.spec.payloadCapacity` attributes:

```
apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
metadata:
  name: rockets.spaceagency.com
spec:
  group: spaceagency.com
  scope: Namespaced
  names:
    plural: rockets
    singular: rocket
    kind: Rocket
    shortNames:
      - roc
```

```
versions:
- name: v1
  served: true
  storage: true
  schema:
    openAPIV3Schema:
      type: object
      properties:
        spec:
          type: object
          properties:
            type:
              type: string
            fuel:
              type: string
            payloadCapacity:
              type: string
  additionalPrinterColumns:
  - name: Type
    type: string
    jsonPath: .spec.type
  - name: Fuel
    type: string
    jsonPath: .spec.fuel
  - name: Payload Capacity
    type: string
    jsonPath: .spec.payloadCapacity
```

Set resource permissions

To use resources in a supply chain, set resource permissions:

1. Create a new YAML file named `permissions.yaml`.
2. Add a `Role` to define which actions (`verbs`) are allowed on this resource:

   ```
   apiVersion: rbac.authorization.k8s.io/v1
   kind: Role
   metadata:
     namespace: NAMESPACE
     name: NAME
   rules:
   - apiGroups: ["API-GROUPS"]
     resources: ["RESOURCES-NAME"]
     verbs:
     - get
     - list
     - watch
     - create
     - patch
     - update
     - delete
     - deletecollection
   ```

   Where:

   - `NAMESPACE` is the namespace in which the rules apply. For example, `my-apps`.
   - `NAME` is the name for the role. For example, `rocket-reader`.
   - `API-GROUPS` is the name of the groups. For example, `spaceagency.com` or `apiextensions.k8s.io/v1`.
   - `RESOURCES-NAME` is the name of the resources. For example, `rockets` or `customresourcedefinitions`.

3. Add a `RoleBinding` to bind this new `Role` to the `serviceAccount` that you typically use:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: BINDING-NAME
  namespace: NAMESPACE
subjects:
- kind: ServiceAccount
  name: default
  namespace: my-apps
roleRef:
  kind: Role
  name: ROLE-REFERENCE-NAME
  apiGroup: rbac.authorization.k8s.io
```

Where:

- `BINDING-NAME` is the binding name. For example, `rocket-reader-binding`.
- `NAMESPACE` is the namespace. For example, `my-apps`.
- `ROLE-REFERENCE-NAME` is the role reference name. For example, `rocket-reader`.

In this binding you associate the `default` service account that you use with the new role you created. The two definitions together look like this example:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: Role
metadata:
  namespace: my-apps
  name: rocket-reader
rules:
- apiGroups: ["spaceagency.com"]
  resources: ["rockets"]
  verbs:
  - get
  - list
  - watch
  - create
  - patch
  - update
  - delete
  - deletecollection
---
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: rocket-reader-binding
  namespace: my-apps
subjects:
- kind: ServiceAccount
  name: default
  namespace: my-apps
roleRef:
  kind: Role
  name: rocket-reader
  apiGroup: rbac.authorization.k8s.io
```

Important

If you defined `additionalPrinterColumns` in your CRD, you must grant permissions for both the group you defined in the CRD and to the

`apiextensions.k8s.io/v1` group that contains the definition of your resource.

The finished definitions look like the following example:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: Role
metadata:
  namespace: my-apps
  name: rocket-reader
rules:
- apiGroups: ["spaceagency.com", "apiextensions.k8s.io/v1"]
  resources: ["rockets", "customresourcedefinitions"]
  verbs:
  - get
  - list
  - watch
  - create
  - patch
  - update
  - delete
  - deletecollection
---
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: rocket-reader-binding
  namespace: my-apps
subjects:
- kind: ServiceAccount
  name: default
  namespace: my-apps
roleRef:
  kind: Role
  name: rocket-reader
  apiGroup: rbac.authorization.k8s.io
```

Define the supply chain

Now that you have a CRD and the permissions for it, you can define a supply chain that uses this CRD as one of its resources.

The following example is a simple supply chain that has only one stage that uses an instance of the CRD. You can create the supply chain by downloading another supply chain and editing it.

1. List the existing supply chains in your cluster by running:

   ```
   kubectl get ClusterSupplyChain -n NAMESPACE
   ```

   Where `NAMESPACE` is your namespace. For example, `my-apps`.

2. Download one of them to a file by running:

   ```
   kubectl get ClusterSupplyChain SUPPLY-CHAIN -n NAMESPACE -oyaml >> ~/supply-cha
   in.yaml
   ```

   Where:

   - `SUPPLY-CHAIN` is the name a supply chain you discovered earlier.
   - `NAMESPACE` is your namespace.

   For example:

```
$ kubectl get ClusterSupplyChain source-test-scan-to-url -n my-apps -oyaml >>
~/supply-chain.yaml
```

3. Edit the downloaded supply-chain definition as follows:

```
apiVersion: carto.run/v1alpha1
kind: ClusterSupplyChain
metadata:
  name: SUPPLY-CHAIN-NAME
spec:
  resources:
  - name: RESOURCES-NAME
    templateRef:
      kind: ClusterTemplate
      name: TEMPLATE-REFERENCE-NAME
  selector:
    apps.tanzu.vmware.com/LABEL: "true"
  selectorMatchExpressions:
  - key: apps.tanzu.vmware.com/workload-type
    operator: In
    values:
    - web
    - server
    - worker
```

Where:

- `SUPPLY-CHAIN-NAME` is the supply-chain name. For example, `source-scan-test-scan-to-url-rockets`.
- `RESOURCES-NAME` is the resources name. For example, `rocket-provider`.
- `TEMPLATE-REFERENCE-NAME` is the template reference name. For example, `rocket-source-template`.
- `apps.tanzu.vmware.com/LABEL:` is a label that must be present, when creating the workload, to use this supply chain. For example, `apps.tanzu.vmware.com/has-rockets: "true"`.

`apiVersion` and `kind` stay the same. `metadata.name` is created for this new supply chain.

The `spec.selector` field states which label selector is used to select this supply chain when creating a workload.

4. Save the supply-chain YAML file as `NAME-supply-chain.yaml`. For example, `rocket-supply-chain.yaml`.

Define the ClusterTemplate

In this procedure you define, for the `resources` field, a single resource that uses an instance of your CRD.

This example supply chain has just a single resource (stage), which is named `rocket-provider`. The supply chain uses a `templateRef`, of the kind `ClusterTemplate`, which is named `rocket-source-template`.

At its most basic, a supply chain's resource is an object consisting of a `name` and a `templateRef` pointing to an existing `ClusterTemplate`.

To define a new `ClusterTemplate`:

1. List existing `ClusterTemplate` resources by running:

```
kubectl get ClusterTemplates -n NAMESPACE
```

Where `NAMESPACE` is your namespace

2. Download a `ClusterTemplate` resource that you found by running:

```
kubectl get ClusterTemplates TEMPLATE-NAME -n NAMESPACE -oyaml >> ~/cluster-tem
plate.yaml
```

Where:

- `TEMPLATE-NAME` is the name of the `ClusterTemplate` resource you found. For example, `config-writer-template`.
- `NAMESPACE` is your namespace. For example, `my-apps`.

For example:

```
$ kubectl get ClusterTemplates config-writer-template -n my-apps -oyaml >> ~/cl
uster-template.yaml
```

3. Verify that the file, when cleaned up, looks similar to the following:

```
apiVersion: carto.run/v1alpha1
kind: ClusterTemplate
metadata:
  name: rocket-source-template
spec:
  lifecycle: mutable
  ytt: |
    #@ load("@ytt:data", "data")

    #@ def merge_labels(fixed_values):
    #@   labels = {}
    #@   if hasattr(data.values.workload.metadata, "labels"):
    #@     exclusions = ["kapp.k14s.io/app", "kapp.k14s.io/association"]
    #@     for k,v in dict(data.values.workload.metadata.labels).items():
    #@       if k not in exclusions:
    #@         labels[k] = v
    #@       end
    #@     end
    #@   end
    #@   labels.update(fixed_values)
    #@   return labels
    #@ end

    ---
    apiVersion: spaceagency.com/v1
    kind: Rocket
    metadata:
      name: falcon9
      labels: #@ merge_labels({ "app.kubernetes.io/component": "rocket" })
    spec:
      type: Falcon 9
      fuel: RP-1/LOX
      payloadCapacity: 22000 kg
```

`metadata.name` matches the name specified in the supply-chain resource.

An instance of the new CRD is used in the `spec` of this resource through the `ytt` field. ytt is a templating language that can output resource instances.

A function is retained that takes in labels from the workload and propagates them to the resource. This function is not essential, but is usually performed to propagate important labels from the workload down to the individual resources.

4. Save the file as `NAME-cluster-template.yaml`. For example, `rocket-cluster-template.yaml`.

You have now completed all the necessary definitions to create a workload that uses this new supply chain and the new CRD.

Create the workload

Now that you have all of the resources, apply them to a cluster and then create a workload:

1. Apply your CRD by running:

   ```
   kubectl apply -f rockets-crd.yaml
   ```

2. Apply the resource permissions by running:

   ```
   kubectl apply -f permissions.yaml
   ```

3. Apply the cluster template by running:

   ```
   kubectl apply -f rocket-cluster-template.yaml
   ```

4. Apply the supply chain by running:

   ```
   kubectl apply -f rocket-supply-chain.yaml
   ```

   The cluster now has all the necessary resource definitions to create a workload by using the new supply chain, which, in turn, uses an instance of the new resource.

5. Create the workload by running:

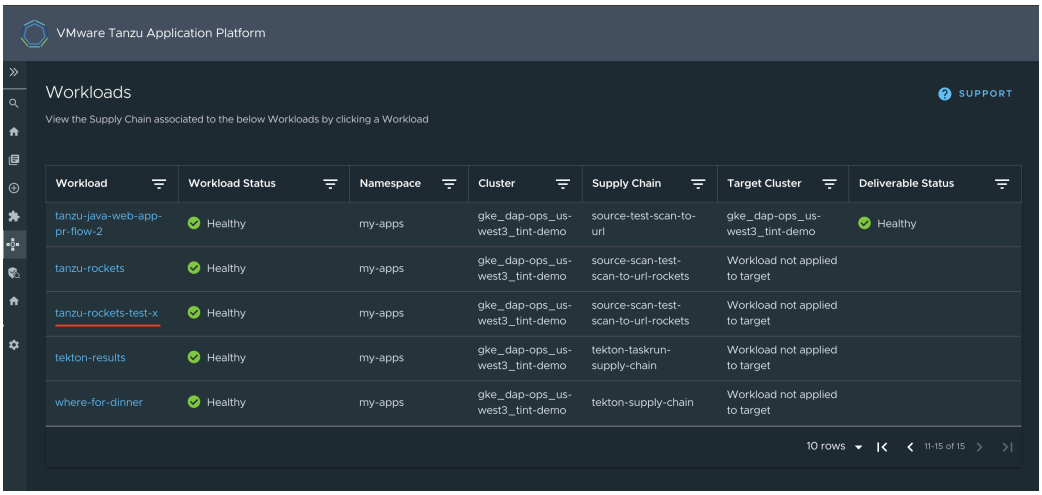
   ```
   tanzu apps workload create tanzu-rockets-test-x \
   --type web \
   --label app.kubernetes.io/part-of=tanzu-rockets \
   --label apps.tanzu.vmware.com/has-rockets=true \
   --yes \
   --namespace my-apps
   ```

   The label `apps.tanzu.vmware.com/has-rockets=true` is explicitly set. The `selector` property, specified when defining the new supply chain, ties the new supply chain with this particular workload.

Visualize the workload

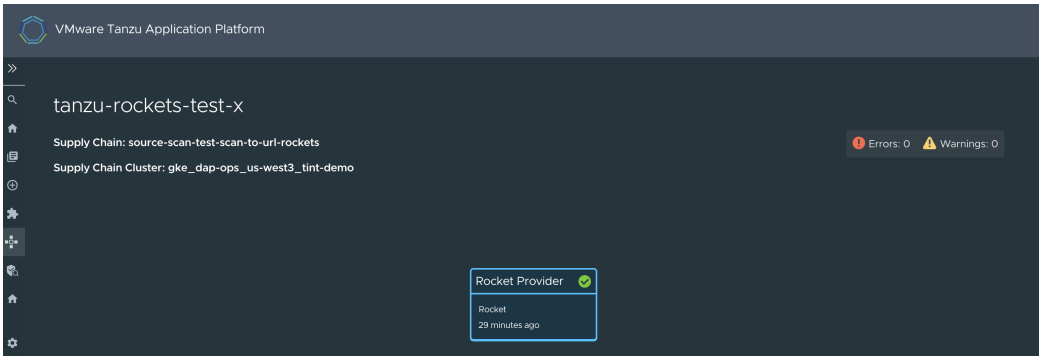
To see the workload rendered through the Supply Chain plug-in:

1. Go to the supply chain plug-in section in Tanzu Developer Portal and locate the workload among the listed ones:

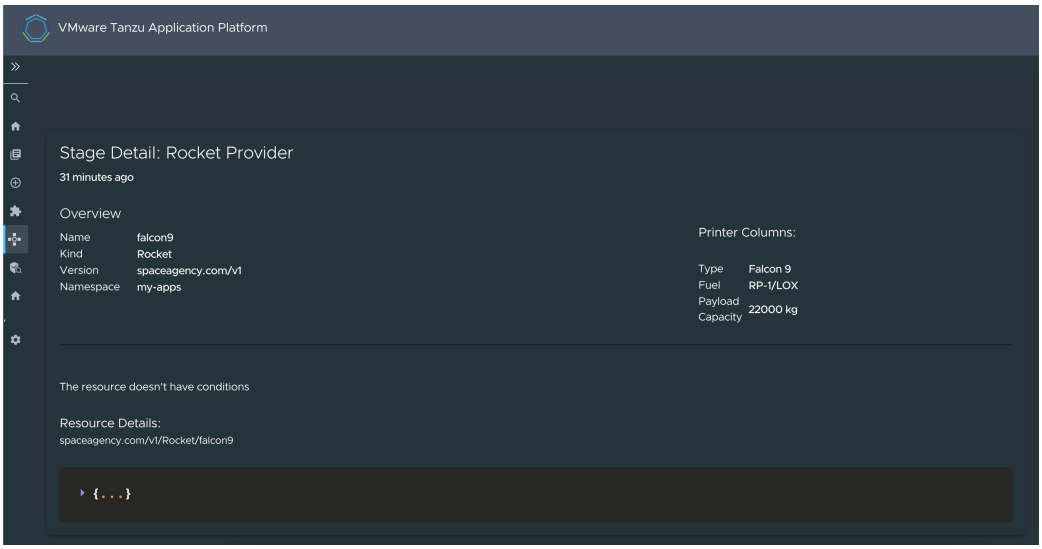


The workload `tanzu-rockets-x` is **Healthy**. The **Supply Chain** column shows that it is using the `source-scan-test-scan-to-url-rockets` supply chain.

2. Click on it to see its details. The **Workload** graph appears. Given that the supply chain `source-scan-test-scan-to-url-rockets` only specified one `resource`, you see a simple single-stage graph.

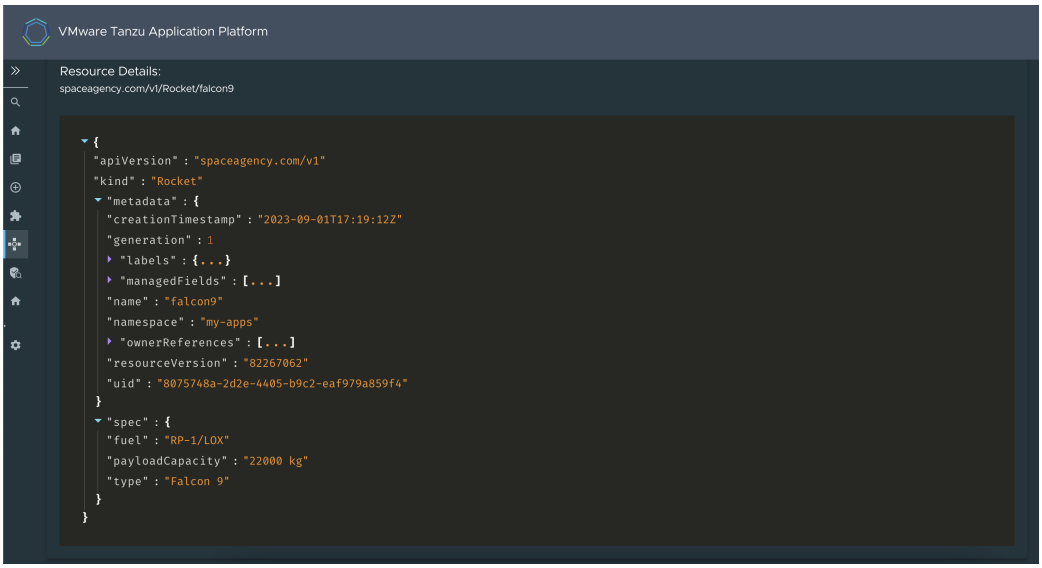


3. Scroll down the screen to see the details associated with the stage.



The printer columns that you defined in the CRD are now rendered in the **Overview** section. This happens with any CRD that you define and that includes the `additionalPrinterColumns` definition.

4. Go to the end of the section to see the full resource in JSON format.



Overview of validated plug-ins for Tanzu Developer Portal

Validated plug-ins are Backstage plug-ins or community plug-ins that VMware has validated for use with Tanzu Developer Portal. You don't need to create custom wrappers to integrate these plug-ins with Tanzu Developer Portal.

Validated plug-ins are listed in the side navigation pane.

Overview of validated plug-ins for Tanzu Developer Portal

Validated plug-ins are Backstage plug-ins or community plug-ins that VMware has validated for use with Tanzu Developer Portal. You don't need to create custom wrappers to integrate these plug-ins with Tanzu Developer Portal.

Validated plug-ins are listed in the side navigation pane.

GitHub Actions in Tanzu Developer Portal

This topic tells you about the GitHub Actions validated front-end plug-in.

The GitHub Actions front-end plug-in visualizes your GitHub Actions integrations. For more information, see the GitHub Actions Backstage documentation.

Add and configure the plug-in

To add the plug-in to your customized Tanzu Developer Portal and configure the plug-in, see the following sections.

Add the plug-in

To add the plug-in to your customized Tanzu Developer Portal, add the front-end plug-in to your `tdp-config.yaml` file:

```
app:
  plugins:
    ...
    - name: '@vmware-tanzu/tdp-plugin-github-actions'
      version: 'VERSION'
    ...
```

Where `VERSION` is the latest version. For example, `^0.0.2`.

Configure the plug-in

To configure the plug-in, update the `app_config` section of your `tap-values.yaml` file to include a GitHub integration. For example:

```
tap_gui:
  # ... existing configuration
  app_config:
    # ... existing configuration
    integrations:
      github:
        - host: 'GITHUB-HOST.com'
          apiBaseUrl: 'https://api.GITHUB-HOST.com'
```

Where `GITHUB-HOST` is your GitHub domain

Grafana in Tanzu Developer Portal

This topic tells you about the Grafana validated front-end plug-in.

The Grafana front-end plug-in visualizes Grafana information in a component **Overview** tab. For more information, see the Grafana plug-in documentation.

Add and configure the plug-in

To add the plug-in to your customized Tanzu Developer Portal and configure the plug-in, see the following sections.

Add the plug-in

To add the plug-in to your custom Tanzu Developer Portal, add the front-end plug-in to your `tdp-config.yaml` file:

```
app:
  plugins:
    ...
    - name: '@vmware-tanzu/tdp-plugin-backstage-grafana'
      version: 'VERSION'
    ...
```

Where `VERSION` is the latest version. For example, `^0.0.2`.

Configure the plug-in

To configure the plug-in, update the `app_config` section of your `tap-values.yaml` file to include a `proxy` entry and `grafana` configuration. For example:

```
tap_gui:
  # ... existing configuration
  app_config:
    # ... existing configuration
    proxy:
      # ... existing configuration
      '/grafana/api':
        # May be a public or an internal DNS
        target: https://test.grafana.net/
        headers:
          Authorization: 'Bearer ${GRAFANA-TOKEN}'
```

```
    grafana:
      # Publicly accessible domain
      domain: https://test.grafana.net/
      # Is unified alerting enabled in Grafana?
      # See: https://grafana.com/blog/2021/06/14/the-new-unified-alerting-system-for-g
rafana-everything-you-need-to-know/
      # Optional. Default: false
      unifiedAlerting: true
```

Where `GRAFANA-TOKEN` is a valid token for your Grafana instance.

Add the annotations entry for Grafana to the catalog entity to display the Grafana alerts and dashboard lists on the component **Overview** tab.

```
apiVersion: backstage.io/v1alpha1
kind: Component
metadata:
  name: grafana-example
  description: An example for Grafana integration.
  annotations:
    grafana/dashboard-selector: 'general'
    grafana/alert-label-selector: 'type=http-requests'
```

Home in Tanzu Developer Portal

This topic tells you about the Home front-end plug-in.

The Home front-end plug-in makes it possible to create a custom home page for your Tanzu Developer Portal to conveniently surface important information. For more information, see the Home plug-in documentation.

Add and configure the plug-in

To add the plug-in to your customized Tanzu Developer Portal and configure the plug-in, see the following sections.

Add the plug-in

To add the plug-in to your customized Tanzu Developer Portal, add the front-end plug-in to your `tdp-config.yaml` file:

```
app:
  plugins:
    ...
    - name: '@vmware-tanzu/tdp-plugin-home'
      version: 'VERSION'
    ...
```

Where `VERSION` is the latest version. For example, `^0.0.2`.

Configure the plug-in

To configure the plug-in, update the `app_config` section of your `tap-values.yaml` file. All of the values are optional. For example:

```
tap_gui:
  # ... existing configuration
  app_config:
```

```
    # ... existing configuration
    customize:
      # ... existing configuration
      features:
        # ... existing configuration
        home:
          # Activate or deactivate the plugin? Default: true
          enabled: true
          # Show or hide the sidebar entry. Default: true
          showInSidebar: true
          # base64 encoded SVG image.
          logo: 'BASE64-ENCODED-LOGO-STRING'
          welcomeMessage: string
          quickLinks:
            url: string
            label: string
            # base64 encoded SVG image.
            icon: 'BASE64-ENCODED-ICON-STRING'
```

Where `BASE64-ENCODED-LOGO-STRING` and `BASE64-ENCODED-ICON-STRING` are Base64-encoded SVG files.

Jira in Tanzu Developer Portal

This topic tells you about the Jira validated front-end plug-in.

The Jira front-end plug-in visualizes your JIRA activity stream in a component **Overview** tab. For more information, see the Jira plug-in documentation.

Add and configure the plug-in

To add the plug-in to your customized Tanzu Developer Portal and configure the plug-in, see the following sections.

Add the plug-in

To add the plug-in to your customized Tanzu Developer Portal, add the front-end plug-in to your `tdp-config.yaml` file:

```
app:
  plugins:
    ...
    - name: '@vmware-tanzu/tdp-plugin-backstage-jira'
      version: 'VERSION'
    ...
```

Where `VERSION` is the latest version. For example, `^0.0.2`.

Configure the plug-in

To configure the Jira plug-in, update the `app_config` section of your `tap-values.yaml` file to include a proxy entry. For example:

```
tap_gui:
  # ... existing configuration
  app_config:
    # ... existing configuration
    proxy:
      # ... existing configuration
      '/jira/api':
```

```
        target: JIRA-URL
        headers:
          Authorization:
            $env: JIRA-TOKEN
          Accept: 'application/json'
          Content-Type: 'application/json'
          X-Atlassian-Token: 'no-check'
          # This is a workaround since Jira APIs reject browser origin requests.
          # Any dummy string without whitespace works.
          User-Agent: 'AnyRandomString'
```

Where:

- `JIRA-URL` is the URL for your Jira instance
- `JIRA-TOKEN` is a valid token for your Jira instance

Add the `annotations` entry for Jira to the catalog entity to display the Jira project results on the component overview tab.

Catalog

```
apiVersion: backstage.io/v1alpha1
kind: Component
metadata:
  name: jira-overview-card
  annotations:
    jira/project-key: YOUR_PROJECT_KEY
```

Prometheus in Tanzu Developer Portal

This topic tells you about the Prometheus front-end plug-in.

The Prometheus front-end plug-in displays Prometheus information in your Tanzu Developer Portal. For more information, see the Prometheus plug-in documentation.

Add and configure the plug-in

To add the plug-in to your customized Tanzu Developer Portal and configure the plug-in, see the following sections.

Add the plug-in

To add the plug-in to your customized Tanzu Developer Portal, add the front-end plug-in to your `tdp-config.yaml` file:

```
app:
  plugins:
    ...
    - name: '@vmware-tanzu/tdp-plugin-prometheus'
      version: 'VERSION'
    ...
```

Where `VERSION` is the latest version. For example, `^0.0.2`.

Configure the plug-in

To configure the Prometheus plug-in, update the `app_config` section of your `tap-values.yaml` file to include a `proxy` entry and `prometheus` configuration. For example:

```
tap_gui:
  # ... existing configuration
  app_config:
    # ... existing configuration
    proxy:
      # ... existing configuration
      '/prometheus/api':
        # url to the api and path of your hosted prometheus instance
        target: http://localhost:9090/api/v1/
        changeOrigin: true
        secure: false
        headers:
          Authorization: AUTH-TOKEN

    # Defaults to /prometheus/api and can be omitted if proxy is configured for that u
rl
    prometheus:
      proxyPath: /prometheus/api
      uiUrl: http://localhost:9090
```

Where `PROMETHEUS-AUTH-TOKEN` is a valid token for your secure `prometheus` instance

Snyk in Tanzu Developer Portal

This topic tells you about the Snyk front-end plug-in.

The Snyk front-end plug-in displays security vulnerabilities from snyk.io.

The plug-in shows an overview of the vulnerabilities found by Snyk on the **Overview** tab of an entity. The plug-in also adds a tab to the entity view, which shows all details related to the scan. For more information, see the Snyk Backstage documentation.

Add the plug-in

To add the plug-in to your customized Tanzu Developer Portal, add the front-end plug-in to your `tdp-config.yaml` file:

```
app:
  plugins:
    ...
    - name: '@vmware-tanzu/tdp-plugin-snyk'
      version: 'VERSION'
    ...
```

Where `VERSION` is the latest version. For example, `^0.0.2`.

SonarQube in Tanzu Developer Portal

This topic tells you about the SonarQube validated front-end and back-end plug-ins.

The SonarQube front-end plug-in displays static analysis code quality statistics. For more information, see the SonarQube Backstage documentation.

Add and configure the plug-in

To add the plug-in to your customized Tanzu Developer Portal and configure the plug-in, see the following sections.

Add the plug-in

To add the plug-in to your customized Tanzu Developer Portal, add the front-end and back-end plug-ins to your `tdp-config.yaml` file:

```
app:
  plugins:
    ...
    - name: '@vmware-tanzu/tdp-plugin-backstage-sonarqube'
      version: 'VERSION'
    ...
backend:
  plugins:
    ...
    - name: '@vmware-tanzu/tdp-plugin-backstage-sonarqube-backend'
      version: 'VERSION'
    ...
```

Where `VERSION` is the latest version for each plug-in. For example, `^0.0.2` and `^0.0.3`.

Configure the plug-in

To connect your SonarQube plug-in to a running instance, update the `app_config` section of your `tap-values.yaml` file. For example:

```
tap_gui:
  # ... existing configuration
  app_config:
    # ... existing configuration
    sonarqube:
      baseUrl: 'SONARQUBE-URL'
      apiKey: 'SONARQUBE-API-KEY'
```

Where:

- `SONARQUBE-URL` is the URL of your SonarQube instance
- `SONARQUBE-API-KEY` is a valid API key for connecting to the SonarQube instance

Add the `annotations` entry for SonarQube to the catalog entity to display the SonarQube project results on the component overview tab.

```
apiVersion: backstage.io/v1alpha1
kind: Component
metadata:
  name: backstage
  annotations:
    sonarqube.org/project-key: YOUR_INSTANCE_NAME/YOUR_PROJECT_KEY
```

For a more detailed explanation of SonarQube configuration, see SonarQube Backstage documentation.

Stack Overflow in Tanzu Developer Portal

This topic tells you about the Stack Overflow front-end plug-in.

The Stack Overflow front-end plug-in provides Stack Overflow functions in Tanzu Developer Portal. For more information, see the Backstage Stack Overflow documentation.

Add and configure the plug-in

To add the plug-in to your customized Tanzu Developer Portal and configure the plug-in, see the following sections.

Add the plug-in

To add the plug-in to your customized Tanzu Developer Portal, add the front-end plug-in to your `tdp-config.yaml` file:

```
app:
  plugins:
    ...
    - name: '@vmware-tanzu/tdp-plugin-stack-overflow'
      version: 'VERSION'
    ...
```

Where `VERSION` is the latest version. For example, `^0.0.2`.

Configure the plug-in

To configure your Stack Overflow plug-in, update the `app_config` section of your `tap-values.yaml` file. For example:

```
tap_gui:
  # ... existing configuration
  app_config:
    # ... existing configuration
    stackoverflow:
      baseUrl: https://api.stackexchange.com/2.2 # alternative: your internal stack ov
erflow instance
```

TechInsights in Tanzu Developer Portal

This topic tells you about the TechInsights front-end and back-end plug-ins.

The TechInsights front-end plug-in visualizes entity checks defined by the back-end plug-in. The TechInsights back-end plug-in performs entity checks and provides an API for the front-end plug-in. For more information about the TechInsights plug-in, see the Backstage TechInsights documentation.

Add the plug-in

To add the plug-in to your customized Tanzu Developer Portal, add the front-end and back-end plug-ins to your `tdp-config.yaml` file:

```
app:
  plugins:
    ...
    - name: '@vmware-tanzu/tdp-plugin-techinsights'
      version: 'VERSION'
    ...
backend:
  plugins:
    ...
    - name: '@vmware-tanzu/tdp-plugin-techinsights-backend'
      version: 'VERSION'
    ...
```

Where `VERSION` is the latest version for each plug-in. For example, `^0.0.2`.

Overview of enabling TLS for Tanzu Developer Portal

Many users want inbound traffic to Tanzu Developer Portal to be properly encrypted. These topics tell you how to enable TLS encryption either with an existing certificate or by using the included cert-manager instance.

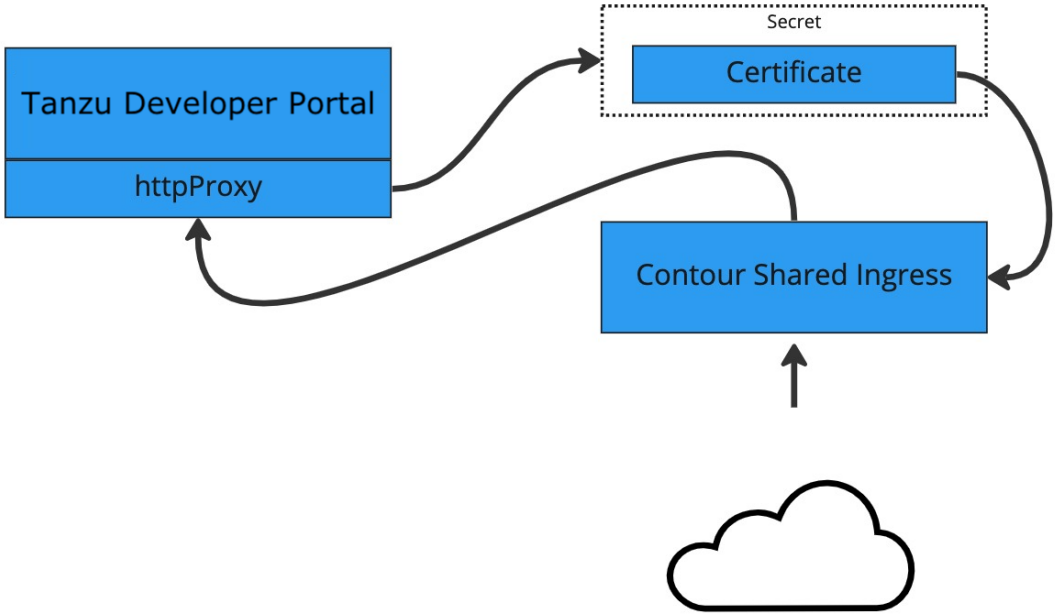
Concepts

The two key concepts are certificate delegation and the relationship between cert-manager, certificates, and ClusterIssuers.

Certificate delegation

Tanzu Developer Portal uses the established shared Contour ingress for TLS termination.

This enables you to store the certificate in a Kubernetes `secret` and then pass that `secret` and `namespace` to the `httpProxy` that was created during installation. To do this, see Configuring a TLS certificate by using an existing certificate.

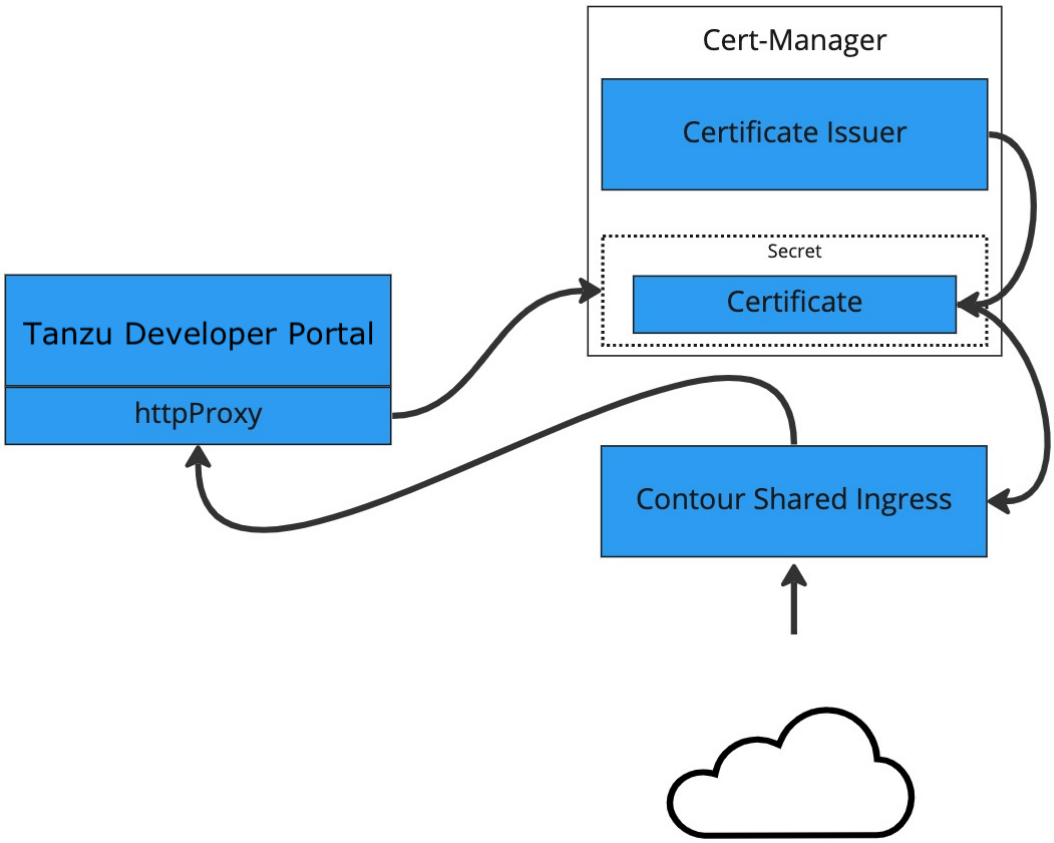


cert-manager, certificates, and ClusterIssuers

Tanzu Developer Portal can also use the `cert-manager` package that is installed when the profile was installed.

This tool allows cert-manager to automatically acquire a certificate from a `clusterIssuer` entity.

This external entity can be an external certificate authority, such as Let's Encrypt, or a self-signed certificate.



Guides

The following topics describe different ways to configure TLS:

- Configuring a TLS certificate by using an existing certificate
- Configuring a TLS certificate by using a self-signed certificate
- Configuring a TLS certificate by using cert-manager and a ClusterIssuer

Overview of enabling TLS for Tanzu Developer Portal

Many users want inbound traffic to Tanzu Developer Portal to be properly encrypted. These topics tell you how to enable TLS encryption either with an existing certificate or by using the included cert-manager instance.

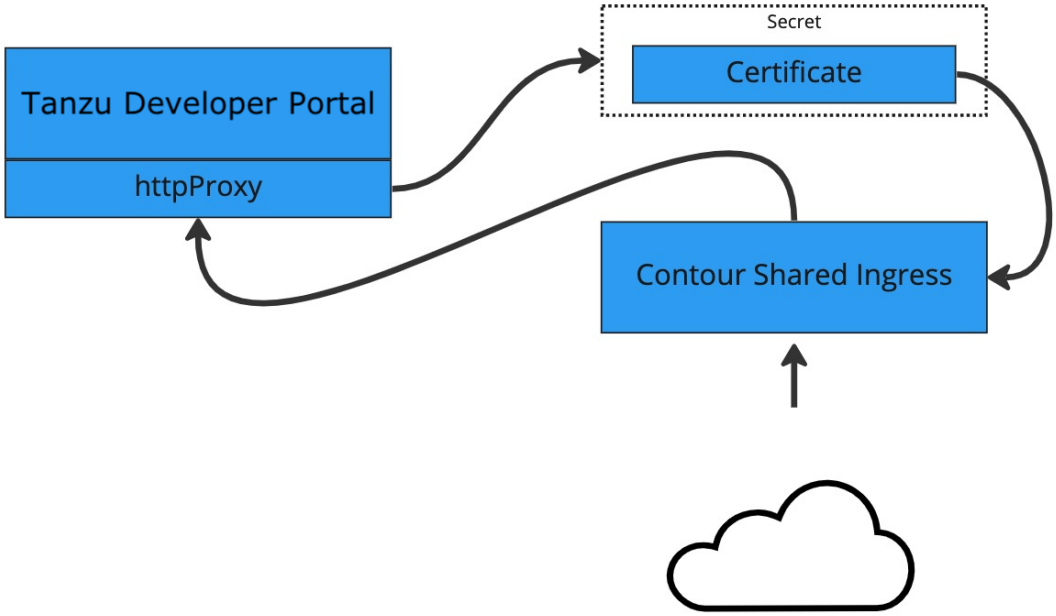
Concepts

The two key concepts are certificate delegation and the relationship between cert-manager, certificates, and ClusterIssuers.

Certificate delegation

Tanzu Developer Portal uses the established shared Contour ingress for TLS termination.

This enables you to store the certificate in a Kubernetes `secret` and then pass that `secret` and `namespace` to the `httpProxy` that was created during installation. To do this, see Configuring a TLS certificate by using an existing certificate.

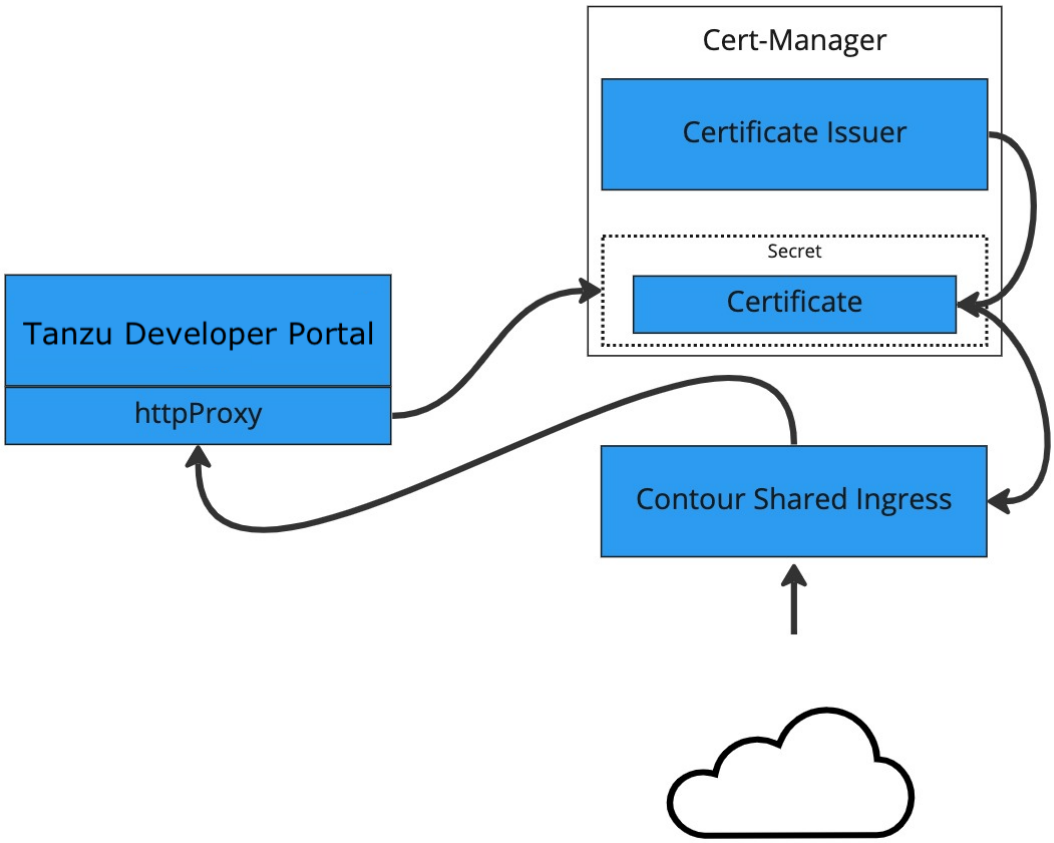


cert-manager, certificates, and ClusterIssuers

Tanzu Developer Portal can also use the `cert-manager` package that is installed when the profile was installed.

This tool allows cert-manager to automatically acquire a certificate from a `clusterIssuer` entity.

This external entity can be an external certificate authority, such as Let's Encrypt, or a self-signed certificate.



Guides

The following topics describe different ways to configure TLS:

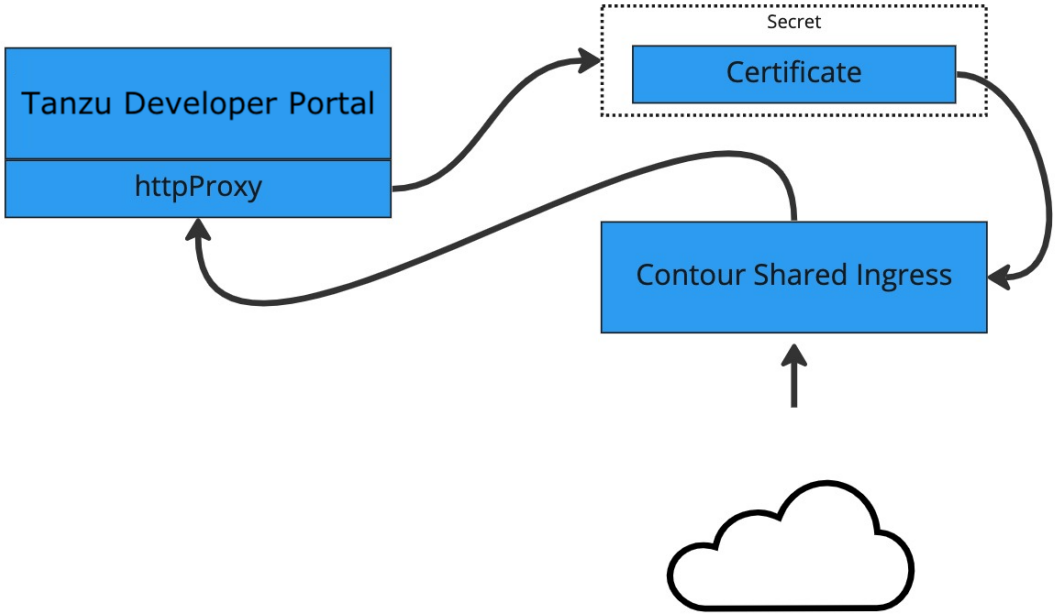
- Configuring a TLS certificate by using an existing certificate
- Configuring a TLS certificate by using a self-signed certificate
- Configuring a TLS certificate by using cert-manager and a ClusterIssuer

Configure a TLS certificate by using an existing certificate

This topic tells you how to use the certificate information from your external certificate authority to encrypt inbound traffic to Tanzu Developer Portal.

Prerequisites

Your certificate authority gave you a certificate file, of the form `CERTIFICATE-FILE-NAME.crt`, and a signing key, of the form `KEY-FILE-NAME.key`. Ensure that these files are present on the host from which you run the CLI commands.



Procedure

To configure Tanzu Developer Portal with an existing certificate:

1. Create the Kubernetes secret by running:

   ```
   kubectl create secret tls tap-gui-cert --key="KEY-FILE-NAME.key" --cert="CERTIF
   ICATE-FILE-NAME.crt" -n tap-gui
   ```

   Where:

   - `KEY-FILE-NAME` is the name of the `key` file that your certificate issuer gave you
   - `CERTIFICATE-FILE-NAME` is the name of the `crt` file that your certificate issuer gave you

2. Configure Tanzu Developer Portal to use the newly created secret. Do so by editing the `tap-values.yaml` file that you used during installation to include the following under the `tap-gui` section:

   - A top-level `tls` key with subkeys for `namespace` and `secretName`
   - A namespace referring to the namespace used earlier
   - A secret name referring to the `secretName` value defined earlier

   Example:

   ```
   tap_gui:
    tls:
      namespace: tap-gui
      secretName: tap-gui-cert
   # Additional configuration below this line as needed
   ```

3. Update the Tanzu Application Platform package with the new values in `tap-values.yaml` by running:

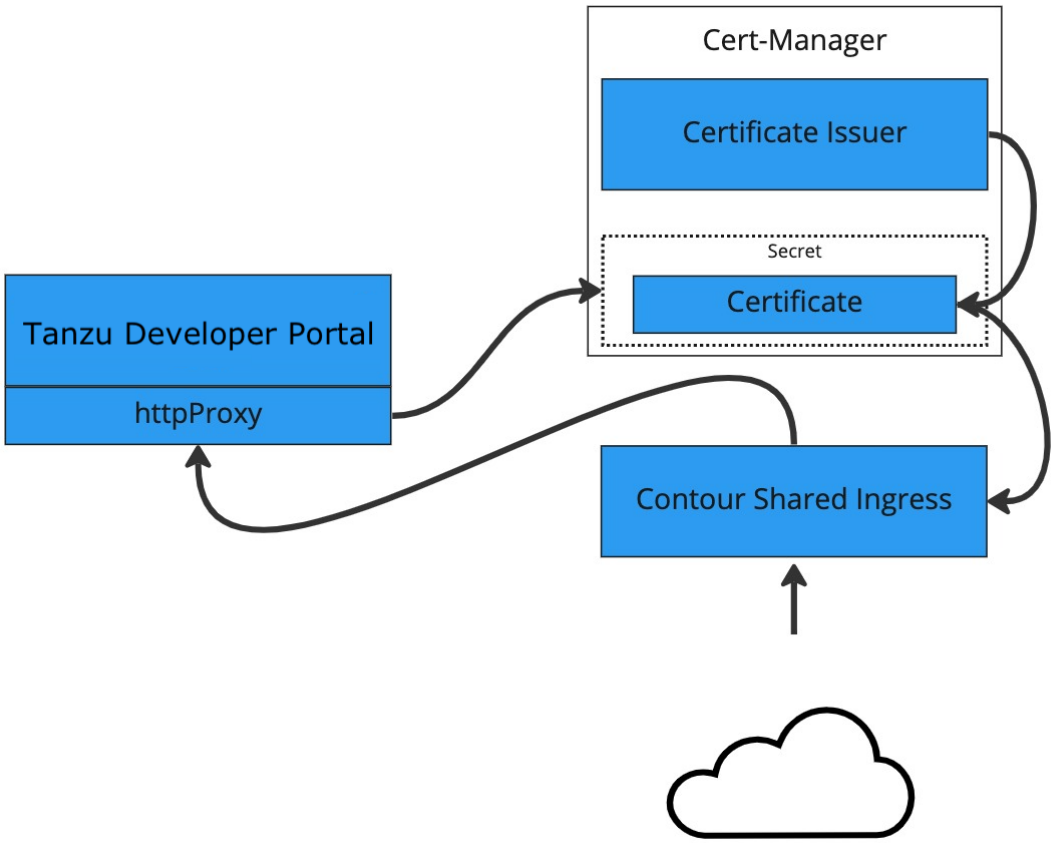
```
tanzu package installed update tap -p tap.tanzu.vmware.com -v TAP-VERSION  --va
lues-file tap-values.yaml -n tap-install
```

Where `TAP-VERSION` is the version number that matches the values you used when you installed your profile.

Configure a TLS certificate by using a self-signed certificate

This topic tells you how to use cert-manager to create a self-signed certificate issuer and then generate a certificate for Tanzu Developer Portal to use based on that issuer.

Some browsers and corporate policies do not allow you to visit webpages that have self-signed certificates. You might need to navigate through a series of error messages to visit the page.



Prerequisite

Install a Tanzu Application Platform profile that includes cert-manager. Verify you did this by running the following command to detect the cert-manager namespace:

```
kubectl get ns
```

Procedure

To configure a self-signed TLS certificate for Tanzu Developer Portal:

1. Create a `certificate.yaml` file that defines an issuer and a certificate. For example:

```
apiVersion: cert-manager.io/v1
kind: Issuer
```

```
metadata:
 name: ca-issuer
 namespace: tap-gui
spec:
 selfSigned: {}
---
apiVersion: cert-manager.io/v1
kind: Certificate
metadata:
 name: tap-gui-cert
 namespace: tap-gui
spec:
 secretName: tap-gui-cert
 dnsNames:
 - tap-gui.INGRESS-DOMAIN
 issuerRef:
   name: ca-issuer
```

Where `INGRESS-DOMAIN` is your domain value that matches the values you used when you installed the profile.

2. Add the issuer and certificate to your cluster by running:

```
kubectl apply -f certificate.yaml
```

3. Configure Tanzu Developer Portal to use the newly created certificate. Update the `tap-values.yaml` file used during installation to include the following under the `tap-gui` section:
    - A top-level `tls` key with subkeys for `namespace` and `secretName`
    - A namespace referring to the namespace containing the `Certificate` object mentioned earlier
    - A secret name referring to the `secretName` value defined in your `Certificate` resource earlier

    Example:

```
tap_gui:
 tls:
   namespace: tap-gui
   secretName: tap-gui-cert
# Additional configuration below this line as needed
```

4. Update the Tanzu Application Platform package with the new values in `tap-values.yaml`:

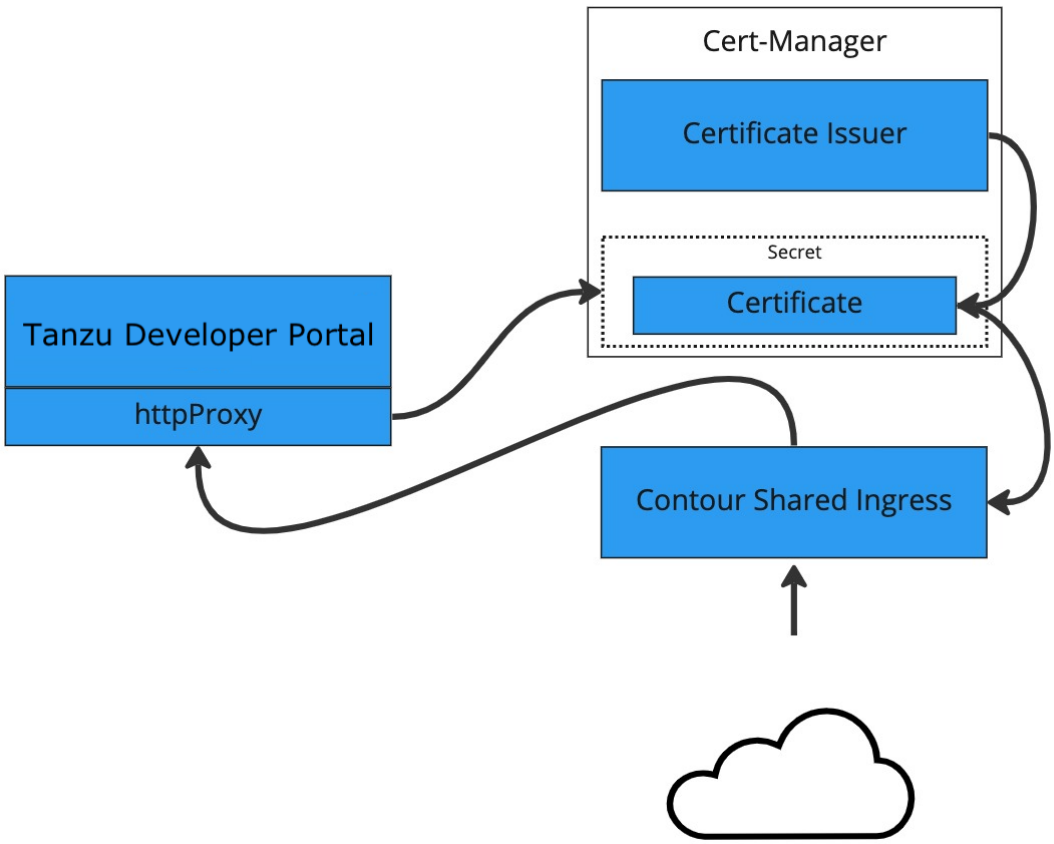
```
tanzu package installed update tap -p tap.tanzu.vmware.com -v TAP-VERSION  --va
lues-file tap-values.yaml -n tap-install
```

Where `TAP-VERSION` is the version that matches the values you used when you installed the profile.

Configure a TLS certificate by using cert-manager and a ClusterIssuer

This topic tells you how to use cert-manager to create a certificate issuer and then generate a certificate for Tanzu Developer Portal to use based on that issuer.

This topic uses the free certificate issuer Let's Encrypt. You can use other certificate issuers compatible with cert-manager in a similar fashion.



Prerequisites

Fulfil these prerequisites:

- Install a Tanzu Application Platform profile that includes cert-manager. Verify you did this by running the following command to detect the cert-manager namespace:

  ```
  kubectl get ns
  ```

- Obtain a domain name that you control or own and have proof that you control or own it. In most cases, this domain name is the one you used for the `INGRESS-DOMAIN` values when you installed Tanzu Application Platform and Tanzu Developer Portal.
- If cert-manager cannot perform the challenge to verify your domain's compatibility, you must do so manually. For more information, see How It Works and Getting Started in the Let's Encrypt documentation.
- Ensure that your domain name is pointed at the shared Contour ingress for the installation. Find the IP address by running:

  ```
  kubectl -n tanzu-system-ingress get services envoy -o jsonpath='{.status.loadBa
  lancer.ingress[0].ip}'
  ```

Procedure

To configure a self-signed TLS certificate for Tanzu Developer Portal:

1. Create a `certificate.yaml` file that defines an issuer and a certificate. For example:

```
apiVersion: cert-manager.io/v1
kind: ClusterIssuer
metadata:
  name: letsencrypt-http01-issuer
  namespace: cert-manager
spec:
  acme:
    server: https://acme-v02.api.letsencrypt.org/directory
    email: EMAIL-ADDRESS
    privateKeySecretRef:
      name: letsencrypt-http01-issuer
    solvers:
    - http01:
        ingress:
          class: contour
---
apiVersion: cert-manager.io/v1
kind: Certificate
metadata:
  namespace: cert-manager
  name: tap-gui
spec:
  commonName: tap-gui.INGRESS-DOMAIN
  dnsNames:
    - tap-gui.INGRESS-DOMAIN
  issuerRef:
    name: letsencrypt-http01-issuer
    kind: ClusterIssuer
  secretName: tap-gui
```

Where:

- `EMAIL-ADDRESS` is the email address that Let's Encrypt shows as responsible for this certificate
- `INGRESS-DOMAIN` is your domain value that matches the values you used when you installed the profile

2. Add the issuer and certificate to your cluster by running:

```
kubectl apply -f certificate.yaml
```

By applying the certificate, cert-manager attempts to perform an HTTP01 challenge by creating an Ingress resource specifically for the challenge. This is automatically removed from your cluster after the challenge is completed. For more information about how this works, and when it might not, see the cert-manager documentation.

3. Validate the certificate was created and is ready by running:

```
kubectl get certs -n cert-manager
```

Wait a few moments for this to take place, if need be.

4. Configure Tanzu Developer Portal to use the newly created certificate. To do so, update the `tap-values.yaml` file that you used during installation to include the following items under the `tap-gui` section:

   - A top-level `tls` key with subkeys for `namespace` and `secretName`
   - A namespace referring to the namespace containing the `Certificate` object from earlier
   - A secret name referring to the `secretName` value defined in your `Certificate` resource earlier

Example:

```
tap_gui:
 tls:
   namespace: cert-manager
   secretName: tap-gui
# Additional configuration below this line as needed
```

5. Update the Tanzu Application Platform package with the new values in `tap-values.yaml` by running:

   ```
   tanzu package installed update tap -p tap.tanzu.vmware.com -v TAP-VERSION  --va
   lues-file tap-values.yaml -n tap-install
   ```

   Where `TAP-VERSION` is the version that matches the values you used when you installed the profile.

Configure a corporate HTTP or HTTPS proxy

You can configure Tanzu Developer Portal to route its traffic through a specified HTTP or HTTPS proxy. This includes all outgoing requests that Backstage or Tanzu Developer Portal makes. This topic shows you how to configure proxy settings through the values file.

Proxy variables

Tanzu Developer Portal uses two optional variables to support HTTP and HTTPS proxy configuration:

- `HTTP_PROXY` is a host or IP address of a server that is a proxy. All outgoing requests, whether they are HTTP or HTTPS, are sent to this proxy instead of their intended destination. This value must include the proxy name or IP address and the port.
- `NO_PROXY` is a comma-separated list of hosts or IP addresses. When both this variable and `HTTP_PROXY` is set, traffic is directed through `HTTP_PROXY` unless it matches the host (or IP address) of one of the entries in this list.

If any plug-ins need access to resources that can only be accessed through a proxy then you add the `HTTP_PROXY` value. For resources that are reachable without going through the proxy server, their domains are listed in the `NO_PROXY` variable.

Define the proxy server

To define the proxy server in `tap-values.yaml` in a Tanzu Application Platform installation, add the following example section and edit it as needed:

```
tap_gui:
  HTTP_PROXY: http://foo:bar@127.0.0.1:8888
  NO_PROXY: 'bar.com,baz.com'
```

`NO_PROXY` default values

Tanzu Developer Portal applies default values for `NO_PROXY` to its Kubernetes manifests. These default values are implemented any time you use the `HTTP_PROXY` variable, even when you have not specified `NO_PROXY`. When you do specify a value for `NO_PROXY`, your input is prepended to the default values with a comma.

`tap-values.yaml` snippet example:

```
tap_gui:
  HTTP_PROXY: http://foo:bar@127.0.0.1:8888
  NO_PROXY: 'bar.com,baz.com'
```

Command output example:

```
$ kubectl -n tap-gui get deployment server -o jsonpath="{.spec.template.spec.container
s[0].env[?(@.name=='NO_PROXY')].value}"
bar.com,baz.com,.local,.local.,localhost,.metadata-store,.accelerator-system,$(KUBERNE
TES_SERVICE_HOST)
```

The list of default values is as follows and only affects requests within the cluster:

```
.local,.local.,localhost,.metadata-store,.accelerator-system,$(KUBERNETES_SERVICE_HOS
T)
```

See which values are in use on your installation

To see which values are in use on your installation, run:

```
kubectl -n tap-gui get deployment server -o jsonpath="{.spec.template.spec.containers
[0].env[?(@.name=='NO_PROXY')].value}"
```

Override the default values

Currently the only way to override the list of default values is to use an overlay and replace the entire list. For example:

```
apiVersion: v1
kind: Secret
metadata:
  name: no-proxy-overlay
  namespace: tap-install
stringData:
  custom-app-image-overlay.yaml: |
    #@ load("@ytt:overlay", "overlay")

    #! makes an assumption that tap-gui is deployed in the namespace: "tap-gui"

    #@overlay/match by=overlay.subset({"kind": "Deployment", "metadata": {"name": "ser
ver", "namespace": "tap-gui"}}), expects="1+"
    ---
    spec:
      template:
        spec:
          containers:
            #@overlay/match by=overlay.subset({"name": "backstage"}),expects="1+"
            #@overlay/match-child-defaults missing_ok=True
            - env:
                - name: NO_PROXY
                  value: 'MY-VALUES'
```

For more information about how to apply overlays, see Customize your package installation.

Upgrade Tanzu Developer Portal

This topic tells you how to upgrade Tanzu Developer Portal outside of a Tanzu Application Platform profile installation. If you installed Tanzu Application Platform through a profile, see Upgrading Tanzu Application Platform instead.

Considerations

As part of the upgrade, Tanzu Application Platform updates its container with the new version.

As a result, if you installed Tanzu Developer Portal without the support of a backing database, you lose your in-memory data for any manual component registrations when the container restarts. While the update is pulling the new pod from the registry, users might experience a short UI interruption and might need to re-authenticate because the in-memory session data is rebuilt.

Upgrade within a Tanzu Application Platform profile

If you installed Tanzu Developer Portal as part of a Tanzu Application Platform profile, see Upgrading Tanzu Application Platform.

Upgrade Tanzu Developer Portal individually

These steps only apply to installing Tanzu Developer Portal individually, not as part of a Tanzu Application Platform profile.

To upgrade Tanzu Developer Portal outside of a Tanzu Application Platform profile:

1. Ensure that your repository has access to the new version of the package by running:

   ```
   tanzu package available list tap-gui.tanzu.vmware.com -n tap-install
   ```

   For example:

   ```
   $ tanzu package available list tap-gui.tanzu.vmware.com -n tap-install
   - Retrieving package versions for tap-gui.tanzu.vmware.com...
     NAME                       VERSION  RELEASED-AT
     tap-gui.tanzu.vmware.com  1.0.1    2021-12-22 17:45:51 +0000 UTC
     tap-gui.tanzu.vmware.com  1.0.2    2022-01-25 01:57:19 +0000 UTC
   ```

2. Perform the package upgrade by using the targeted package update version. Run:

   ```
   tanzu package installed update tap-gui -p tap-gui.tanzu.vmware.com -v VERSION
   --values-file \
   TAP-GUI-VALUES.yaml -n tap-install
   ```

   Where:

   - `VERSION` is the target version of Tanzu Developer Portal that you want.
   - `TAP-GUI-VALUES` is the configuration values file that contains the configuration used when you installed Tanzu Developer Portal.

3. Verify that you upgraded your application by running:

   ```
   tanzu package installed get tap-gui -n tap-install
   ```

Troubleshoot Tanzu Developer Portal

This topic tells you how to troubleshoot issues encountered when installing Tanzu Developer Portal. The topic is divided into sections:

- General issues
- Runtime Resources tab issues
- Accelerators page issues

- Supporting ImageVulnerabilityScan issues
- Security Analysis plug-in issues
- Supply Chain Choreographer plug-in issues

General issues

The following are general issues:

Tanzu Developer Portal reports that the port range is not valid

Symptom

You provided a full URL in a `backend.reading.allow` entry, as in this example `tap-values.yaml` snippet:

```
tap_gui:
  app_config:
    backend:
      reading:
        allow:
          - host: http://gitlab.example.com/some-group/some-repo/-/blob/main/catalog-i
nfo.yaml
```

and you see the following error message:

```
Backend failed to start up, Error: Port range is not valid: //gitlab.example.com/some-
group/some-repo/-/blob/main/catalog-info.yaml
```

Cause

Tanzu Developer Portal expects a host name to be passed into the field `backend.reading.allow[].host`.

Solution

Edit your `tap-values.yaml` file as in the following example:

```
tap_gui:
  app_config:
    backend:
      reading:
        allow:
          - host: gitlab.example.com
            paths: ['/some-group/some-repo/']
```

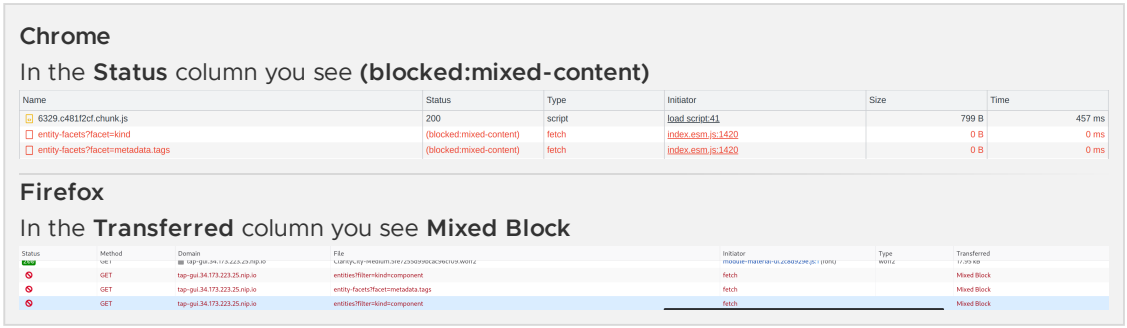
Tanzu Developer Portal does not load the catalog

Symptom

You are able to visit Tanzu Developer Portal, but it does not load the catalog and you see the following error message.

```
> Error: Could not fetch catalog entities.
> TypeError: Failed to fetch
```

When viewing your network tab you see that your browser has not downloaded mixed content. This might look different on different browsers.



Cause

As of Tanzu Application Platform v1.5, Tanzu Developer Portal provides TLS connections by default. Because of this, if you visit a Tanzu Developer Portal site your connection is automatically upgraded to https.

You might have manually set the fields `app.baseUrl`, `backend.baseUrl`, and `backend.cors.origin` in your `tap-values.yaml` file. Tanzu Developer Portal uses the `baseUrl` to determine how to create links to fetch from its APIs. The combination of these two factors causes your browser to attempt to fetch mixed content.

Solution

The solution is to delete these fields or update your values in `tap-values.yaml` to reflect that your Tanzu Developer Portal instance is serving https, as in the following example:

```
tap_gui:
  app_config:
    app:
      baseUrl: https://tap-gui.INGRESS-DOMAIN/
    backend:
      baseUrl: https://tap-gui.INGRESS-DOMAIN/
      cors:
        origin: https://tap-gui.INGRESS-DOMAIN/
```

Where `INGRESS-DOMAIN` is the ingress domain you have configured for Tanzu Application Platform.

The installer determines acceptable values based on your `tap_gui.ingressDomain` or `shared.ingress_domain` and the TLS status of the installation.

Updating a supply chain causes an error (`Can not create edge...`)

Symptom

Updating a supply chain causes an error (`Can not create edge...`) when an existing workload is clicked in the Workloads table and that supply chain is no longer present.

Solution

Recreate the same workload to execute through the new or updated supply chain.

Catalog not found

Symptom

When you pull up Tanzu Developer Portal, you get the error `Catalog Not Found`.

Cause

The catalog plug-in can't read the Git location of your catalog definition files.

Solution

1. Ensure you have built your own Backstage-compatible catalog or that you have downloaded one of the Tanzu Developer Portal catalogs from VMware Tanzu Network.
2. Ensure you defined the catalog in the values file that you input as part of installation. To update this location, change the definition file:
    - Change the Tanzu Application Platform profile file if installed by using a profile.
    - Change the standalone Tanzu Developer Portal values file if you're only installing that package on its own.

    ```
    namespace: tap-gui
    service_type: SERVICE-TYPE
    app_config:
      catalog:
        locations:
          - type: url
            target: https://GIT-CATALOG-URL/catalog-info.yaml
    ```

3. Provide the proper integration information for the Git location you specified earlier.

    ```
    namespace: tap-gui
    service_type: SERVICE-TYPE
    app_config:
      app:
        baseUrl: https://EXTERNAL-IP:PORT
      integrations:
        gitlab: # Other integrations available
          - host: GITLAB-HOST
            apiBaseUrl: https://GITLAB-URL/api/v4
            token: GITLAB-TOKEN
    ```

You can substitute for other integrations as defined in the Backstage documentation.

No configured authentication provider

Symptom

When you load Tanzu Developer Portal in a browser, the following message appears:

```
No configured authentication providers. Please configure at least one.
```

Cause

You have not configured any authentication providers and you have not allowed guest access.

Solution

Configure an authentication provider or allow guest access.

Issues updating the values file

Symptom

After updating the configuration of Tanzu Developer Portal, either by using a profile or as a standalone package installation, you don't know whether the configuration has reloaded.

Solution

1. Get the name you need by running:

   ```
   kubectl get pods -n tap-gui
   ```

   For example:

   ```
   $ kubectl get pods -n tap-gui
   NAME                       READY   STATUS    RESTARTS   AGE
   server-6b9ff657bd-hllq9    1/1     Running   0          13m
   ```

2. Read the log of the pod to see if the configuration reloaded by running:

   ```
   kubectl logs NAME -n tap-gui
   ```

   Where `NAME` is the value you recorded earlier, such as `server-6b9ff657bd-hllq9`.

3. Search for a line similar to this one:

   ```
   2021-10-29T15:08:49.725Z backstage info Reloaded config from app-config.yaml, a
   pp-config.yaml
   ```

4. If need be, delete and re-instantiate the pod.

   Caution

   Depending on your database configuration, deleting, and re-instantiating the pod might cause the loss of user preferences and manually registered entities. If you have configured an external PostgreSQL database, `tap-gui` pods are not stateful. In most cases, state is held in ConfigMaps, Secrets, or the database. For more information, see Configuring the Tanzu Developer Portal database and Register components.

   To delete and re-instantiate the pod, run:

   ```
   kubectl delete pod -l app=backstage -n tap-gui
   ```

Pull logs from Tanzu Developer Portal

Symptom

You have a problem with Tanzu Developer Portal, such as `Catalog: Not Found`, and don't have enough information to diagnose it.

Solution

Get timestamped logs from the running pod and review the logs:

1. Pull the logs by using the pod label by running:

```
kubectl logs -l app=backstage -n tap-gui
```

2. Review the logs.

Ad-blocking software interference

Symptom

One or both of the following is true:

- You cannot access some, or all, of Tanzu Developer Portal.
- Telemetry collection within the VMware Customer Experience Improvement Program is failing.

Cause

Your ad-blocking browser extension or standalone ad-blocking software is causing interference.

Solution

Add Tanzu Developer Portal to your ad-blocking allowlist. Alternatively, deactivate the ad-blocking software or turn off Pendo telemetry collection.

Runtime Resources tab issues

Here are some common troubleshooting steps for errors presented in the **Runtime Resources** tab.

Error communicating with Tanzu Application Platform web server

Symptom

When accessing the **Runtime Resource Visibility** tab, the system displays `Error communicating with TAP GUI back end.`

Causes

- An interrupted Internet connection
- Error with the back end service

Solution

1. Confirm that you have Internet access.
2. Confirm that the back-end service is running correctly.
3. Confirm the cluster configuration is correct.

No data available

Symptom

When accessing the **Runtime Resource Visibility** tab, the system displays

```
One or more resources are missing. This could be due to a label mismatch. \
Please make sure your resources have the label(s) "LABEL_SELECTOR".
```

Cause

No communications error has occurred, but no resources were found.

Solution

Confirm that you are using the correct label:

1. Verify the Component definition includes the annotation `backstage.io/kubernetes-label-selector`.
2. Confirm your Kubernetes resources correspond to that label drop-down menu.

Errors retrieving resources

Symptom

When opening the **Runtime Resource Visibility** tab, the system displays `One or more resources might be missing because of cluster query errors.`

The reported errors might not indicate a real problem. A build cluster might not have runtime CRDs installed, such as Knative Service, and a run cluster might not have build CRDs installed, such as a Cartographer workload. In these cases, 403 and 404 errors might be false positives.

You might receive the following error messages because these resources might not be required for your specific Tanzu Application Platform profile. These error messages are known issues:

- `Access error when querying cluster CLUSTER_NAME for resource KUBERNETES_RESOURCE_PATH (status: 401). Contact your administrator.`
- `Access error when querying cluster CLUSTER_NAME for resource KUBERNETES_RESOURCE_PATH (status: 403). Contact your administrator.`
- `Knative is not installed on CLUSTER_NAME (status: 404). Contact your administrator.`
- `Error when querying cluster CLUSTER_NAME for resource KUBERNETES_RESOURCE_PATH (status: 404). Contact your administrator.`

Accelerators page issues

Here are some common troubleshooting steps for errors displayed on the **Accelerators** page.

No accelerators

Symptom

When the `app_config.backend.reading.allow` section is configured in the `tap-values.yaml` file during the `tap-gui` package installation, there are no accelerators on the **Accelerators** page.

Cause

This section in `tap-values.yaml` overrides the default configuration that gives Tanzu Developer Portal access to the accelerators.

Solution

As a workaround, provide a value for Application Accelerator in this section. For example:

```
app_config:
  # Existing tap-values yaml above
  backend:
    reading:
      allow:
      - host: acc-server.accelerator-system.svc.cluster.local
```

Supporting ImageVulnerabilityScan issues

The following troubleshooting issues concern `ImageVulnerabilityScan`.

No Vulnerability data

Symptom

SCST - Scan 2.0 is enabled and there is no vulnerability data on the Security Analysis and Supply Chain Choreographer dashboards.

Cause

Tanzu Developer Portal lacks the required access to detect the new `ImageVulnerabilityScan` custom resource.

Solution

As a workaround, you can apply a ytt overlay to add permissions to the Kubernetes role that is used to access the `ImageVulnerabilityScan` resource. For more information about how overlays work with Tanzu Application Platform, see Customize your package installation.

1. Create a `secret.yml` file with a `Secret` that contains your ytt overlay. For example:

   ```
   kind: Secret
   metadata:
     name: add-tap-portal-ivs-permissions
     namespace: tap-install
     annotations:
       kapp.k14s.io/change-group: "tap-overlays"
   type: Opaque
   stringData:
     add-tap-portal-ivs-permissions.yaml: |
       #@ load("@ytt:overlay", "overlay")
       #@overlay/match by=overlay.subset({"metadata":{"name":"k8s-reader"}, "kin
   d": "ClusterRole"})
       ---
       rules:
         #@overlay/append
           - apiGroups:
             - app-scanning.apps.tanzu.vmware.com
             resources:
             - imagevulnerabilityscans
             verbs:
             - get
             - watch
             - list
   ```

2. Apply the `Secret` to your cluster by running:

   ```
   kubectl apply -f secret.yml
   ```

3. Update your values file to include a `package_overlays` field:

```
package_overlays:
- name: tap-gui
secrets:
- name: add-tap-portal-ivs-permissions
```

4. Update Tanzu Developer Portal with the new Tanzu Application Platform values by running:

```
tanzu package installed update tap -p tap.tanzu.vmware.com -n tap-install --val
ues-file tap-values.yaml
```

Scanner name not shown in Tanzu Developer Portal for SCST - Scan 2.0

Symptom

SCST - Scan 2.0 is enabled and the scanner name in the Security Analysis and Supply Chain Choreographer dashboards does not appear.

Cause

The `ImageVulnerabilityScan` custom resource lacks the required annotation for Tanzu Developer Portal to detect it.

Solution

Add the `app-scanning.apps.tanzu.vmware.com/scanner-name` annotation to `ImageVulnerabilityScan`:

```
apiVersion: app-scanning.apps.tanzu.vmware.com/v1alpha1
kind: ImageVulnerabilityScan
metadata:
  annotations:
    app-scanning.apps.tanzu.vmware.com/scanner-name: SCANNER-NAME
```

Where `SCANNER-NAME` is the name that is reported in Tanzu Developer Portal.

Security Analysis plug-in issues

These are troubleshooting issues for the Security Analysis plug-in.

Empty Impacted Workloads table

Symptom

The Impacted Workloads table is empty on the **CVE and Package Details** pages.

Cause

The relevant CVE belongs to a workload that has only completed one type of vulnerability scan (either image or source).

Solution

A fix is planned for Tanzu Developer Portal v1.5.1.

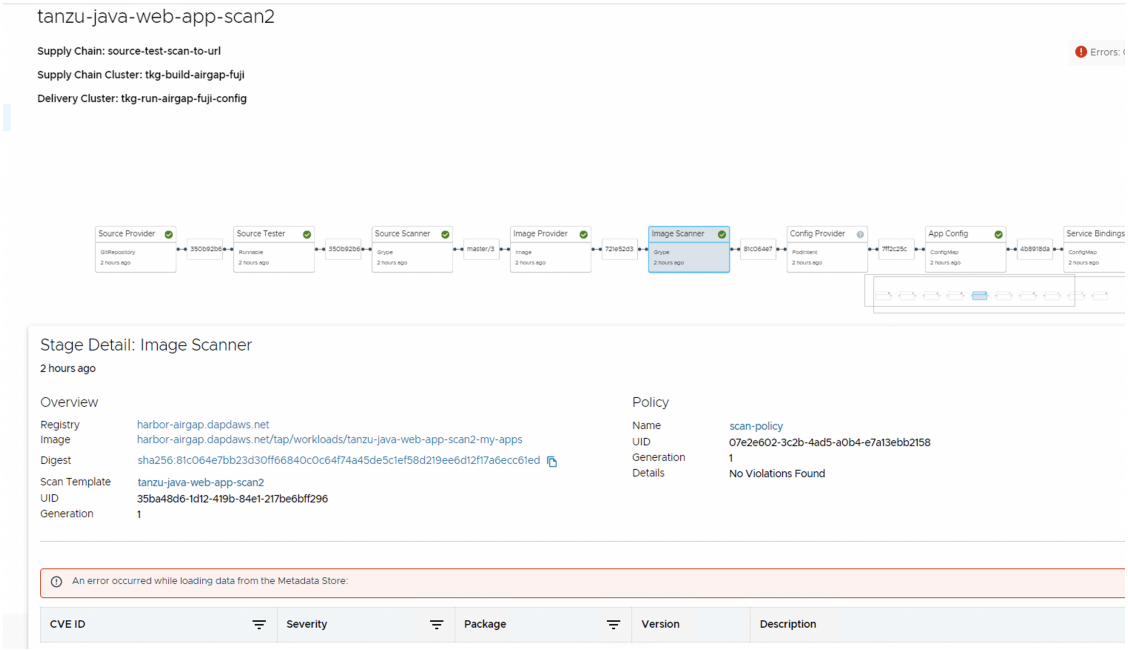
Supply Chain Choreographer plug-in issues

These are troubleshooting issues for the Supply Chain Choreographer plug-in.

An error occurred while loading data from the Metadata Store

Symptom

In the Supply Chain Choreographer plug-in, you see the error message `An error occurred while loading data from the Metadata Store`.



Cause

There are multiple potential causes. The most common cause is `tap-values.yaml` missing the configuration that enables Tanzu Developer Portal to communicate with Supply Chain Security Tools - Store.

Solution

See Supply Chain Choreographer - Enable CVE scan results for the necessary configuration to add to `tap-values.yaml`. After adding the configuration, update your Tanzu Application Platform deployment or Tanzu Developer Portal deployment with the new values.

SBOMs do not download when automatically configuring Tanzu Developer Portal for SCST - Store

Symptom

The auto configuration between Tanzu Developer Portal and SCST - Store prevents the SBOM feature from working. The SBOM feature was introduced in Tanzu Application Platform v1.6.

Cause

Backstage expects `allowedHeaders` values for SCST - Store to reply with proper XML and JSON SBOM responses. The `allowedHeaders` values are missing.

Solution

Edit your `tap-values.yaml` file so that `allowedHeaders` and the accompanying values are included:

```
tap_gui:
  app_config:
    proxy:
      /metadata-store:
        target: https://metadata-store-app.metadata-store:8443/api/v1
        changeOrigin: true
        secure: false
        allowedHeaders: ['Accept', 'Report-Type-Format']
        headers:
          Authorization: "Bearer ACCESS-TOKEN"
          X-Custom-Source: project-star
```

Where `ACCESS-TOKEN` is the token you obtained after creating a read-write service account. For more information, see Manually connect Tanzu Developer Portal to Metadata Store.

Overview of Tanzu Developer Tools for IntelliJ

Tanzu Developer Tools for IntelliJ is the official VMware Tanzu IDE extension for IntelliJ IDEA. The extension helps you develop with Tanzu Application Platform and enables you to rapidly iterate on your workloads on supported Kubernetes clusters that have Tanzu Application Platform installed.

Tanzu Developer Tools for IntelliJ currently supports Java applications on macOS and Windows.

Extension features

This extension gives the following features:

- **Deploy applications directly from IntelliJ:**

  Rapidly iterate on your applications on Tanzu Application Platform and deploy them as workloads directly from within IntelliJ.

- **See code updates running on-cluster in seconds:**

  With the use of Live Update facilitated by Tilt, deploy your workload once, save changes to the code and then, seconds later, see those changes reflected in the workload running on the cluster.

- **Debug workloads directly on the cluster:**

  Debug your application in a production-like environment by debugging on your Kubernetes cluster that has Tanzu Application Platform. An environment's similarity to production relies on keeping dependencies updated, among other variables.

- **See workloads running on the cluster:**

  From the Workloads panel you can see any workload found within the cluster and namespace specified in the current kubectl context.

- **Work with microservices in a Java monorepo:**

  Tanzu Developer Tools for IntelliJ v1.3 and later supports working with a monorepo containing multiple modules that represent different microservices. This makes it possible to deploy, debug, and Live Update multiple workloads simultaneously from the same IntelliJ multimodule project. For more information about projects with multiple modules, see the IntelliJ documentation. For more information about a typical monorepo setup, see Working with microservices in a monorepo.

- **Connect to a sandbox cluster:**

  You can connect to a Tanzu Application Platform sandbox instance from Tanzu Developer Tools for IntelliJ to try Tanzu Application Platform and see its benefits. To use Developer Sandbox and connect to it from your IDE, see the Tanzu Academy website.

Note

The new variation of Out of the Box (OOTB) Basic supply chains, which outputs Carvel packages to enable configuring multiple runtime environments, is not currently supported. For more information about the variation, see Carvel Package Supply Chains.

Next steps

Follow the steps to install the extension.

Overview of Tanzu Developer Tools for IntelliJ

Tanzu Developer Tools for IntelliJ is the official VMware Tanzu IDE extension for IntelliJ IDEA. The extension helps you develop with Tanzu Application Platform and enables you to rapidly iterate on your workloads on supported Kubernetes clusters that have Tanzu Application Platform installed.

Tanzu Developer Tools for IntelliJ currently supports Java applications on macOS and Windows.

Extension features

This extension gives the following features:

- **Deploy applications directly from IntelliJ:**

  Rapidly iterate on your applications on Tanzu Application Platform and deploy them as workloads directly from within IntelliJ.

- **See code updates running on-cluster in seconds:**

  With the use of Live Update facilitated by Tilt, deploy your workload once, save changes to the code and then, seconds later, see those changes reflected in the workload running on the cluster.

- **Debug workloads directly on the cluster:**

  Debug your application in a production-like environment by debugging on your Kubernetes cluster that has Tanzu Application Platform. An environment's similarity to production relies on keeping dependencies updated, among other variables.

- **See workloads running on the cluster:**

  From the Workloads panel you can see any workload found within the cluster and namespace specified in the current kubectl context.

- **Work with microservices in a Java monorepo:**

  Tanzu Developer Tools for IntelliJ v1.3 and later supports working with a monorepo containing multiple modules that represent different microservices. This makes it possible to deploy, debug, and Live Update multiple workloads simultaneously from the same IntelliJ multimodule project. For more information about projects with multiple modules, see the IntelliJ documentation. For more information about a typical monorepo setup, see Working with microservices in a monorepo.

- **Connect to a sandbox cluster:**

  You can connect to a Tanzu Application Platform sandbox instance from Tanzu Developer Tools for IntelliJ to try Tanzu Application Platform and see its benefits. To use Developer Sandbox and connect to it from your IDE, see the Tanzu Academy website.

> **Note**
>
> The new variation of Out of the Box (OOTB) Basic supply chains, which outputs Carvel packages to enable configuring multiple runtime environments, is not currently supported. For more information about the variation, see Carvel Package Supply Chains.

Next steps

Follow the steps to install the extension.

Install Tanzu Developer Tools for IntelliJ

This topic explains how to install the VMware Tanzu Developer Tools for IntelliJ IDE extension. The extension currently only supports Java applications on macOS and Windows.

Prerequisites

Before installing the extension, you must have:

- IntelliJ
- kubectl
- Tilt v0.30.12 or later
- Tanzu CLI and plug-ins
- A cluster with the Tanzu Application Platform Full profile or Iterate profile

> **Note**
>
> If you are an app developer, someone else in your organization might have already set up the Tanzu Application Platform environment.

Install

To install VMware Tanzu Developer Tools for IntelliJ:

1. Open IntelliJ.
2. Open the command palette, enter `Plugins`, and then click **Plugins**.
3. Select the **Marketplace** tab in the **Plugins Settings** dialog box.
4. In the search box enter `Tanzu`.
5. Click **Tanzu Developers Tools** and then click **Install**.

Update

To update to a later version, repeat the steps in the Install section. You do not need to uninstall the current version.

Uninstall

To uninstall the VMware Tanzu Developer Tools for IntelliJ:

1. Open the **Preferences** pane and then go to **Plugins**.
2. Select the extension, click the gear icon, and then click **Uninstall**.
3. Restart IntelliJ.

Next steps

Proceed to Getting started.

Get Started with Tanzu Developer Tools for IntelliJ

This topic guides you through getting started with Tanzu Developer Tools for IntelliJ.

Prerequisite

Install Tanzu Developer Tools for IntelliJ.

Configure Local Source Proxy or use a source image registry

Configure Local Source Proxy if you're able to do so. For more information, see the Local Source Proxy documentation.

If you cannot use Local Source Proxy, use a source image registry. Before deploying a workload, you must authenticate with an image registry to store your source code. You can use the Docker CLI to authenticate or you can set environment variables that the Tanzu CLI can use to authenticate.

Docker CLI
To authenticate by using the Docker CLI, run:

```
docker login $REGISTRY_HOSTNAME -u $REGISTRY_USERNAME -p $REGISTRY_PASSWORD
```

Tanzu CLI
To authenticate by using the Tanzu CLI, export environment variables by running:

```
export TANZU_APPS_REGISTRY_CA_CERT=PATH-TO-CA-CERT.nip.io.crt
export TANZU_APPS_REGISTRY_PASSWORD=USERNAME
export TANZU_APPS_REGISTRY_USERNAME=PASSWORD
```

`CA_CERT` is only needed for a custom or private registry.

For more information, see Workload creation fails due to authentication failure in Docker Registry.

Run Tanzu Developer Tools for IntelliJ

Run IntelliJ from a CLI, instead of through your operating system GUI, to avoid restricting the set of environment variables the app receives. This is especially relevant for macOS.

Limited environment variables can cause problems with cluster authentication for Tanzu Developer Tools for IntelliJ. For example, a common situation is that a sanitized `PATH` does not provide access to the `gke-cloud-auth-plugin` installed on your system. This makes Tanzu Developer Tools for IntelliJ unable to authenticate and access your GKE cluster.

This situation is complex and different things can go wrong depending on:

- Precisely how you installed various cloud-related CLI tools
- How you set environment variables
- Your OS version
- Which cloud provider and authentication method you are using

All of these problems are most easily avoided by running IntelliJ from a CLI. Run IntelliJ from a CLI in macOS by running:

```
open /Applications/IntelliJ\ IDEA.app
```

Set up Tanzu Developer Tools for IntelliJ

The extension makes use of the following files within your project:

- `workload.yaml`
- `catalog-info.yaml`
- `Tiltfile`
- `.tanzuignore`

You can create these files by using the instructions in this topic, or use the files in the View an example project section.

There are two ways to create these files:

- Using the code snippets that Tanzu Developer Tools provide, which create templates in empty files that you then fill in with the required information.
- Writing the files manually.

Create the `workload.yaml` file

You must include a file named `workload.yaml` in your project. For example, `my-project/config/workload.yaml`.

`workload.yaml` provides instructions to Supply Chain Choreographer about how to build and manage a workload. For more information, see Supply Chain Choreographer for Tanzu.

The Tanzu Developer Tools for IntelliJ extension requires only one `workload.yaml` file per project. `workload.yaml` must be a single-document YAML file, not a multi-document YAML file.

To create a `workload.yaml` file by using code snippets:

1. Right-click the IntelliJ project explorer and then click **New**.
2. Select the Tanzu workload.
3. Add the filename `workload`.
4. Fill in the template.

See the following `workload.yaml` example:

```
apiVersion: carto.run/v1alpa1
kind: Workload
metadata:
 name: APP-NAME
 labels:
   apps.tanzu.vmware.com/workload-type: WORKLOAD-TYPE
   app.kubernetes.io/part-of: APP-NAME
spec:
 source:
   git:
     url: GIT-SOURCE-URL
     ref:
       branch: GIT-BRANCH-NAME
```

Where:

- `APP-NAME` is the name of your application. For example, `my app`.
- `WORKLOAD-TYPE` is the type of workload for your app. For example, `web`. For more information, see Workload types.
- `GIT-SOURCE-URL` is the Git source code URL for your app. For example, `github.com/mycompany/myapp`.
- `GIT-BRANCH-NAME` is the branch of the Git source code you want to use. For example, `main`.

Alternatively you can use the Tanzu CLI to create a `workload.yaml` file. For more information, see Create or update a workload.

Create the `catalog-info.yaml` file

You must include a file named `catalog-info.yaml` in your project. For example, `my-project/catalog/catalog-info.yaml`.

`catalog-info.yaml` enables the workloads created with Tanzu Developer Tools for IntelliJ to be visible in Tanzu Developer Portal. For more information, see Overview of Tanzu Developer Portal.

To create a `catalog-info.yaml` file by using the code snippets:

1. Right-click the IntelliJ project explorer and then click **New**.
2. Select the Tanzu Catalog.
3. Add the filename `catalog-info`.
4. Fill in the template.

See the following `workload.yaml` example:

```
apiVersion: backstage.io/v1alpha1
kind: Component
metadata:
 name: APP-NAME
 description: APP-DESCRIPTION
 tags:
   - tanzu
 annotations:
   'backstage.io/kubernetes-label-selector': 'app.kubernetes.io/part-of=APP-NAME'
spec:
 type: service
 lifecycle: experimental
 owner: default-team
```

Where:

- `APP-NAME` is the name of your application.
- `APP-DESCRIPTION` is a description of your application.

Create the Tiltfile file

In your project you must include a file named `Tiltfile` with no extension (no filetype), such as `my-project/Tiltfile`.

The `Tiltfile` provides the configuration for Tilt to enable your project to Live Update on the Tanzu Application Platform-enabled Kubernetes cluster. For more information, see the Tilt documentation.

The Tanzu Developer Tools for IntelliJ extension requires only one Tiltfile per project.

The following is an example `Tiltfile`:

```
LOCAL_PATH = os.getenv("LOCAL_PATH", default='.')
NAMESPACE = os.getenv("NAMESPACE", default='default')

k8s_custom_deploy(
   'APP-NAME',
   apply_cmd="tanzu apps workload apply -f PATH-TO-WORKLOAD-YAMl --live-update" +
       " --local-path " + LOCAL_PATH +
       " --namespace " + NAMESPACE +
       " --yes >/dev/null" +
       " && kubectl get workload APP-NAME --namespace " + NAMESPACE + " -o yaml",
   delete_cmd="tanzu apps workload delete -f PATH-TO-WORKLOAD-YAML --namespace " + NAM
ESPACE + " --yes" ,
   deps=['pom.xml', './target/classes'],
   container_selector='workload',
   live_update=[
       sync('./target/classes', '/workspace/BOOT-INF/classes')
   ]
)

k8s_resource('APP-NAME', port_forwards=["8080:8080"],
   extra_pod_selectors=[{'carto.run/workload-name': 'APP-NAME', 'app.kubernetes.io/com
ponent': 'run'}])
allow_k8s_contexts('CONTEXT-NAME')
```

Where:

- `APP-NAME` is the name of your application.
- `PATH-TO-WORKLOAD-YAML` is the local file system path to your `workload.yaml` file. For example, `config/workload.yaml`.
- `CONTEXT-NAME` is the name of your current Kubernetes context. If your Tanzu Application Platform-enabled Kubernetes cluster is running on your local machine, you can remove the entire `allow_k8s_contexts` line. For more information about this line, see the Tilt documentation.

If you want to compile the source image from a local directory other than the project directory, change the value of `local_path`. For more information, see local path in the glossary.

Create the `.tanzuignore` file

In your project, you can include a file named `.tanzuignore` with no file extension. For example, `my-project/.tanzuignore`.

When working with local source code, `.tanzuignore` excludes files from the source code that are uploaded within the image. It has syntax similar to the `.gitignore` file.

For an example, see the `.tanzuignore` file in GitHub that is used for the sample Tanzu Java web app. You can use the file as it is or edit it for your needs.

View an example project

Before you begin, you need a container image registry to use the sample application. There are two ways to view a sample application that demonstrates the necessary configuration files.

Use Application Accelerator
If your company has configured Application Accelerator, you can obtain the sample application there if it was not removed. To view the example using Application Accelerator:

1. Open Application Accelerator. The Application Accelerator location varies based on where your company placed it. Contact the appropriate team to learn its location.
2. Search for `Tanzu Java Web App` in the Application Accelerator.
3. Add the required configuration information and generate the application.
4. Unzip the application and open the directory in IntelliJ.

Clone from GitHub
To clone the example from GitHub:

1. Use `git clone` to clone the application-accelerator-samples repository from GitHub.
2. Go to the `tanzu-java-web-app` directory.
3. Open the `Tiltfile` and replace `your-registry.io/project` with your registry.

Next steps

Use Tanzu Developer Tools for IntelliJ.

Use Tanzu Developer Tools for IntelliJ

Ensure that the project you want to use the Tanzu Developer Tools for IntelliJ extension with has the required files specified in Getting started.

The extension requires only one Tiltfile and one `workload.yaml` file per project. `workload.yaml` must be a single-document YAML file, not a multi-document YAML file.

Workload Actions

The extension enables you to apply, debug, and Live Update your application on a Kubernetes cluster that has Tanzu Application Platform. The developer sandbox experience enables developers to Live Update their code and simultaneously debug the updated code, without having to deactivate Live Update when debugging.

Apply a workload

The extension enables you to apply workloads on your Kubernetes cluster that has Tanzu Application Platform.

To apply a workload:

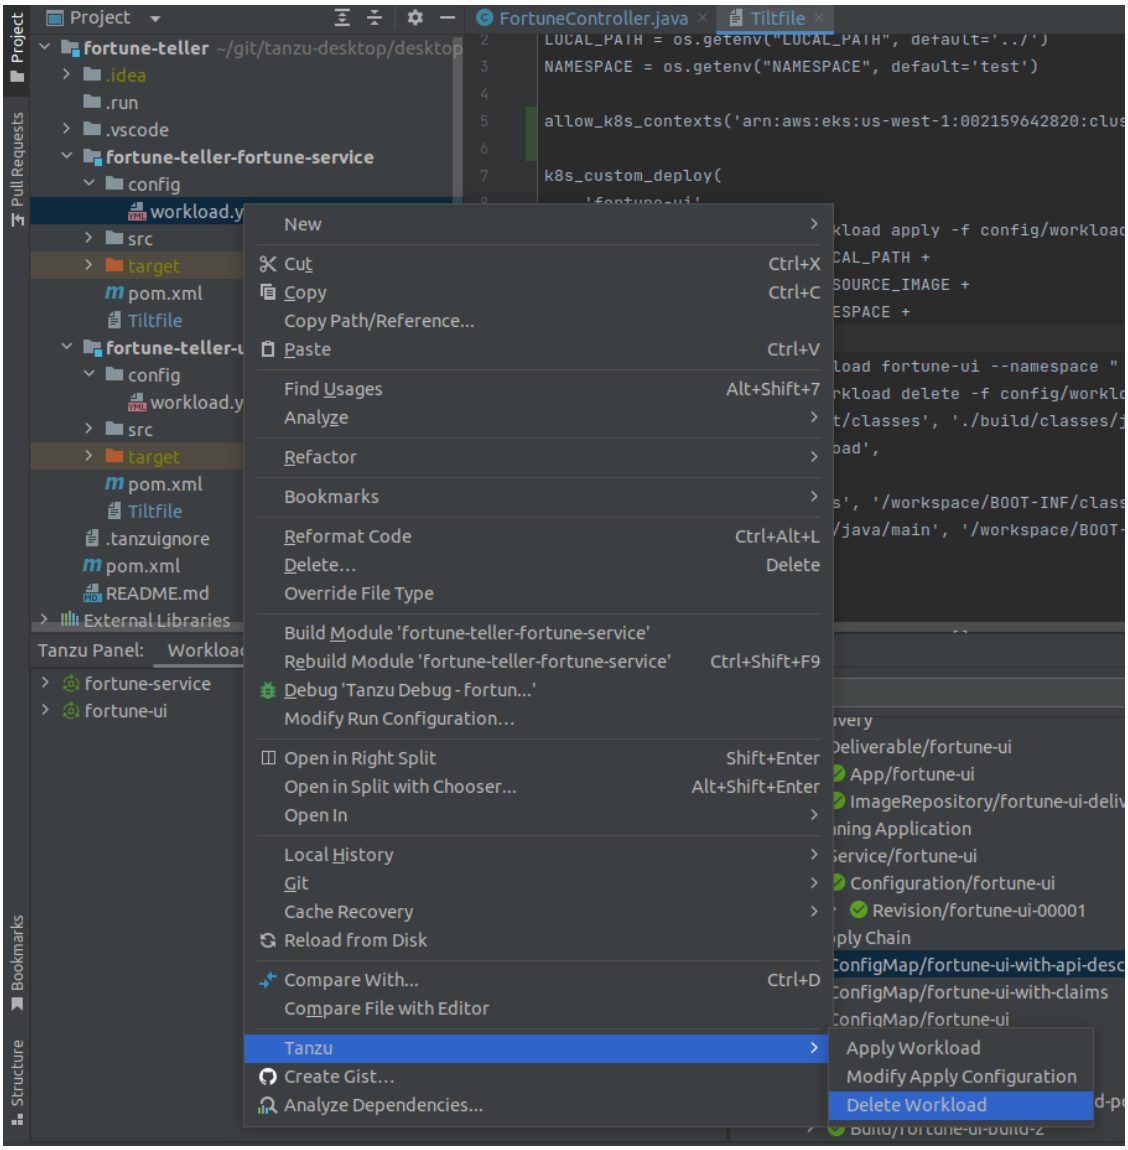
1. Right-click anywhere in the IntelliJ project explorer and click **Tanzu** > **Apply Workload** or right-click on an associated workload in the Workloads panel and click **Apply Workload**.
2. Click **Tanzu > Modify Apply Configuration**.

The `Tanzu workload apply` command is triggered in the terminal and the workload is applied. A new workload appears on the Tanzu panel.

Delete a workload

The extension enables you to delete workloads on your Kubernetes cluster that has Tanzu Application Platform.

To delete a workload right-click anywhere in the IntelliJ project explorer and click **Tanzu** > **Delete Workload** or right-click on an associated workload in the Workloads panel and click **Delete Workload**.



A message appears that prompts you to delete the workload and not warn again, delete the workload, or cancel. A notification appears showing that the workload was deleted.

Debugging on the cluster

The extension enables you to debug your application on a Kubernetes cluster that has Tanzu Application Platform.

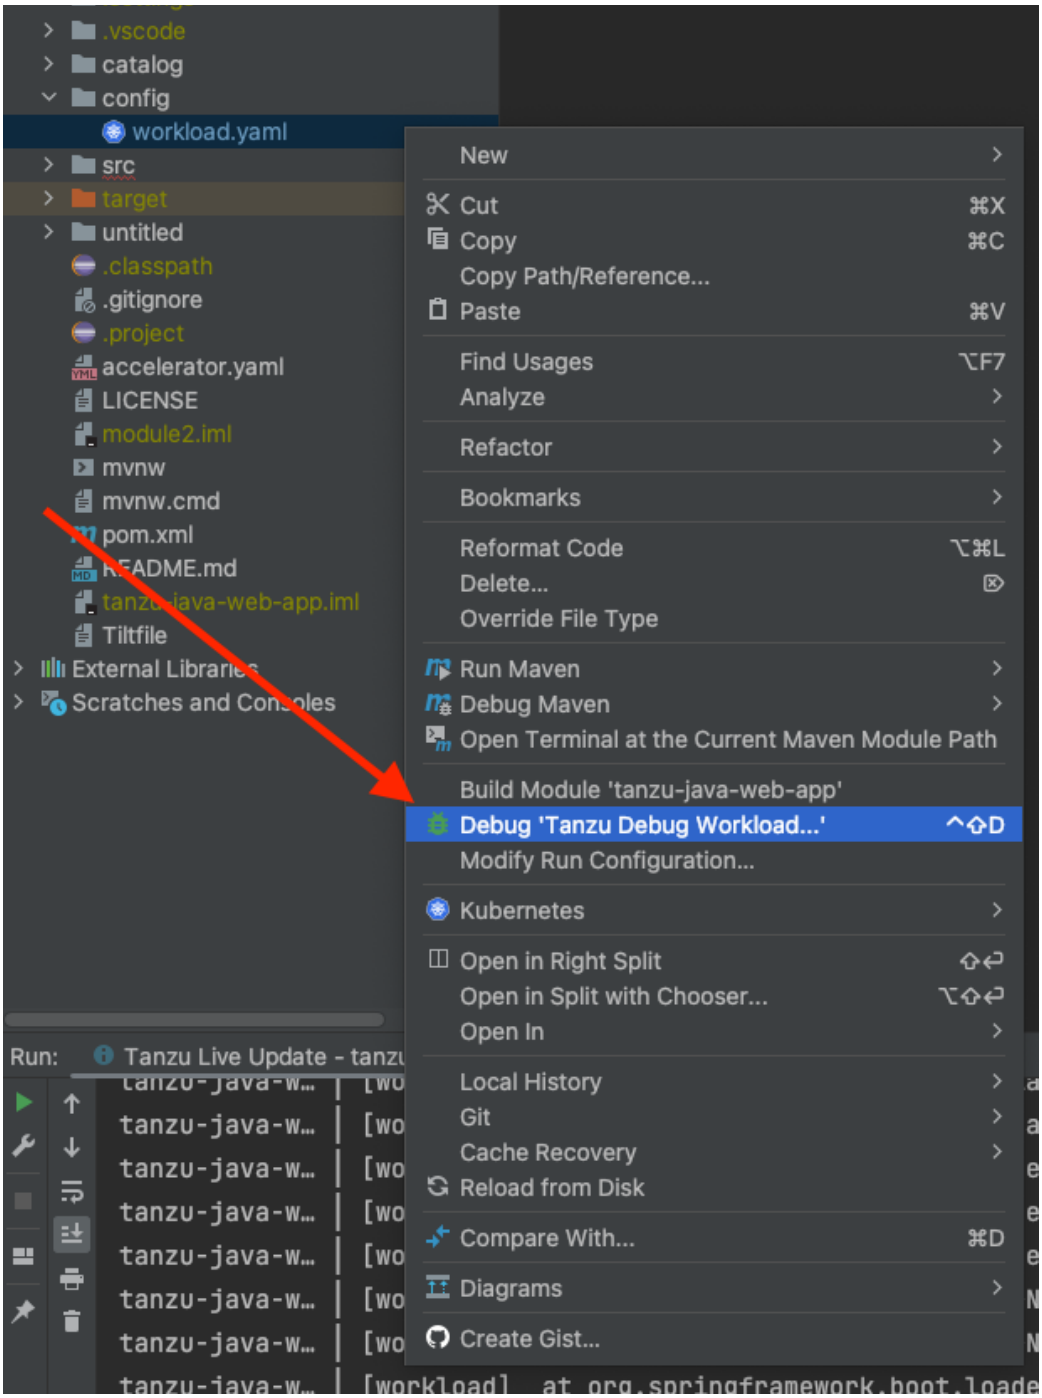
Debugging requires a single-document `workload.yaml` file in your project. For how to create `workload.yaml`, see Set up Tanzu Developer Tools.

The developer sandbox experience enables developers to Live Update their code, and simultaneously debug the updated code, without having to deactivate Live Update when debugging.

Start debugging on the cluster

To start debugging on the cluster:

1. Add a breakpoint in your code.
2. Right-click the `workload.yaml` file in your project and click **Debug 'Tanzu Debug Workload...'** in the pop-up menu or right-click on an associated workload in the Workloads panel and click **Debug Workload**.



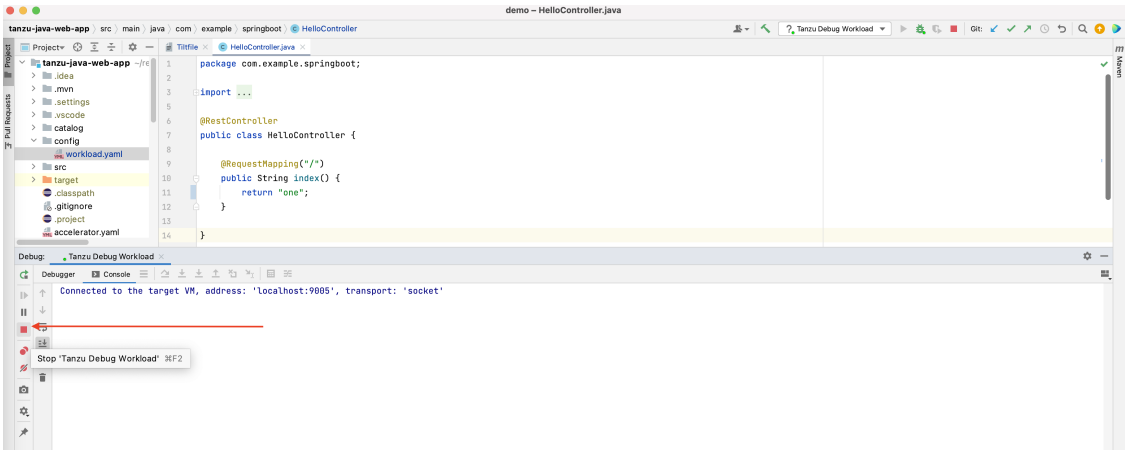
3. Ensure that the configuration parameters are set:

    - **Source Image:** This is the registry location for publishing local source code. For example, `registry.io/yourapp-source`. The source image parameter is optional if you have configured Local Source Proxy.
    - **Local Path:** This is the path on the local file system to a directory of source code to build.
    - **Namespace:** This is the namespace that workloads are deployed into.

    You can also manually create Tanzu Debug configurations by using the **Edit Configurations** IntelliJ UI.

Stop Debugging on the Cluster

Click the stop button in the **Debug** overlay to stop debugging on the cluster.



Live Update

See the following sections for how to use Live Update.

Start Live Update

Before using Live Update, verify that your auto-save setting is either off or on with a delay. The delay must be long enough for the application to restart between auto saves to allow enough time for your app to Live Update when files change. This auto-save setting is in **Preferences** > **Appearance & Behavior** > **System Settings** > **Autosave**.

To start Live Update:

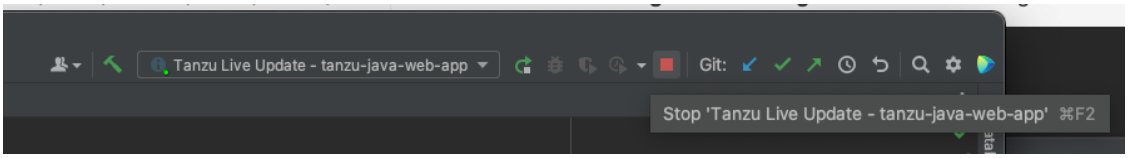
1. Right-click your project's Tiltfile and then click **Run 'Tanzu Live Update - ...'** or right-click on an associated workload in the Workloads panel and then click **Live Update Workload**.
2. Ensure that the configuration parameters are set:
    - **Source Image:** This is the registry location for publishing local source code. For example, `registry.io/yourapp-source`. It must include both a registry and a project name. The source image parameter is optional if you have configured Local Source Proxy.
    - **Local Path:** This is the path on the local file system to a directory of source code to build.
    - **Namespace:** This is the namespace that workloads are deployed into.

Note

You must compile your code before the changes are synchronized to the container. For example, `Build Project`: `⌘+F9`.

Stop Live Update

To stop Live Update, use the native controls to stop the Tanzu Live Update Run Configuration that is running.



Tanzu Workloads panel

The current state of the workloads is visible in the Tanzu Workloads view. This view is a separate section in the bottom of the Explorer view in the Side Bar. The view shows the current status of each workload, namespace, and cluster. It also shows whether Live Update and Debug is running, stopped, or deactivated.

The Tanzu Activity tab in the Panels view enables developers to visualize the supply chain, delivery, and running application pods. The tab enables a developer to view and describe logs on each resource associated with a workload from within their IDE. The tab displays detailed error messages for each resource in an error state.

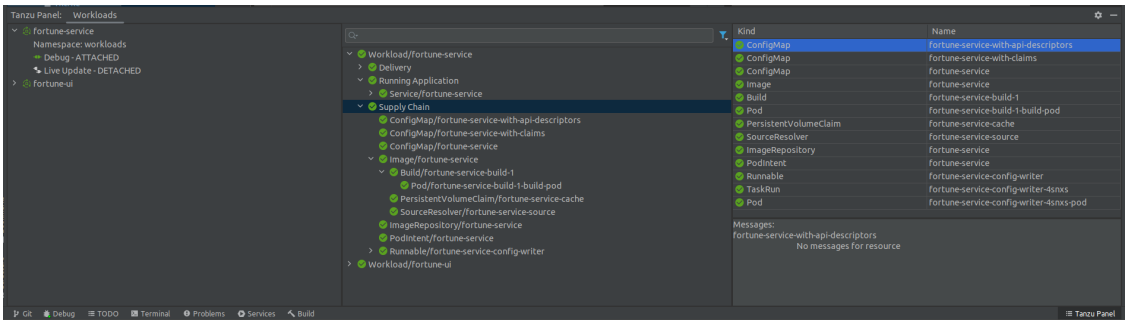
Workload commands are available from the Tanzu Workloads panel on workloads that have an associated module in the current project.

This association is based on a module name and a workload name matching. For example, a project with a module named `my-app` is associated with a deployed workload named `my-app`.

When taking an action from the Tanzu Workloads panel, the action uses the namespace of the deployed workload regardless of the configuration in the module.

For example, you might have a Live Update configuration with a namespace argument of `my-apps-1`, but running the action from a deployed workload in namespace `my-apps-2` starts a Live Update session with a namespace argument of `my-apps-2`.

The Tanzu Workloads panel uses the cluster and defaults to the namespace specified in the current kubectl context.



To add a namespace:

1. View the current context and namespace by running:

   ```
   kubectl config get-contexts
   ```

2. Set a namespace for the current context by running:

   ```
   kubectl config set-context --current --namespace=YOUR-NAMESPACE
   ```

3. If you are using the `KUBECONFIG` environment variable to organize access to different clusters on macOS, use the CLI to run the IDE instead of Dock or Spotlight. For why, see Troubleshooting.

To add additional namespaces to your Workloads panel:

1. Click on the gear icon in the upper right corner of the Workloads panel.
2. Click on **Select Namespaces...**
3. Select the checkboxes of the namespaces that you want to add to your panel.

Working with microservices in a monorepo

A monorepo is single Git repository that contains multiple workloads. Each individual workload is placed in a subfolder of the main repository.

You can find an example of this in Application Accelerator.

The relevant accelerator is called Spring SMTP Gateway, and you can obtain its source code as an accelerator or directly from the application-accelerator-samples GitHub repository.

This project is an example of a typical layout:

- `MONO-REPO-ROOT/`
  - `pom.xml` (parent pom)
  - `microservice-app-1/`
  - `pom.xml`
  - `mvnw` (and other mvn-related files for building the workload)
  - `Tiltfile` (supports Live Update)
  - `config`
    - `workload.yaml` (supports deploying and debugging from IntelliJ)
  - `src/` (contains source code for this microservice)
  - `microservice-app-2/`
  - …similar layout

Recommended structure: Microservices that can be built independently

In this example, each of the microservices can be built independently of one another. Each subfolder contains everything needed to build that workload.

This is reflected in the `source` section of `workload.yaml` by using the `subPath` attribute:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: microservice-app-1
  ...
spec:
  source:
    git:
      ref:
        branch: main
      url: https://github.com/kdvolder/sample-mono-repo.git
    subPath: microservice-app-1 # build only this
  ...
```

For setting up your own repositories, it's best practice to set up a monorepo so that each microservice can be built completely independently.

To work with these monorepos:

1. Import the monorepo as a project into IntelliJ.
2. Interact with each of the subfolders as you would interact with a project containing a single workload.

Alternative structure: Services with build-time interdependencies

Some monorepos do not have submodules that can be independently built. Instead the `pom.xml` files of the submodules are set up to have some build-time interdependencies. For example:

- A submodule `pom.xml` can reference the parent `pom.xml` as a common place for centralized dependency management.
- A microservice submodule can reference another, as a maven dependency.
- Several microservice submodules can reference one or more shared library modules.

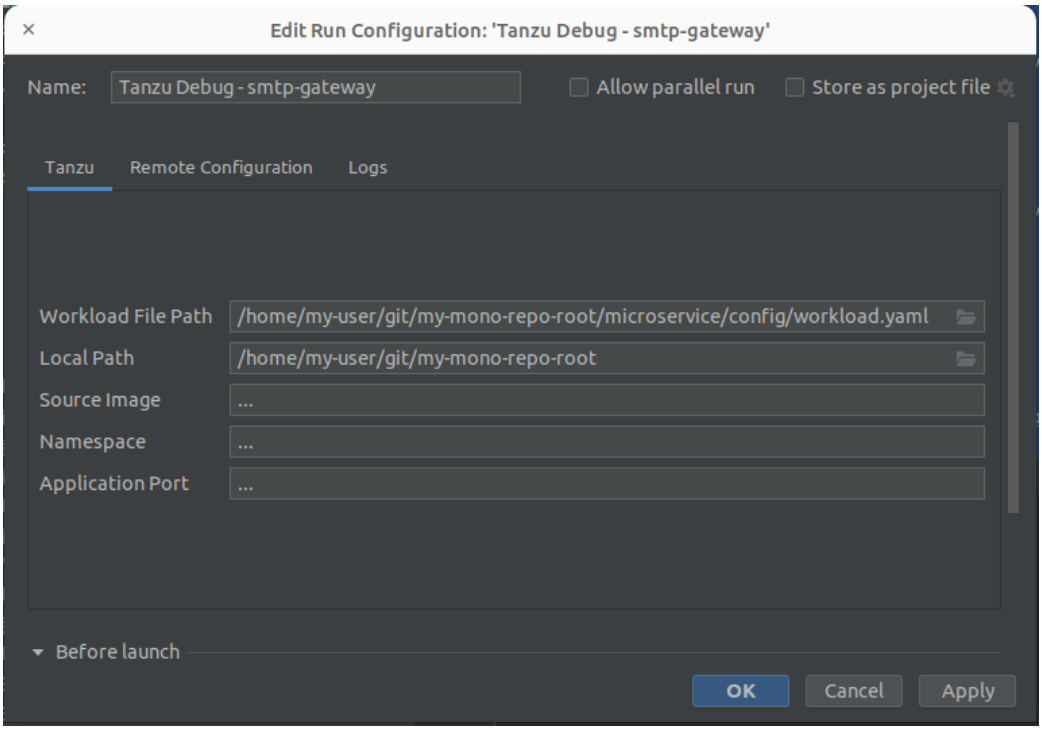
For these projects, make these adjustments:

1. Make `workload.yaml` point to the repository root, not a subfolder. Because submodules have dependencies on code outside of their own subfolder, all source code from the repository must be supplied to the workload builder.
2. Make `workload.yaml` specify additional buildpack arguments through environment variables. They differentiate the submodule that the build is targeting.

   Both of these `workload.yaml` changes are in the following example:

   ```
   apiVersion: carto.run/v1alpha1
   kind: Workload
   metadata:
   name: fortune-ui
   labels:
     apps.tanzu.vmware.com/workload-type: web
     app.kubernetes.io/part-of: fortune-ui
   spec:
   build:
     env:
        - name: BP_MAVEN_BUILD_ARGUMENTS
        value: package -pl fortune-teller-ui -am # indicate which module to build.
        - name: BP_MAVEN_BUILT_MODULE
        value: fortune-teller-ui # indicate where to find the built artefact to de
   ploy.
   source:
     git:
        url: https://github.com/my-user/fortune-teller # repository root
        ref:
        branch: main
   ```

   For more information about these and other `BP_xxx` buildpack parameters, see the Buildpack documentation.
3. Make the local path attribute in the launch configuration for each workload point to the path of the repository root. Because submodules have dependencies on code outside of their own subfolder, all source code from the repository must be supplied to the workload builder.



Change logging verbosity

The Tanzu Language Server saves logs to `~/tanzu-langserver.log`. You can change the log verbosity in **Preferences** > **Tools** > **Tanzu Developer Tools**.

Work with Native Image for Java

Native Image is technology for compiling Java code ahead of time to a binary, which is a native executable file. For more information about Native Image, see the GraalVM documentation.

Native Image requires some changes to your `workload.yaml` files, such as adding new environment variables to the build section of the workload specifications:

```
spec:
  build:
    env:
      - name: BP_NATIVE_IMAGE
        value: "true"
      - name: BP_MAVEN_BUILD_ARGUMENTS
        value: -Dmaven.test.skip=true --no-transfer-progress package -Pnative
      - name: BP_JVM_VERSION
        value: 17 ## only JVM 17 and later versions support native images. Depending o
n your configuration, this might already be the default value.
```

Use native images with Maven

If you are using Maven, you must also add a native profile that includes `native-maven-plugin` for the build phase in `pom.xml`:

```
<profiles>
        <profile>
        <id>native</id>
        <build>
           <plugins>
              <plugin>
                 <groupId>org.graalvm.buildtools</groupId>
```

```
                    <artifactId>native-maven-plugin</artifactId>
                </plugin>
            </plugins>
         </build>
        </profile>
</profiles>
```

Supported Features

There are some differences on supported features when working with Native images:

- You can deploy workloads with native images by running the `Tanzu: Apply Workload` command.
- You can delete workloads with native images by running the `Tanzu: Delete Workload` command.
- Debug and Live Update are not supported when using native images. However you can add an additional `workload.yaml` file that doesn't use a native image to iterate on your development.

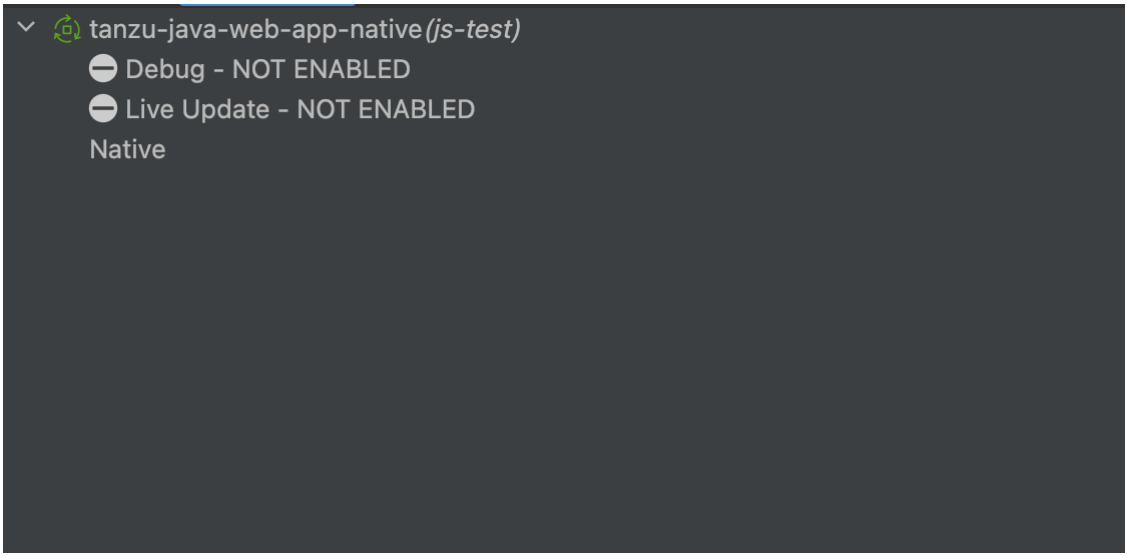
This example `workload.yaml` specification has a native image flag:

```
...
spec:
  build:
    env:
      - name: BP_NATIVE_IMAGE
        value: "true"
...
```

This example `workload.yaml` specification doesn't have a native image flag:

```
...
spec:
  build:
    env:
      #- name: BP_NATIVE_IMAGE
      #  value: "true"
...
```

The Tanzu Workloads panel adds the `Native` label to any workloads that contain native images.



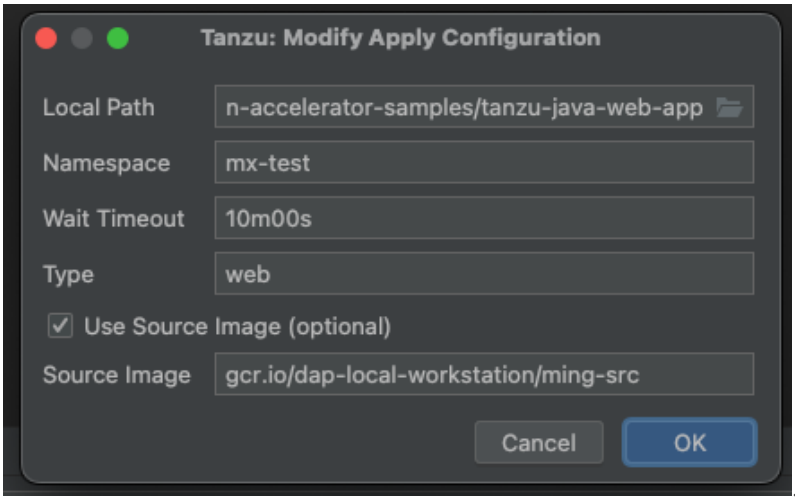
.

Update Workload Apply configurations

The `--wait-timeout` and the `--type` flags can be configured.

For more information, see the Tanzu CLI Command Reference documentation.

To use Telepresence, use `--type server`.



Use a `portforward` to access an application locally

You can create a `portforward` by clicking **Port Forward** in the pop-up menu in the Tanzu Workloads panel.

A `portforward` enables you to easily access the application, when iterating locally, in the Tanzu Workloads panel from a local URL (via the pop-up menu action) or a Knative URL (for the web type of workloads).

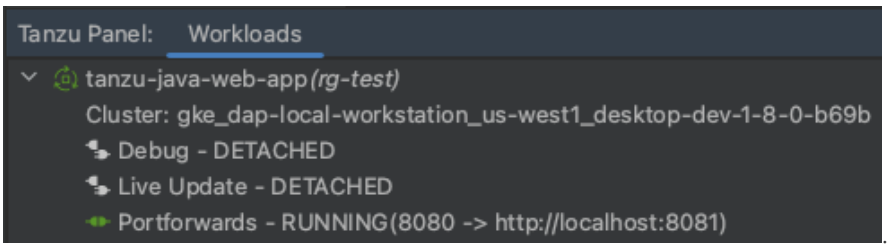
The option to use a `portforward` is only available if containers in your workload have either:

- A `PORT` environment variable
- An entry in the `ports` array that specifies `TCP` as the `protocol`

For example:

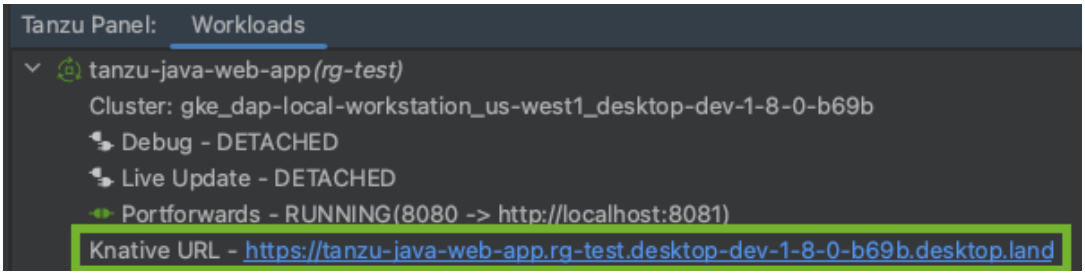
```
ports:
- containerPort: 8080
  name: user-port
  protocol: TCP
```

Existing `portforwards` are shown in the Tanzu Workloads panel. You can stop a `portforward` by clicking **Stop Port Forward** in the pop-up menu in the Tanzu Workloads panel. The option to stop a `portforward` is only available if there is an existing `portforward`.



View the Knative URL

If your workload deploys a Knative service, you can view the Knative URL through the Tanzu Workloads panel.



Glossary of terms

This topic gives you explanations of common terms used throughout the Tanzu Developer Tools for IntelliJ documentation, and within the extension itself. Some of these terms are unique to Tanzu Application Platform, while others might have a different meaning outside of Tanzu Application Platform and are included here for clarification.

Live Update

Live Update, facilitated by Tilt, enables you to deploy your workload once, save changes to the code, and see those changes reflected in the workload running on the cluster within seconds.

Tiltfile

The Tiltfile is a file with no extension that is required for Tilt to enable the Live Update feature. For more information about the Tiltfile, see the Tilt documentation.

Debugging on the cluster

The Tanzu Developer Tools on IntelliJ extension enables you to debug your application in an environment similar to production by debugging on your Tanzu Application Platform enabled Kubernetes cluster.

Note

An environment's similarity to production relies on keeping dependencies updated, among other variables.

YAML file format

YAML is a human-readable data-serialization language. It is commonly used for configuration files. For more information, see the YAML Wikipedia entry.

workload.yaml file

The workload YAML file is a required configuration file used by the Tanzu Application Platform to specify the details of an application including its name, type, and source code URL.

catalog-info.yaml file

The catalog-info YAML file enables the workloads created with the Tanzu Developer Tools for IntelliJ extension to be visible in Tanzu Developer Portal.

Code snippet

Code snippets enable you to quickly add project files that are necessary to develop using Tanzu Application Platform by creating a template in an empty file that you fill out with the required information.

Source image

The source image is the registry location to publish local source code, for example, `registry.io/yourapp-source`. This must include both a registry and a project name.

Local path

The local path value tells the Tanzu Developer Tools for IntelliJ extension which directory on your local file system to bring into the source image container image. The default local path value is the current directory where you saved the files for your open IntelliJ project.

Kubernetes context

A Kubernetes context is a set of access parameters that contains a Kubernetes cluster, a user, and a namespace. A Kubernetes context acts like a set of coordinates that describe the target of the Kubernetes commands that you run. For more information, see the Kubernetes documentation.

Kubernetes namespace

As defined by the Kubernetes documentation, in Kubernetes, namespaces provide a mechanism for isolating groups of resources within a single cluster. Names of resources need to be unique within a namespace, but not across namespaces.

Troubleshoot Tanzu Developer Tools for IntelliJ

This topic helps you troubleshoot issues with Tanzu Developer Tools for IntelliJ.

Unable to view workloads on the panel when connected to GKE cluster

Symptom

When connecting to Google's GKE clusters, an error appears with the text `WARNING: the gcp auth plugin is deprecated in v1.22+, unavailable in v1.25+; use gcloud instead.`

Cause

GKE authentication was extracted into a separate plug-in and is no longer inside the Kubernetes client or libraries.

Solution

Download and configure the GKE authentication plug-in. For instructions, see the Google documentation.

Deactivated launch controls after running a launch configuration

Symptom

When you run or debug a launch configuration, IntelliJ deactivates the launch controls.

Cause

IntelliJ deactivates the launch controls to prevent other launch configurations from being launched at the same time. These controls are reactivated when the launch configuration is started. As such, starting multiple Tanzu debug and live update sessions is a synchronous activity.

Starting a Tanzu Debug session fails with `Unable to open debugger port`

Symptom

You try to start a Tanzu Debug session and it immediately fails with an error message similar to:

```
Error running 'Tanzu Debug - fortune-teller-fortune-service': Unable to open debugger
port (localhost:5005): java.net.ConnectException "Connection refused"
```

Cause

Old Tanzu Debug launch configurations sometimes appear to be corrupted after installing a later version of the plug-in. You can see whether this is the problem you are experiencing by opening the launch configuration:

1. Right-click `workload.yaml`.
2. Click **Modify Run Configuration...** in the menu.
3. Scroll down and expand the **Before Launch** section of the dialog.
4. Verify that it contains the two Unknown Task entries `com.vmware.tanzu.tanzuBeforeRunPortForward` and `com.vmware.tanzu.tanzuBeforeRunWorkloadApply`.

Because these two tasks are unknown causes, these steps of the debug launch are not run. This in turn means that the target application is not deployed and accessible on the expected port, which causes an error when the debugger tries to connect to it.

It might be that although the launch configuration appears corrupt when seen in the launch config editor, in fact there is no corruption. It's suspected that this problem only occurs when you install a new version of the plug-in and start using it before first restarting IntelliJ.

There is possibly an issue in the IntelliJ platform that prevents completely or correctly initializing the plug-in when the plug-in is hot-swapped into an active session instead of loaded on startup.

Solution

Closing and restarting IntelliJ typically fixes this problem. If that doesn't work for you, delete the old corrupted launch configuration and recreate it.

Timeout error when Live Updating

Symptom

When you attempt to Live Update your workload, the following error message appears in the log:

```
ERROR: Build Failed: apply command timed out after 30s - see }}{{https://docs.tilt.dev/api.html#api.update_settings{{ for how to increase}}
```

Cause

Kubernetes times out on upserts over 30 seconds.

Solution

Add `update_settings (k8s_upsert_timeout_secs = 300)` to the Tiltfile. For more information, see the Tiltfile documentation.

Tanzu Panel empty when using a GKE cluster on macOS

Symptom

On macOS, the Tanzu Panel doesn't display workloads or any other resources when using a GKE cluster. Other tools, such as the Tanzu CLI Apps plug-in, display resources correctly.

Cause

`gke-cloud-auth-plugin` is required to properly authenticate to a GKE cluster. However, when starting IntelliJ from Dock or Spotlight, environment variables set by using `.profile`, `.bash_profile`, or `.zshrc` are not available. For more information, see this YouTrack issue.

This might cause `gke-cloud-auth-plugin` to be missing from `PATH` when launching IntelliJ and prevent the Tanzu Panel from reaching the cluster.

Solution

Open IntelliJ from the CLI. Example command:

```
open /Applications/IntelliJ\ IDEA.app
```

Tanzu Panel is empty when the context is set by using the `KUBECONFIG` environment variable

Symptom

On macOS, the Tanzu Panel doesn't display workloads or any other resources when setting the Kubernetes context by using a `KUBECONFIG` environment variable. Other tools, such as the Tanzu CLI Apps plug-in, display resources correctly.

Cause

When starting IntelliJ from Dock or Spotlight, environment variables set by using `.profile`, `.bash_profile`, or `.zshrc` are not available. This causes the panels to be empty because the extension can't find the right Kubernetes context. For more information, see this YouTrack issue.

Solution

Open IntelliJ from the CLI. For example:

```
open /Applications/IntelliJ\ IDEA.app
```

Tanzu panel shows workloads but doesn’t show Kubernetes resources

Symptom

The Tanzu panel shows workloads but doesn’t show Kubernetes resources in the center panel of the activity pane.

Cause

When switching the Kubernetes context, the activity pane doesn’t automatically update the namespace, but the workload pane detects the new namespace. Therefore, the Tanzu panel shows workloads but doesn’t show Kubernetes resources in the center panel of the activity pane.

Solution

Restart IntelliJ to properly detect the context change.

Tanzu Workloads panel workloads only have describe and delete action

Symptom

Some or all workloads in the Tanzu Workloads panel only have describe and delete actions.

Cause

By design, only associated workloads have apply, debug, and Live Update workload actions available.

Solution

Open a project that contains a module that can be associated with your deployed workloads.

Workload actions do not work when in a project with spaces in the name

Symptom

Workload actions and Live Update do not work. The console displays an error message similar to:

```
Error: unknown command "projects/my-app" for "apps workload apply". Process finished w
ith exit code 1
```

Cause

Improper handling of paths that contain spaces causes the shell to misinterpret some commands, such as `tanzu workload apply ...`. This causes anything executing these commands to fail when the name of a project, or any parts of its path on disk, contain spaces.

Solution

1. Close the code editor.
2. Move or rename your project folder on the disk, ensuring that no part of its path contains any spaces.

3. Delete the project settings folder from the project to start with a clean slate. The folder is `.idea` if using IntelliJ and `.vscode` if using VS Code.
4. Open the code editor and then open the project in its new location.

A lock wrongly prevents Live Update from starting again

Symptom

A lock incorrectly shows that Live Update is still running and prevents Live Update from starting again.

Cause

Restarting your computer while running Live Update without terminating the Tilt process beforehand.

Solution

Delete the Tilt lock file. The default location for the file is `~/.tilt-dev/config.lock`.

UI liveness check causes an EDT Thread Exception error

Symptom

An **EDT Thread Exception** error is logged or reported as a notification with a message similar to `"com.intellij.diagnostic.PluginException: 2007 ms to call on EDT TanzuApplyAction#update@ProjectViewPopup"`.

Cause

A UI liveness check detected something taking more time than planned on the UI thread and freezing the UI. You might experience a brief UI freeze at the same time. This happens more commonly when starting IntelliJ because some initialization processes are still running. This issue is also commonly reported by users with large projects.

If slow startup processes cause the issue, the UI freeze is likely to be brief. If a large number of files causes the issue, the UI freeze is likely to be more severe.

Solution

There is no workaround currently other than trying to reduce the number of files in your project, though that might not be practical in some cases. A fix is planned for the next release.

Frequent application restarts

Symptom

When an application is applied from IntelliJ it restarts frequently.

Cause

An application or environment behavior is triggering the application to restart.

Observed trigger behaviors include:

- The application itself writing logs to the file system in the application directory that Live Update is watching

- Autosave being set to a very high frequency in the IDE configuration

Solution

Prevent the trigger behavior. Example solutions include:

- Prevent 12-factor applications from writing to the file system.
- Reduce the autosave frequency to once every few minutes.

Overview of Tanzu Developer Tools for Visual Studio

VMware Tanzu Developer Tools for Visual Studio is the official VMware Tanzu IDE extension for Visual Studio 2022. The extension helps you develop with Tanzu Application Platform and enables you to rapidly iterate on your workloads on supported Kubernetes clusters that have Tanzu Application Platform installed.

Tanzu Developer Tools for Visual Studio currently supports .NET C# applications.

This extension is for Microsoft Visual Studio 2022 only. It is incompatible with Visual Studio Code and Visual Studio for Mac.

Note

This extension is in the beta stage of development.

Extension features

The extension has the following features:

- **Deploy applications directly from Visual Studio:**

  Rapidly iterate on your applications on Tanzu Application Platform and deploy them as workloads directly from within Visual Studio.

- **See code updates running on-cluster in seconds:**

  With the use of Live Update facilitated by Tilt, deploy your workload once, save changes to the code and then, seconds later, see those changes reflected in the workload running on the cluster.

- **Debug workloads directly on the cluster:**

  Debug your application in a production-like environment by debugging on your Kubernetes cluster that has Tanzu Application Platform. An environment's similarity to production relies on keeping dependencies updated, among other variables.

- **See workloads running on the cluster:**

  From the Tanzu Panel, you can see any workload found within the cluster and namespace specified in the current kubectl context.

- **Work with microservices in a Visual Studio solution:**

  Work with multiple solution projects that represent discrete microservices. This makes it possible to deploy, debug, and Live Update multiple workloads simultaneously from the same solution.

Note

The new variation of Out of the Box (OOTB) Basic supply chains, which outputs Carvel packages to enable configuring multiple runtime environments, is not currently supported. For more information about the variation, see Carvel Package Supply Chains.

Next steps

Install Tanzu Developer Tools for Visual Studio.

Overview of Tanzu Developer Tools for Visual Studio

VMware Tanzu Developer Tools for Visual Studio is the official VMware Tanzu IDE extension for Visual Studio 2022. The extension helps you develop with Tanzu Application Platform and enables you to rapidly iterate on your workloads on supported Kubernetes clusters that have Tanzu Application Platform installed.

Tanzu Developer Tools for Visual Studio currently supports .NET C# applications.

This extension is for Microsoft Visual Studio 2022 only. It is incompatible with Visual Studio Code and Visual Studio for Mac.

Note

This extension is in the beta stage of development.

Extension features

The extension has the following features:

- **Deploy applications directly from Visual Studio:**

  Rapidly iterate on your applications on Tanzu Application Platform and deploy them as workloads directly from within Visual Studio.

- **See code updates running on-cluster in seconds:**

  With the use of Live Update facilitated by Tilt, deploy your workload once, save changes to the code and then, seconds later, see those changes reflected in the workload running on the cluster.

- **Debug workloads directly on the cluster:**

  From the Tanzu Panel, you can see any workload found within the cluster and namespace specified in the current kubectl context.

- **Work with microservices in a Visual Studio solution:**

  Work with multiple solution projects that represent discrete microservices. This makes it possible to deploy, debug, and Live Update multiple workloads simultaneously from the same solution.

Note

The new variation of Out of the Box (OOTB) Basic supply chains, which outputs Carvel packages to enable configuring multiple runtime environments, is not currently supported. For more information about the variation, see Carvel Package Supply Chains.

Next steps

Install Tanzu Developer Tools for Visual Studio.

Install Tanzu Developer Tools for Visual Studio

This topic tells you how to install VMware Tanzu Developer Tools for Visual Studio.

Prerequisites

Before installing the extension, you must have:

- Visual Studio 2022 v17.7 or later
- kubectl
- Tilt v0.30.12 or later
- Tanzu CLI and plug-ins
- A cluster with the Tanzu Application Platform Full profile or Iterate profile

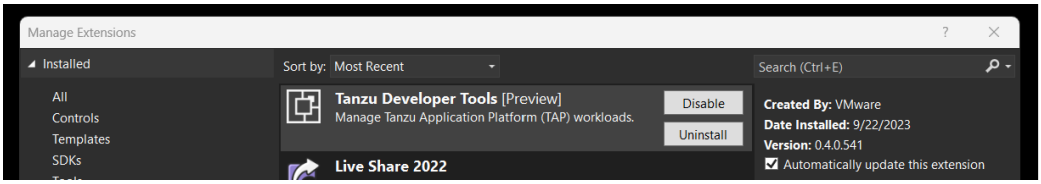
Note

If you are an app developer, someone else in your organization might have already set up the Tanzu Application Platform environment.

Install

To install Tanzu Developer Tools for Visual Studio:

1. Download VMware Tanzu Developer Tools for Visual Studio from VMware Tanzu Network.
2. Double-click the `.vsix` install file and click through the prompts.
3. Open Visual Studio and, from top menu, click **Extensions** > **Manage Extensions**.
4. Verify that the extension is installed and that it is the version you want.



Update

To update to a later version, repeat the steps in the Install section. You do not need to uninstall the current version.

Uninstall

To uninstall:

1. From the top menu, click the **Extensions** tab and then click **Manage Extensions**.
2. Select the **Installed** section and then click the **Uninstall** button for this extension.

Next steps

Getting Started with Tanzu Developer Tools for Visual Studio.

Get Started with Tanzu Developer Tools for Visual Studio

This topic guides you through getting started with VMware Tanzu Developer Tools for Visual Studio.

Prerequisite

Install Tanzu Developer Tools for Visual Studio.

Configure Local Source Proxy

Configure Local Source Proxy if you're able to do so. For more information, see the Local Source Proxy documentation.

If you cannot use Local Source Proxy, use a source image registry. Before deploying a workload, you must authenticate with an image registry to store your source code. You can use the Docker CLI to authenticate or you can set environment variables that the Tanzu CLI can use to authenticate.

Docker CLI
To authenticate by using the Docker CLI, run:

```
docker login $REGISTRY_HOSTNAME -u $REGISTRY_USERNAME -p $REGISTRY_PASSWORD
```

Tanzu CLI
To authenticate by using the Tanzu CLI, export environment variables by running:

```
export TANZU_APPS_REGISTRY_CA_CERT=PATH-TO-CA-CERT.nip.io.crt
export TANZU_APPS_REGISTRY_PASSWORD=USERNAME
export TANZU_APPS_REGISTRY_USERNAME=PASSWORD
```

`CA_CERT` is only needed for a custom or private registry.

For more information, see Workload creation fails due to authentication failure in Docker Registry.

Set up Tanzu Developer Tools

The extension makes use of the following files within your project:

- `workload.yaml`
- `catalog-info.yaml`
- `Tiltfile`
- `.tanzuignore`

You can create these files by using the instructions in this topic, or use the files in the View an example project section.

There are two ways to create these files:

- Using the code snippets that Tanzu Developer Tools provide, which create templates in empty files that you then fill in with the required information.
- Writing the files manually.

Create the `workload.yaml` file

Your project must contain a file named `workload.yaml`. For example, `MyApp\Config\workload.yaml`.

`workload.yaml` provides instructions to Supply Chain Choreographer for how to build and manage a workload. For more information, see Supply Chain Choreographer for Tanzu.

The Tanzu Developer Tools for Visual Studio extension requires at least one `workload.yaml` file per project. `workload.yaml` must be a single-document YAML file, not a multi-document YAML file.

To create a `workload.yaml` file by using Visual Studio:

1. Right-click the Solution Explorer project.
2. Click **Add** > **New Folder**.
3. Name the folder `Config`.
4. Right-click the new `Config` folder and then click **Add** > **New Item...**.
5. From the available list of items, click **Tanzu Workload** > **Add**.
6. Follow the instructions at the top of the created file.

See the following `workload.yaml` example:

```
apiVersion: carto.run/v1alpa1
kind: Workload
metadata:
 name: APP-NAME
 labels:
   apps.tanzu.vmware.com/workload-type: WORKLOAD-TYPE
   app.kubernetes.io/part-of: APP-NAME
spec:
 source:
   git:
     url: GIT-SOURCE-URL
     ref:
       branch: GIT-BRANCH-NAME
```

Where:

- `APP-NAME` is the name of your application. For example, `my-app`.
- `WORKLOAD-TYPE` is the type of workload for your app. For example, `web`. For more information, see Workload types.
- `GIT-SOURCE-URL` is the Git source code URL for your app. For example, `github.com/mycompany/myapp`.
- `GIT-BRANCH-NAME` is the branch of the Git source code you want to use. For example, `main`.

Alternatively, you can use the Tanzu CLI to create a `workload.yaml` file. For more information, see Create or update a workload.

Create the `catalog-info.yaml` file

Your project must contain a file named `catalog-info.yaml`. For example, `MyApp\Catalog\catalog-info.yaml`.

`catalog-info.yaml` enables the workloads created with Tanzu Developer Tools for Visual Studio to appear in Tanzu Developer Portal. For more information, see Overview of Tanzu Developer Portal.

To create a `catalog-info.yaml` file by using Visual Studio:

1. Right-click the Solution Explorer project.
2. Click **Add** > **New Folder**.
3. Name the folder `Catalog`.
4. Right-click the new `Catalog` folder and then click **Add** > **New Item...**.
5. From the available list of items, click **Tanzu Catalog Info** > **Add**.
6. Follow the instructions at the top of the created file.

See the following `catalog-info.yaml` example:

```
apiVersion: backstage.io/v1alpha1
kind: Component
metadata:
 name: APP-NAME
 description: APP-DESCRIPTION
 tags:
   - tanzu
 annotations:
   'backstage.io/kubernetes-label-selector': 'app.kubernetes.io/part-of=APP-NAME'
spec:
 type: service
 lifecycle: experimental
 owner: default-team
```

Where:

- `APP-NAME` is the name of your application.
- `APP-DESCRIPTION` is a description of your application.

Create the Tiltfile file

Your project must contain a file named `Tiltfile`. For example, `MyApp\Tiltfile`.

The `Tiltfile` provides the configuration for Tilt to enable your project to Live Update on the Tanzu Application Platform-enabled Kubernetes cluster. For more information, see the Tilt documentation.

To create a `Tiltfile` file by using Visual Studio:

1. Right-click the Solution Explorer project.
2. Click **Add** > **New Item...**
3. From the available list of items, click **Tanzu Tiltfile** > **Add**.
4. Follow the instructions at the top of the created file.

See the following `Tiltfile` example:

```
SOURCE_IMAGE = os.getenv("SOURCE_IMAGE", default='SOURCE-IMAGE-VALUE')
LOCAL_PATH = os.getenv("LOCAL_PATH", default='.')
NAMESPACE = os.getenv("NAMESPACE", default='default')
LIVE_UPDATE_PATH = os.getenv("LIVE_UPDATE_PATH", default='bin/Debug/net6.0')

k8s_custom_deploy(
```

```
   'APP-NAME',
   apply_cmd="tanzu apps workload apply -f Config/workload.yaml --live-update" +
       " --local-path " + LOCAL_PATH +
       " --build-env BP_DEBUG_ENABLED=true" +
       " --namespace " + NAMESPACE +
       " --output yaml" +
       " --yes",
   delete_cmd="tanzu apps workload delete " +  APP-NAME + " --namespace " + NAMESPACE
+ " --yes" ,
   deps=['bin'],
   container_selector='workload',
   live_update=[
       sync(LIVE_UPDATE_PATH, '/workspace')
   ]
)

k8s_resource('APP-NAME', port_forwards=["8080:8080"],
   extra_pod_selectors=[{'carto.run/workload-name': 'APP-NAME', 'app.kubernetes.io/com
ponent': 'run'}])
allow_k8s_contexts('CONTEXT-NAME')
```

Where `APP-NAME` is the name of your application

If your Tanzu Application Platform-enabled Kubernetes cluster is running on your local machine, you can remove the entire `allow_k8s_contexts` line. For more information about this line, see the Tilt documentation.

Create the `.tanzuignore` file

Your project can contain a file named `.tanzuignore`. When working with local source code, `.tanzuignore` excludes files from the source code that is uploaded within the image. It has syntax similar to the `.gitignore` file.

This file must be placed in the project root to work. For example, `MyApp\.tanzuignore`.

To create a `Tiltfile` file by using Visual Studio:

1. Right-click the Solution Explorer project.
2. Click **Add** > **New Item...**.
3. From the available list of items, click **Tanzu Ignore file** > **Add**.

For an example, see the `.tanzuignore` file in GitHub that is used for the sample Tanzu Java web app. You can use the file as it is or edit it for your needs.

View an example project

Before you begin, you need a container image registry to use the sample application. There are two ways to view a sample application that demonstrates the necessary configuration files:

Use Application Accelerator
If your company has configured Application Accelerator, you can obtain the sample application there if it was not removed.

To view the example by using Application Accelerator:

1. Open Application Accelerator. You might need to contact a separate team in your organization to learn they placed it.
2. Search for `Steeltoe Weather Forecast` in Application Accelerator.
3. Add the required configuration information and generate the application.

4. Unzip the application and open the directory in Visual Studio.

Clone from GitHub

To clone the example from GitHub:

1. Use `git clone` to clone the application-accelerator-samples repository from GitHub.
2. Go to the `weatherforecast-steeltoe` directory.
3. Open the `Tiltfile` and replace `your-registry.io/project` with your registry.

Next steps

Use Tanzu Developer Tools for Visual Studio.

Use Tanzu Developer Tools for Visual Studio

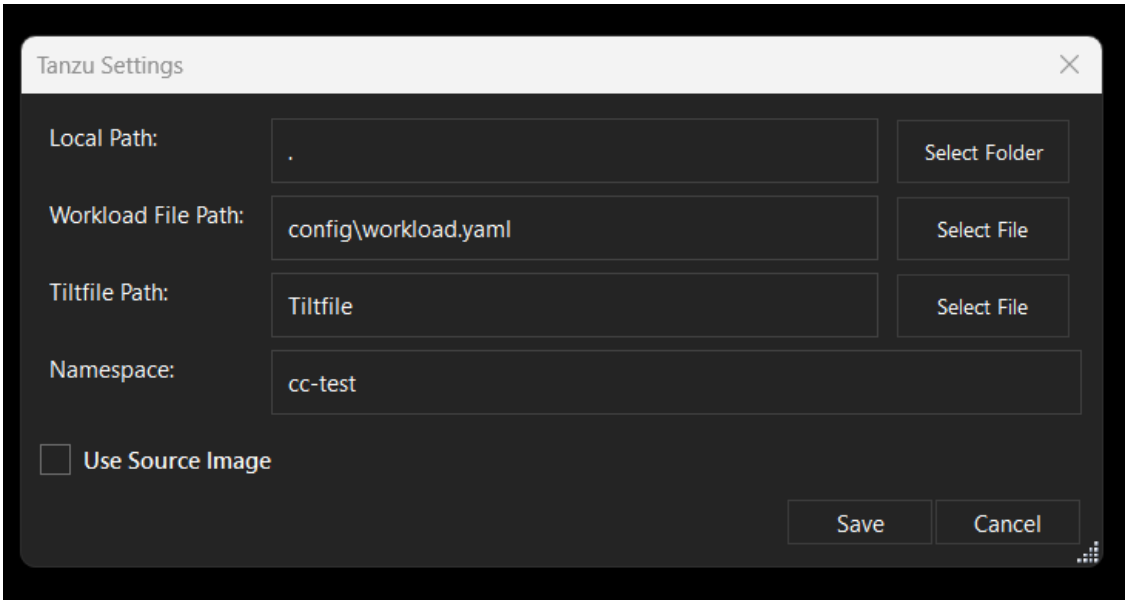
This topic tells you how to use VMware Tanzu Developer Tools for Visual Studio.

Note

This extension is in the beta stage of development.

Configure settings

To configure settings, right-click anywhere in the Solution Explorer and click **Tanzu** > **Settings...**.



Workload Actions

The extension enables you to apply, debug, and Live Update your application on a Kubernetes cluster that has Tanzu Application Platform. The developer sandbox experience enables you to Live Update your code, and simultaneously debug the updated code, without deactivating Live Update.

Apply a workload

To apply a workload, right-click anywhere in the Solution Explorer and click **Tanzu** > **Apply Workload**. Alternatively, right-click an associated workload in the Tanzu Panel and click **Apply**

Workload.

Delete a workload

To delete a workload, right-click anywhere in the Solution Explorer and click **Tanzu** > **Delete Workload**. Alternatively, right-click an associated workload in the Tanzu Panel and click **Delete Workload**.

Start debugging on the cluster

To remote debug a workload, right-click anywhere in the Solution Explorer and click **Tanzu** > **Debug Workload**. Alternatively, right-click an associated workload in the Tanzu Panel and click **Debug Workload**.

Caution

Do not use the red square Stop button to end your debugging session. Using the red square Stop button might cause the Tanzu Application Platform workload to fail. Instead, in the top menu click **Debug** > **Detach All**.

If the name of your running app process (the app DLL process), does not match the name of your .NET project as shown in the Visual Studio Solution Explorer, the remote debugging agent might fail to attach.

Live Update

See the following sections for how to use Live Update.

Start Live Update

Ensure that the following Tanzu Settings parameters are set:

- **Local Path**, which is the path on the local file system to a directory of source code to build.
- **Namespace**, which is the namespace that workloads are deployed into. Optional.
- **Source Image**, which is the registry location for publishing local source code. For example, `registry.io/yourapp-source`. It must include both a registry and a project name. The source image parameter is not needed if you configured Local Source Proxy.

To start Live Update, right-click anywhere in the Solution Explorer and click **Tanzu** > **Start Live Update**. Alternatively, right-click an associated workload in the Tanzu Panel and click **Start Live Update**.

After starting Live Update, local builds changes are synchronized with the container.

Stop Live Update

To stop Live Update, right-click anywhere in the Solution Explorer and click **Tanzu** > **Stop Live Update**. Alternatively, right-click an associated workload in the Tanzu Panel and click **Stop Live Update**.

Tanzu Workloads panel

The current state of the workloads is visible in the Tanzu Workloads view. This view is a separate section in the bottom of the Explorer view in the Side Bar. The view shows the current status of

each workload, namespace, and cluster. It also shows whether Live Update and Debug is running, stopped, or deactivated.

The Tanzu Activity tab in the Panels view enables developers to visualize the supply chain, delivery, and running application pods. The tab enables a developer to view and describe logs on each resource associated with a workload from within their IDE. The tab displays detailed error messages for each resource in an error state.

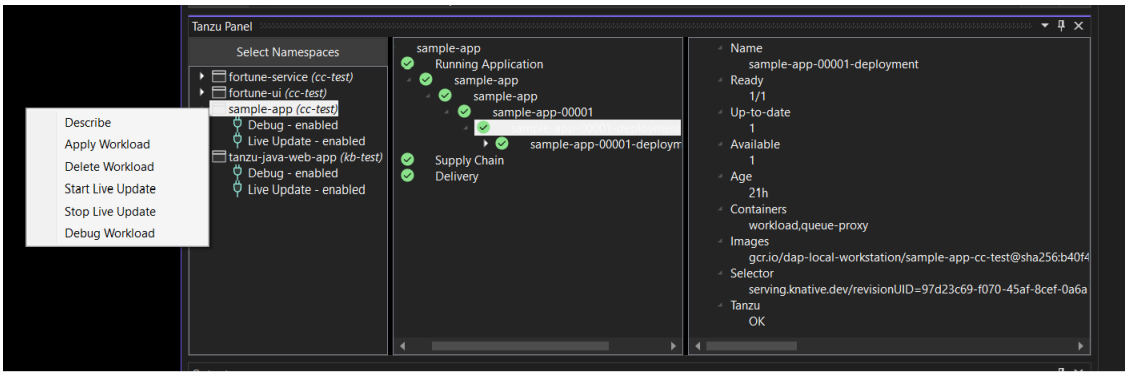
Workload commands are available from the Tanzu Workloads panel on workloads that have an associated module in the current project.

This association is based on a module name and a workload name matching. For example, a project with a module named `my-app` is associated with a deployed workload named `my-app`.

When taking an action from the Tanzu Workloads panel, the action uses the namespace of the deployed workload regardless of the configuration in the module.

For example, you might have a Live Update configuration with a namespace argument of `my-apps-1`, but running the action from a deployed workload in namespace `my-apps-2` starts a Live Update session with a namespace argument of `my-apps-2`.

The Tanzu Workloads panel uses the cluster and defaults to the namespace specified in the current kubectl context. To view the Tanzu Workloads panel, right-click anywhere in the Solution Explorer and click **Tanzu** > **View Workloads**.



Extension logs

The extension creates log entries in two files named `tanzu-dev-tools-{GUID}.log` and `tanzu-language-server-{GUID}.log`. These files are in the directory where Visual Studio Installer installed the extension.

To find the log files from PowerShell, run:

```
dir $Env:LOCALAPPDATA\Microsoft\VisualStudio\*\Extensions\*\Logs\tanzu-*.log
```

To find the log files from CMD, run:

```
dir %LOCALAPPDATA%\Microsoft\VisualStudio\*\Extensions\*\Logs\tanzu-*.log
```

You can override the log file paths by setting the environment variables `TANZU_DT_LOG` and `TANZU_LS_LOG`.

Troubleshoot Tanzu Developer Tools for Visual Studio

This topic tells you how to troubleshoot issues you encounter with VMware Tanzu Developer Tools for Visual Studio.

Stop button causes workload to fail

Symptom

Clicking the red square Stop button in the Visual Studio top toolbar causes the Tanzu Application Platform workload to fail or become unresponsive indefinitely.

Solution

To end a debugging session, in the top menu click **Debug** > **Detach All**.

Frequent application restarts

Symptom

When an application is applied from Visual Studio it restarts frequently.

Cause

An application or environment behavior is triggering the application to restart.

Observed trigger behaviors include:

- The application itself writing logs to the file system in the application directory that Live Update is watching
- Autosave being set to a very high frequency in the IDE configuration

Solution

Prevent the trigger behavior. Example solutions include:

- Prevent 12-factor applications from writing to the file system.
- Reduce the autosave frequency to once every few minutes.

Overview of Tanzu Developer Tools for VS Code

VMware Tanzu Developer Tools for Visual Studio Code (VS Code) is the official VMware Tanzu IDE extension for VS Code. The extension helps you develop with Tanzu Application Platform and enables you to rapidly iterate on your workloads on supported Kubernetes clusters that have Tanzu Application Platform installed.

Tanzu Developer Tools for VS Code currently supports VS Code on macOS and Windows OS for Java applications.

Extension features

The extension has the following features:

- **Deploy applications directly from VS Code:**

  Rapidly iterate on your applications on Tanzu Application Platform by deploying them as workloads directly from within VS Code.

- **See code updates running on-cluster in seconds:**

  With Live Update (facilitated by Tilt), you can deploy your workload once, save changes to the code and then see those changes reflected within seconds in the workload running on the cluster.

- **Debug workloads directly on the cluster:**

  Debug your application in a production-like environment by debugging on your Kubernetes cluster that has Tanzu Application Platform. An environment's similarity to production relies on keeping dependencies and other variables updated.

- **See workloads running on the cluster:**

  From the Tanzu Workloads panel you can see any workload found within the cluster and namespace specified in the current kubectl context.

- **Make a ready-to-code development environment by using development containers (alpha):**

  Use developer containers to make a ready-to-code development environment. This enables developers to connect to a pre-configured development container that includes all Tanzu tools and IDE extensions required for development on Tanzu pre-installed.

- **Connect to a sandbox cluster:**

  You can connect to a Tanzu Application Platform sandbox instance from Tanzu Developer Tools for VS Code to try Tanzu Application Platform and see its benefits. To use Developer Sandbox and connect to it from your IDE, see the Tanzu Academy website.

Note

The new variation of Out of the Box (OOTB) Basic supply chains, which outputs Carvel packages to enable configuring multiple runtime environments, is not currently supported. For more information about the variation, see Carvel Package Supply Chains.

Overview of Tanzu Developer Tools for VS Code

VMware Tanzu Developer Tools for Visual Studio Code (VS Code) is the official VMware Tanzu IDE extension for VS Code. The extension helps you develop with Tanzu Application Platform and enables you to rapidly iterate on your workloads on supported Kubernetes clusters that have Tanzu Application Platform installed.

Tanzu Developer Tools for VS Code currently supports VS Code on macOS and Windows OS for Java applications.

Extension features

The extension has the following features:

- **Deploy applications directly from VS Code:**

  Rapidly iterate on your applications on Tanzu Application Platform by deploying them as workloads directly from within VS Code.

- **See code updates running on-cluster in seconds:**

- **Make a ready-to-code development environment by using development containers (alpha):**

  Use developer containers to make a ready-to-code development environment. This enables developers to connect to a pre-configured development container that includes all Tanzu tools and IDE extensions required for development on Tanzu pre-installed.

- **Connect to a sandbox cluster:**

  You can connect to a Tanzu Application Platform sandbox instance from Tanzu Developer Tools for VS Code to try Tanzu Application Platform and see its benefits. To use Developer Sandbox and connect to it from your IDE, see the Tanzu Academy website.

Note

The new variation of Out of the Box (OOTB) Basic supply chains, which outputs Carvel packages to enable configuring multiple runtime environments, is not currently supported. For more information about the variation, see Carvel Package Supply Chains.

Install Tanzu Developer Tools for VS Code

This topic tells you how to install VMware Tanzu Developer Tools for Visual Studio Code (VS Code).

Prerequisites

Before installing the extension, you must have:

- VS Code
- kubectl
- Tilt v0.30.12 or later
- Tanzu CLI and plug-ins
- A cluster with the Tanzu Application Platform Full profile or Iterate profile

If you are an app developer, someone else in your organization might have already set up the Tanzu Application Platform environment.

Docker Desktop and local Kubernetes are not prerequisites for using Tanzu Developer Tools for VS Code.

Install

To install VMware Tanzu Developer Tools for VS Code:

1. Open Visual Studio Code.
2. Open the command palette.
3. In the search box enter `Extension`.
4. Click **Extensions: Install Extensions**.

5. The **Extensions** view opens on the left side of your screen. In the search box enter `Tanzu`.
6. Click **Tanzu Developer Tools** and then click **Install**.

Configure

To configure VMware Tanzu Developer Tools for VS Code:

1. Ensure that you are targeting the correct cluster. For more information, see the Kubernetes documentation.
2. Go to **Code** > **Preferences** > **Settings** > **Extensions** > **Tanzu Developer Tools** and set the following:
    - **Confirm Apply Config**: This controls whether the extension asks to confirm user input when applying a workload.
    - **Confirm Debug Port**: This controls whether the extension asks for the debug port when running `Tanzu: Start Java Debug`.
    - **Confirm Local Port**: This controls whether the extension asks for the local port when running `Tanzu: Start Java Debug`.
    - **Confirm Delete**: This controls whether the extension asks for confirmation when deleting a workload.
    - **Enable Live Hover**: This enables Live Hover. For more information, see Integrating Live Hover by using Spring Boot Tools. Restart VS Code for this change to take effect.
    - **Source Image**: The registry location for publishing local source code. For example, `registry.io/yourapp-source`. This must include both a registry and a project name. A source image registry location is optional when Local Source Proxy is configured.
    - **Local Path**: (Optional) The path on the local file system to a directory of source code to build. This is the current directory by default.
    - **Namespace**: (Optional) This is the namespace that workloads are deployed into. The namespace set in kubeconfig is the default.
    - **Tracked Namespaces**: (Optional) Comma-separated list of namespaces. Resources in these namespaces appear in the Tanzu Workloads panel and the Activity panel. If empty, the namespace in the current context is the default.
    - **Wait Timeout**: (Optional) This sets how long to wait for a workload to become ready.
    - **Workload Type**: (Optional) This distinguishes the workload type. Examples include web and server.

Uninstall

To uninstall VMware Tanzu Developer Tools for VS Code:

1. Go to **Code** > **Preferences** > **Settings** > **Extensions**.
2. Right-click the extension and then click **Uninstall**.

Next steps

Proceed to Getting started with Tanzu Developer Tools for Visual Studio Code.

Get started with Tanzu Developer Tools for VS Code

This topic guides you through getting started with VMware Tanzu Developer Tools for Visual Studio Code (VS Code).

Prerequisite

Install VMware Tanzu Developer Tools for Visual Studio Code.

Configure Local Source Proxy or use a source image registry

Configure Local Source Proxy if you're able to do so. For more information, see the Local Source Proxy documentation.

If you cannot use Local Source Proxy, use a source image registry. Before deploying a workload, you must authenticate with an image registry to store your source code. You can use the Docker CLI to authenticate or you can set environment variables that the Tanzu CLI can use to authenticate.

Docker CLI
To authenticate by using the Docker CLI, run:

```
docker login $REGISTRY_HOSTNAME -u $REGISTRY_USERNAME -p $REGISTRY_PASSWORD
```

Tanzu CLI
To authenticate by using the Tanzu CLI, export environment variables by running:

```
export TANZU_APPS_REGISTRY_CA_CERT=PATH-TO-CA-CERT.nip.io.crt
export TANZU_APPS_REGISTRY_PASSWORD=USERNAME
export TANZU_APPS_REGISTRY_USERNAME=PASSWORD
```

`CA_CERT` is only needed for a custom or private registry.

For more information, see Workload creation fails due to authentication failure in Docker Registry.

Set up Tanzu Developer Tools

The extension makes use of the following files within your project:

- `workload.yaml`
- `catalog-info.yaml`
- `Tiltfile`
- `.tanzuignore`

You can create these files by using the instructions in this topic, or use the files in the View an example project section.

There are two ways to create these files:

- Using the code snippets that Tanzu Developer Tools provide, which create templates in empty files that you then fill in with the required information.
- Writing the files manually.

Create the `workload.yaml` file

`workload.yaml` provides instructions to the Supply Chain Choreographer about how to build and manage a workload.

The extension requires only one `workload.yaml` file per project. `workload.yaml` must be a single-document YAML file, not a multidocument YAML file.

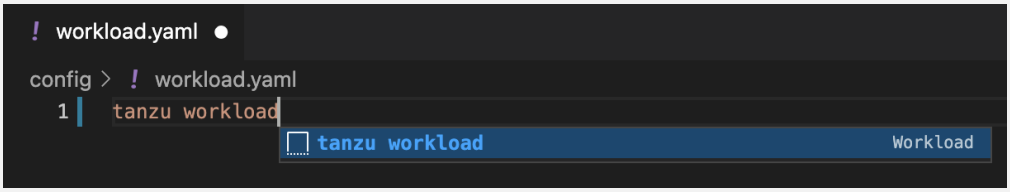
Before beginning to write your `workload.yaml` file, ensure that you know:

- The name of your application. For example, `my app`.
- The workload type of your application. For example, `web`.
- The GitHub source code URL. For example, `github.com/mycompany/myapp`.
- The Git branch of the source code that you intend to use. For example, `main`.

Code snippets

To create a `workload.yaml` file by using code snippets:

1. (Optional) Create a directory named `config` in the root directory of your project. For example, `my project/config`.
2. Create a file named `workload.yaml` in the new config directory. For example, `my project/config/workload.yaml`.
3. Open the new `workload.yaml` file in VS Code, enter `tanzu workload` in the file to trigger the code snippets, and either press Enter or left-click the `tanzu workload` text in the drop-down menu.



4. Fill in the template by pressing the Tab key.

Manual

To create your `workload.yaml` file manually, follow this example:

```
apiVersion: carto.run/v1alpa1
kind: Workload
metadata:
 name: APP-NAME
 labels:
   apps.tanzu.vmware.com/workload-type: WORKLOAD-TYPE
   app.kubernetes.io/part-of: APP-NAME
spec:
 source:
   git:
     url: GIT-SOURCE-URL
     ref:
       branch: GIT-BRANCH-NAME
```

Where:

- `APP-NAME` is the name of your application.
- `WORKLOAD-TYPE` is the type of this workload. For example, `web`.
- `GIT-SOURCE-URL` is your GitHub source code URL.
- `GIT-BRANCH-NAME` is the Git branch of your source code.

Alternatively, you can use the Tanzu CLI to create a `workload.yaml` file. For more information about the Tanzu CLI command, see Create or update a workload in the Tanzu CLI documentation.

Create the `catalog-info.yaml` file

`catalog-info.yaml` enables the workloads of this project to appear in Tanzu Developer Portal.

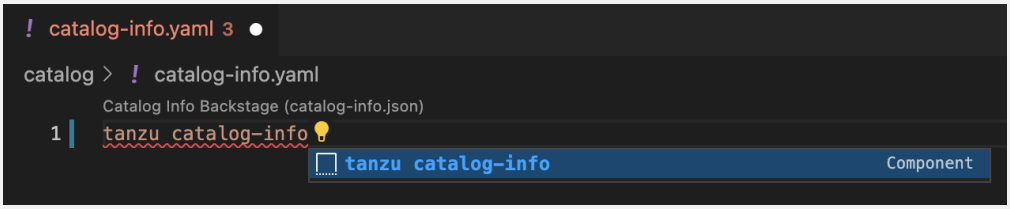
Before beginning to write your `catalog-info.yaml` file, ensure that you:

- Know the name of your application. For example, `my app`.
- Have a description of your application ready.

Code snippets

To create a `catalog-info.yaml` file by using the code snippets:

1. (Optional) Create a directory named `catalog` in the root directory of your project. For example, `my project/catalog`.
2. Create a file named `catalog-info.yaml` in the new config directory. For example, `my project/catalog/catalog-info.yaml`.
3. Open the new `catalog-info.yaml` file in VS Code, enter `tanzu catalog-info` in the file to trigger the code snippets, and then either press Enter or left-click the `tanzu catalog-info` text in the drop-down menu.



4. Fill in the template by pressing the Tab key.

Manual

To create your `catalog-info.yaml` file manually, follow this example:

```
apiVersion: backstage.io/v1alpha1
kind: Component
metadata:
 name: APP-NAME
 description: APP-DESCRIPTION
 tags:
   - tanzu
 annotations:
   'backstage.io/kubernetes-label-selector': 'app.kubernetes.io/part-of=APP-NAME'
spec:
 type: service
 lifecycle: experimental
 owner: default-team
```

Where:

- `APP-NAME` is the name of your application
- `APP-DESCRIPTION` is the description of your application

Create the Tiltfile file

The Tiltfile file provides the Tilt configuration to enable your project to Live Update on your Kubernetes cluster that has Tanzu Application Platform. The Tanzu Developer Tools extension requires only one **Tiltfile** per project.

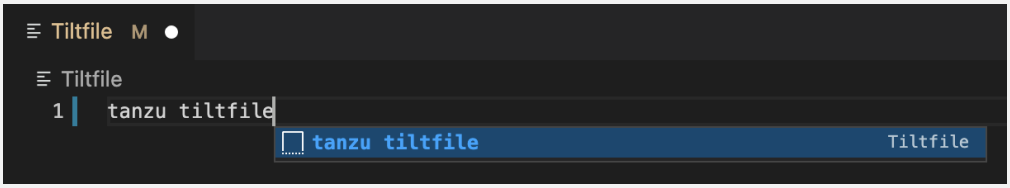
Before beginning to write your Tiltfile file, ensure that you know:

- The name of your application. For example, `my app`.
- Whether you want to compile the source image from a local directory other than the project directory or otherwise leave the `local path` value unchanged. For more information, see local path in the glossary.
- The path to your `workload.yaml` file. For example, `config/workload.yaml`.
- The name of your current Kubernetes context, if the targeting Kubernetes cluster enabled by Tanzu Application Platform is not running on your local machine.

Code Snippets

To create a Tiltfile file by using the code snippets:

1. Create a file named `Tiltfile` with no file extension in the root directory of your project. For example, `my project/Tiltfile`.
2. Open the new Tiltfile file in VS Code and enter `tanzu tiltfile` in the file to trigger the code snippets, and then either press Enter or left-click the `tanzu tiltfile` text in the drop-down menu.



3. Fill in the template by pressing the Tab key.
4. If the targeting Kubernetes cluster enabled by Tanzu Application Platform is not running on your local machine, add a new line to the end of the **Tiltfile** template and enter:

```
allow_k8s_contexts('CONTEXT-NAME')
```

Where `CONTEXT-NAME` is the name of your current Kubernetes context.

Manual

To create a Tiltfile file manually, follow this example:

```
LOCAL_PATH = os.getenv("LOCAL_PATH", default='.')
NAMESPACE = os.getenv("NAMESPACE", default='default')

k8s_custom_deploy(
   'APP-NAME',
   apply_cmd="tanzu apps workload apply -f PATH-TO-WORKLOAD-YAML --live-update" +
       " --local-path " + LOCAL_PATH +
       " --namespace " + NAMESPACE +
       " --yes >/dev/null" +
       " && kubectl get workload APP-NAME --namespace " + NAMESPACE + " -o yaml",
   delete_cmd="tanzu apps workload delete -f PATH-TO-WORKLOAD-YAML --namespace " + N
AMESPACE + " --yes" ,
   deps=['pom.xml', './target/classes'],
   container_selector='workload',
   live_update=[
       sync('./target/classes', '/workspace/BOOT-INF/classes')
   ]
)
```

```
k8s_resource('APP-NAME', port_forwards=["8080:8080"],
   extra_pod_selectors=[{'carto.run/workload-name': 'APP-NAME', 'app.kubernetes.io/component': 'run'}])
allow_k8s_contexts('CONTEXT-NAME')
```

Where:

- `APP-NAME` is the name of your application.
- `PATH-TO-WORKLOAD-YAML` is the local file system path to `workload.yaml`. For example, `config/workload.yaml`.
- `CONTEXT-NAME` is the name of your current Kubernetes context. If your Kubernetes cluster enabled by Tanzu Application Platform is running locally on your local machine, you can remove the entire `allow_k8s_contexts` line. For more information, see the Tilt documentation.

Create a `.tanzuignore` file

The `.tanzuignore` file specifies the file paths to exclude from the source code image. When working with local source code, you can exclude files from the source code to be uploaded within the image. Directories must not end with the system path separator (`/` or `\`). See this example. in GitHub.

View an example project

Before you begin, you need a container registry for the sample application.

You can view a sample application that demonstrates the necessary configuration files. There are two ways to obtain the sample application:

Application Accelerator
If your company has configured Application Accelerator, you can obtain the sample application there if it was not removed. To do so:

1. Open Application Accelerator.
2. Search for `Tanzu Java Web App` in Application Accelerator.
3. Add the required configuration information and generate the application.
4. Unzip the file and open the project in a VS Code workspace.

Clone from GitHub
To clone the sample application from GitHub:

1. Run `git clone` to clone the tanzu-java-web-app repository from GitHub.
2. Change into the `tanzu-java-web-app` directory.
3. Open the Tiltfile and replace `your-registry.io/project` with your container registry.

Next steps

Use Tanzu Developer Tools for VS Code.

Use Tanzu Developer Tools for VS Code

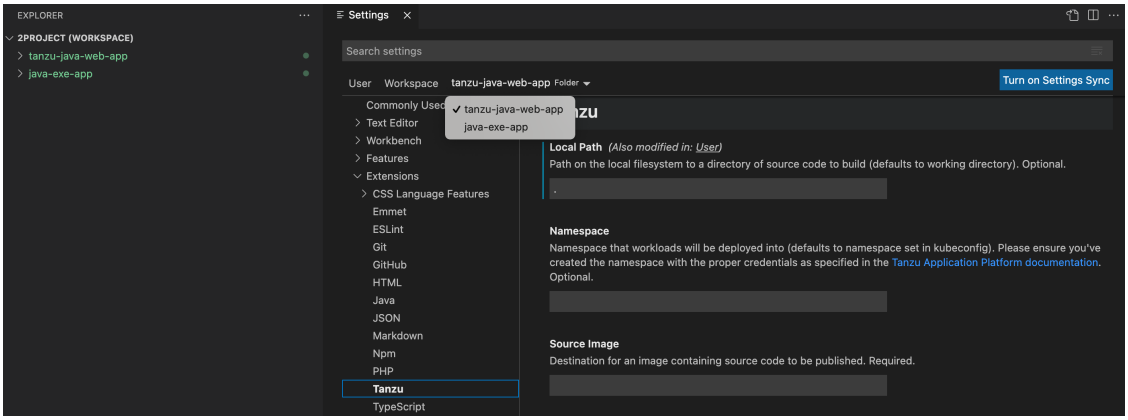
This topic tells you how to use VMware Tanzu Developer Tools for Visual Studio Code (VS Code).

Ensure that the project you want to use the extension with has the required files specified in Get started with Tanzu Developer Tools for VS Code.

The extension requires only one Tiltfile and one `workload.yaml` per project. The `workload.yaml` must be a single-document YAML file, not a multidocument YAML file.

Configure for multiple projects in the workspace

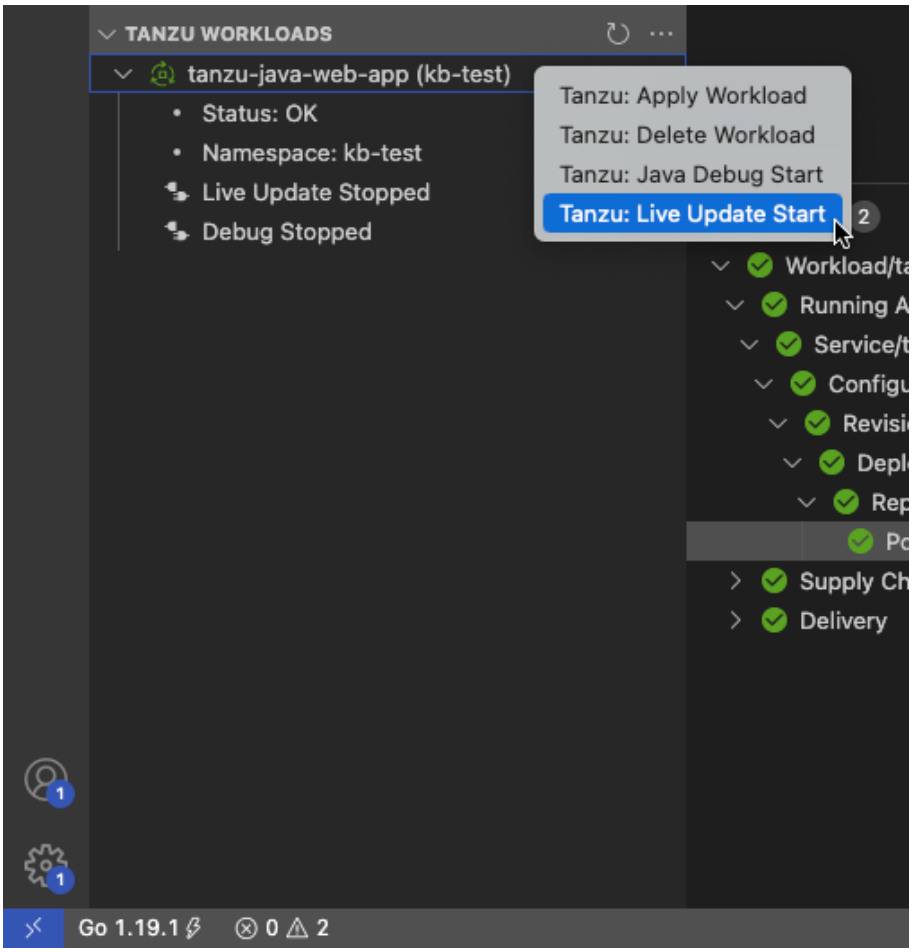
When working with multiple projects in a single workspace, you can configure the extension settings on a per-project basis by using the drop-down menu in **Settings**.



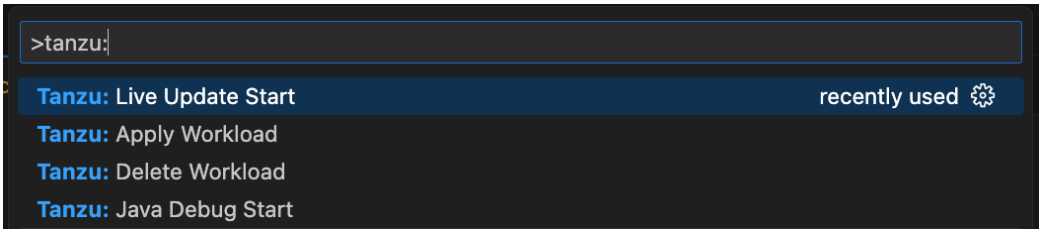
Workload Commands

All commands are available by right-clicking anywhere in the VS Code project explorer, on an associated workload in the Tanzu Workloads panel, or in the Command Palette (⇧⌘P on Mac and Ctrl+Shift+P on Windows).

- Screenshot of pop-up menu opened from the workload panel:



- Screenshot of the command palette

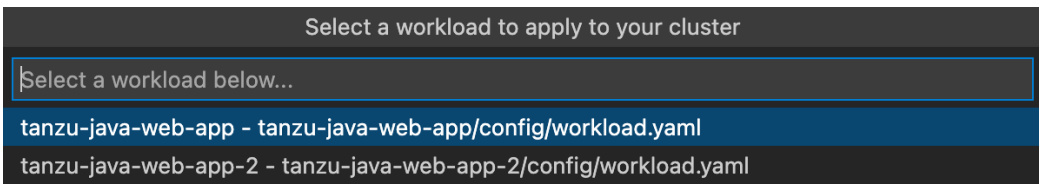


Apply a workload

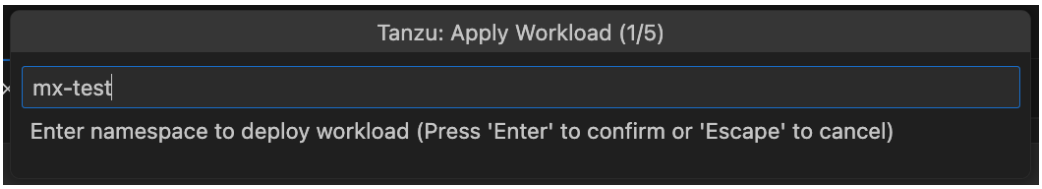
The extension enables you to apply workloads on your Kubernetes cluster that has Tanzu Application Platform.

To apply a workload:

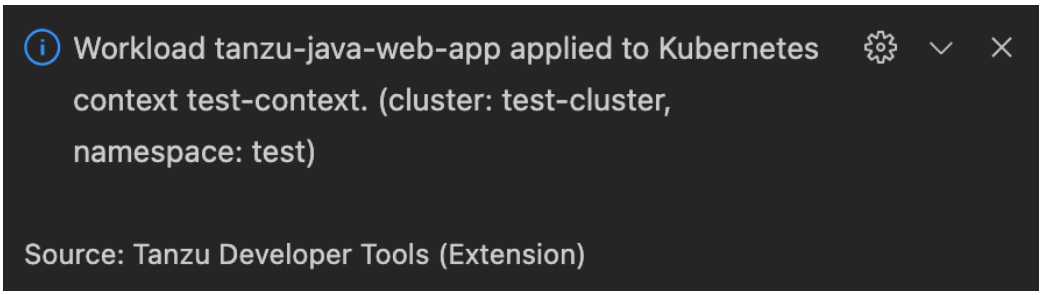
1. Right-click anywhere in the VS Code project explorer, on an associated workload in the Tanzu Workloads panel, or open the Command Palette (⇧⌘P on Mac and Ctrl+Shift+P on Windows).
2. Select the `Tanzu: Apply Workload` command.
3. If applicable, select the workload to apply.



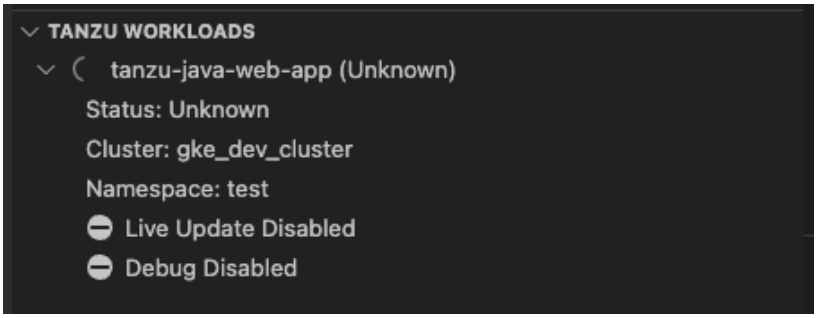
A series of dialog boxes appear that ask for information.



A notification appears showing that the workload was applied.



A new workload appears on the Tanzu Workloads panel.



After the workload is deployed, the status on the Tanzu Workloads panel changes to `Ready`.

Debugging on the cluster

The extension enables you to debug your application on your Kubernetes cluster that has Tanzu Application Platform.

Debugging requires a `workload.yaml` file in your project. For information about creating a `workload.yaml` file, see Get Started with Tanzu Developer Tools for VS Code.

The developer sandbox experience enables developers to Live Update their code, and simultaneously debug the updated code, without having to deactivate Live Update when debugging.

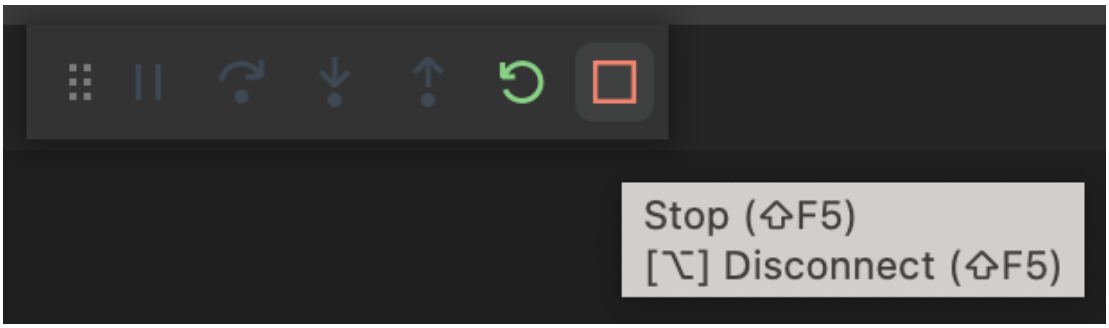
Start debugging on the cluster

To start debugging on the cluster:

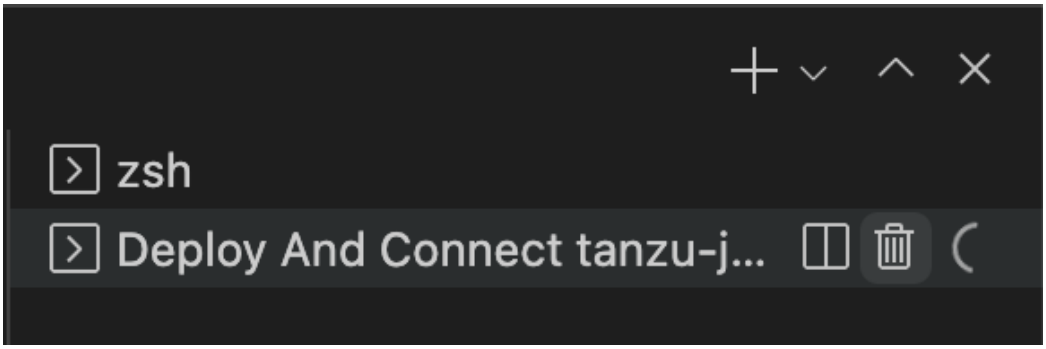
1. Add a breakpoint in your code.
2. Right-click anywhere in the VS Code project explorer, on an associated workload in the Tanzu Workloads panel, or open the Command Palette (⇧⌘P on Mac and Ctrl+Shift+P on Windows).
3. Select the `Tanzu: Java Debug Start` command..

Stop Debugging on the cluster

To stop debugging on the cluster, you can click the stop button in the Debug overlay.



Alternatively, you can press ⌘+J (Ctrl+J on Windows) to open the panel and then click the trash can button for the debug task running in the panel.



Debug apps in a microservice repository

To debug multiple apps in a microservice repository:

1. Add each app folder as a workspace folder. For instructions, see the Visual Studio Code documentation.
2. Update the `tanzu.debugPort` setting so that it does not conflict with other debugging sessions. For how to update individual workspace folder settings, see the Visual Studio Code documentation.

Live Update

With the use of Live Update facilitated by Tilt, the extension enables you to deploy your workload once, save changes to the code, and see those changes reflected in the workload running on the cluster within seconds.

Live Update requires a `workload.yaml` file and a Tiltfile in your project. For information about how to create a `workload.yaml` and a Tiltfile, see Get Started with Tanzu Developer Tools for VS Code.

The developer sandbox experience enables developers to Live Update their code, and simultaneously debug the updated code, without having to deactivate Live Update when debugging.

Start Live Update

Before using Live Update, verify that your auto-save setting is either off or on with a delay. The delay must be long enough for the application to restart between auto saves to allow enough time for your app to Live Update when files change. The auto-save setting is in **Preferences** > **Text Editor** > **Files** > **Auto Save** > **Auto Save Delay**.

To start Live Update:

1. Right-click anywhere in the VS Code project explorer, on an associated workload in the Tanzu Workloads panel, or open the Command Palette (⇧⌘P on Mac and Ctrl+Shift+P on

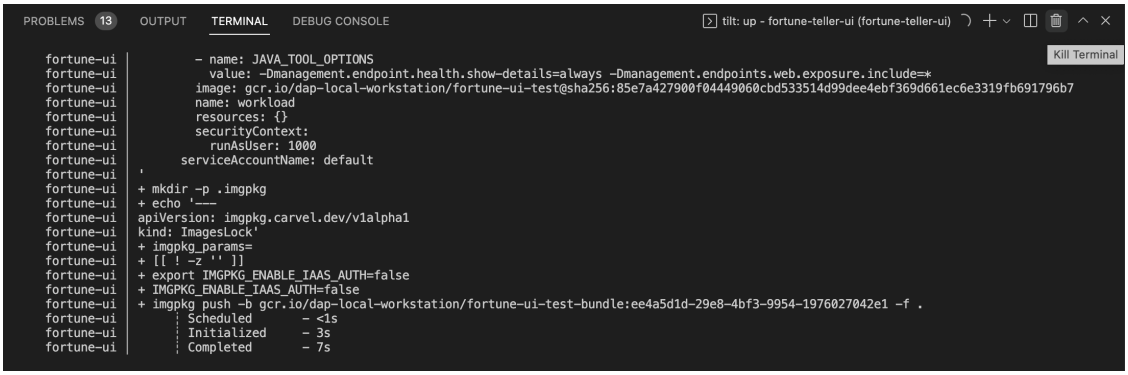
Windows).

2. Select the `Tanzu: Live Update Start` command.

Stop Live Update

When Live Update stops, your application continues to run on the cluster, but the changes you made and saved in your editor are not present in your running application unless you redeploy your application to the cluster.

To stop Live Update, click the trash can button in the terminal pane to stop the Live Update process.



Live Update apps in a microservices repository

To Live Update multiple apps in a microservice repository:

1. Add each app folder as a workspace folder. For instructions, see the Visual Studio Code documentation.
2. Ensure that a port is available to port-forward the Knative service. For example, you might have this in your Tiltfile:

   ```
   k8s_resource('tanzu-java-web-app', port_forwards=["NUMBER:8080"],
                extra_pod_selectors=[{'carto.run/workload-name': 'tanzu-java-web-ap
   p', 'app.kubernetes.io/component': 'run'}])
   ```

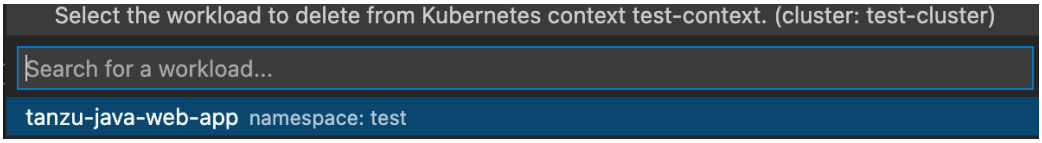
   Where `NUMBER` is the port you choose. For example, `port_forwards=["9999:8080"]`.

Delete a workload

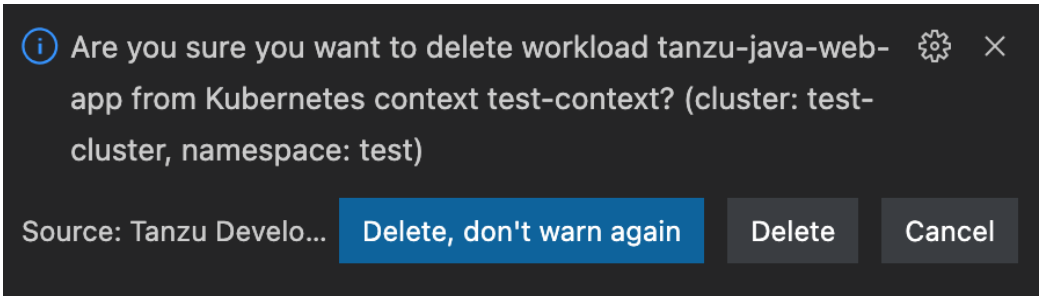
The extension enables you to delete workloads on your Kubernetes cluster that has Tanzu Application Platform.

To delete a workload:

1. Right-click anywhere in the VS Code project explorer, on an associated workload in the Tanzu Workloads panel, or open the Command Palette (⇧⌘P on Mac and Ctrl+Shift+P on Windows).
2. Select the `Tanzu: Delete Workload` command.
3. If applicable, select the workload to delete.



If the **Tanzu: Confirm Delete** setting is enabled, a message appears that prompts you to delete the workload and not warn again, delete the workload, or cancel.

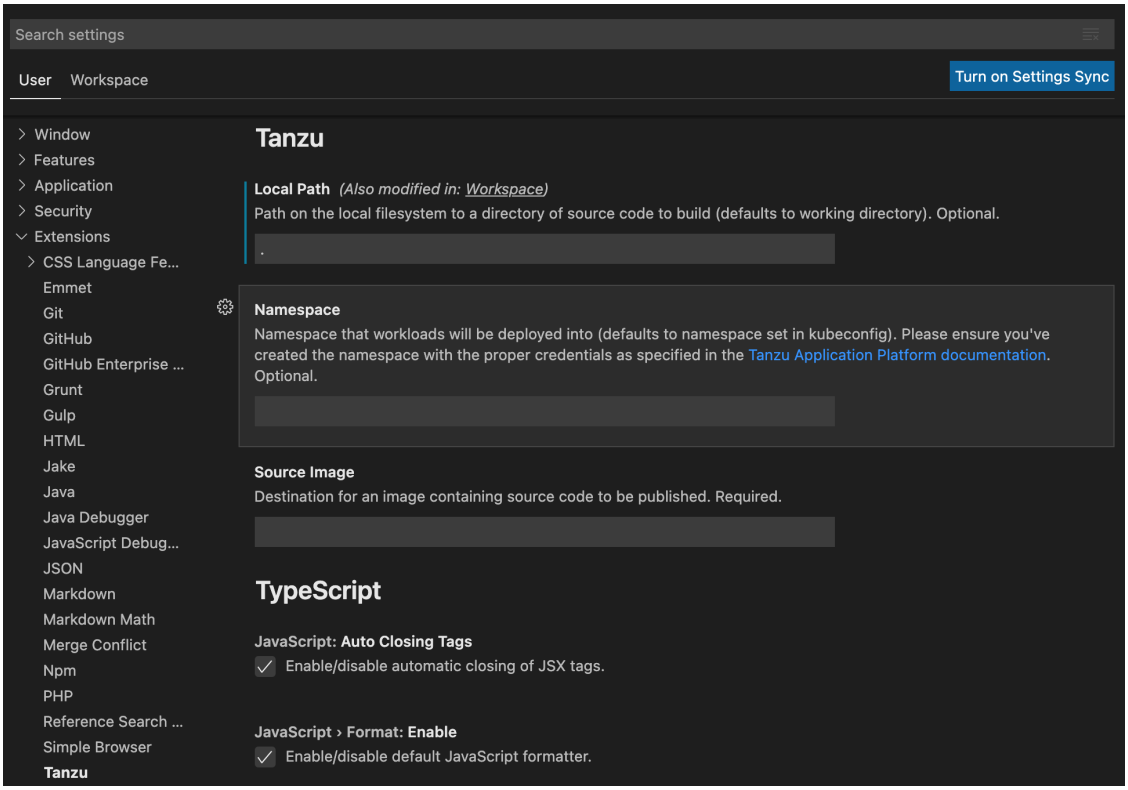


A notification appears showing that the workload was deleted.

Deploy to different namespaces

To deploy to a different namespace from where you created the workload:

1. Go to **Code** > **Preferences** > **Settings**.
2. Expand the **Extensions** section of the settings and click **Tanzu**.
3. In the **Namespace** option, add the namespace you want to deploy to. This is the `default` namespace by default.



Tanzu Workloads panel

The current state of the workloads is visible in the Tanzu Workloads view. This view is a separate section in the bottom of the Explorer view in the Side Bar. The view shows the current status of each workload, namespace, and cluster. It also shows whether Live Update and Debug is running, stopped, or deactivated.

The Tanzu Activity tab in the Panels view enables developers to visualize the supply chain, delivery, and running application pods. The tab enables a developer to view and describe logs on each

resource associated with a workload from within their IDE. The tab displays detailed error messages for each resource in an error state.

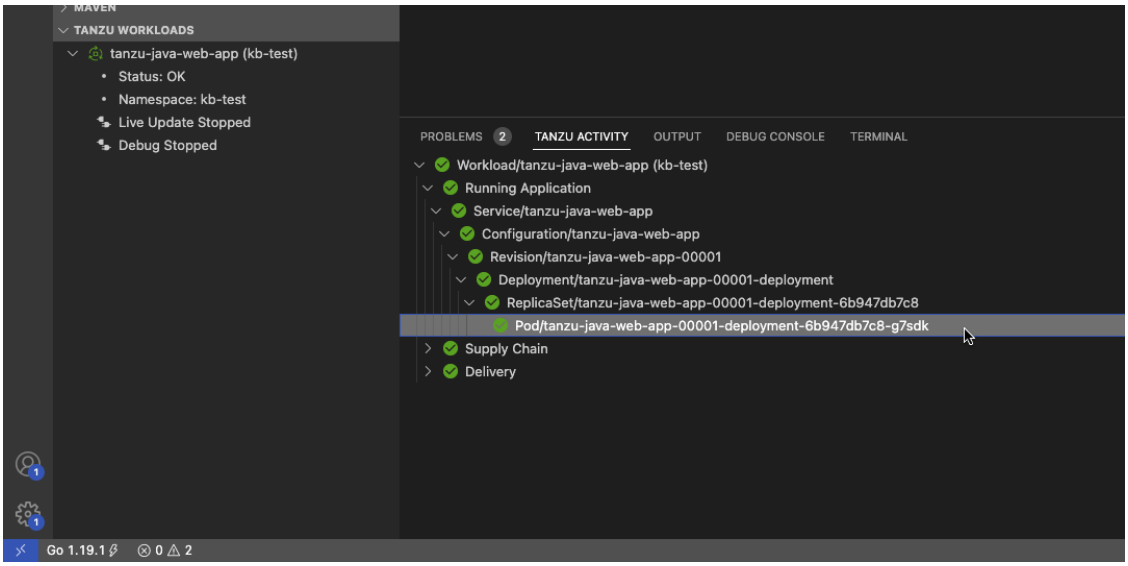
Workload commands are available from the Tanzu Workloads panel on workloads that have an associated module in the current project.

This association is based on a module name and a workload name matching. For example, a project with a module named `my-app` is associated with a deployed workload named `my-app`.

When taking an action from the Tanzu Workloads panel, the action uses the namespace of the deployed workload regardless of the configuration in the module.

For example, you might have a Live Update configuration with a namespace argument of `my-apps-1`, but running the action from a deployed workload in namespace `my-apps-2` starts a Live Update session with a namespace argument of `my-apps-2`.

The Tanzu Workloads panel uses the cluster and defaults to the namespace specified in the current kubectl context.



To add a namespace:

1. View the current context and namespace by running:

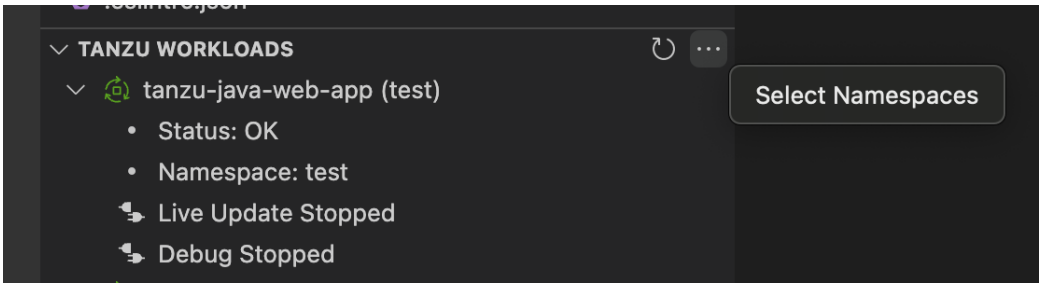
   ```
   kubectl config get-contexts
   ```

2. Set a namespace for the current context by running:

   ```
   kubectl config set-context --current --namespace=YOUR-NAMESPACE
   ```

3. Use one of these methods to add additional namespaces to your Tanzu Workloads panel:

   - Go to **Preferences** > **Extensions** > **Tanzu Developer Tools** > **Tracked Namespaces** and then select the namespaces that you want.
   - Go to **Workload Panel** > **Additional Options** > **Select Namespaces** and then select the namespaces that you want.



Working with Microservices in a Monorepo

A monorepo is single Git repository that contains multiple workloads. Each individual workload is placed in a subfolder of the main repository.

You can find an example of this in Application Accelerator. The relevant accelerator is called Spring SMTP Gateway, and you can obtain its source code as an accelerator or directly from the application-accelerator-samples GitHub repository.

This project exemplifies a typical layout:

- `MONO-REPO-ROOT/`
  - `pom.xml` (parent pom)
  - `microservice-app-1/`
  - `pom.xml`
  - `mvnw` (and other mvn-related files for building the workload)
  - `Tiltfile` (supports Live Update)
  - `config`
    - `workload.yaml` (supports deploying and debugging from IntelliJ)
  - `src/` (contains source code for this microservice)
  - `microservice-app-2/`
  - …similar layout

Recommended structure: Microservices that can be built independently

In this example, each of the microservices can be built independently of one another. Each subfolder contains everything needed to build that workload.

This is reflected in the `source` section of `workload.yaml` by using the `subPath` attribute:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: microservice-app-1
  ...
spec:
  source:
    git:
      ref:
        branch: main
      url: https://github.com/kdvolder/sample-mono-repo.git
    subPath: microservice-app-1 # build only this
  ...
```

For setting up your own repositories, it's best practice to set up a monorepo so that each microservice can be built completely independently.

To work with these monorepos:

- Import the monorepo as a project into VS Code.
- Interact with each of the subfolders in the same way you would interact with a project containing a single workload.

Alternative structure: Services with build-time interdependencies

Some monorepos do not have submodules that can be independently built. Instead the `pom.xml` files of the submodules are set up to have some build-time interdependencies. For example:

- A submodule `pom.xml` can reference the parent `pom.xml` as a common place for centralized dependency management.
- A microservice submodule can reference another, as a maven dependency.
- Several microservice submodules can reference one or more shared library modules.

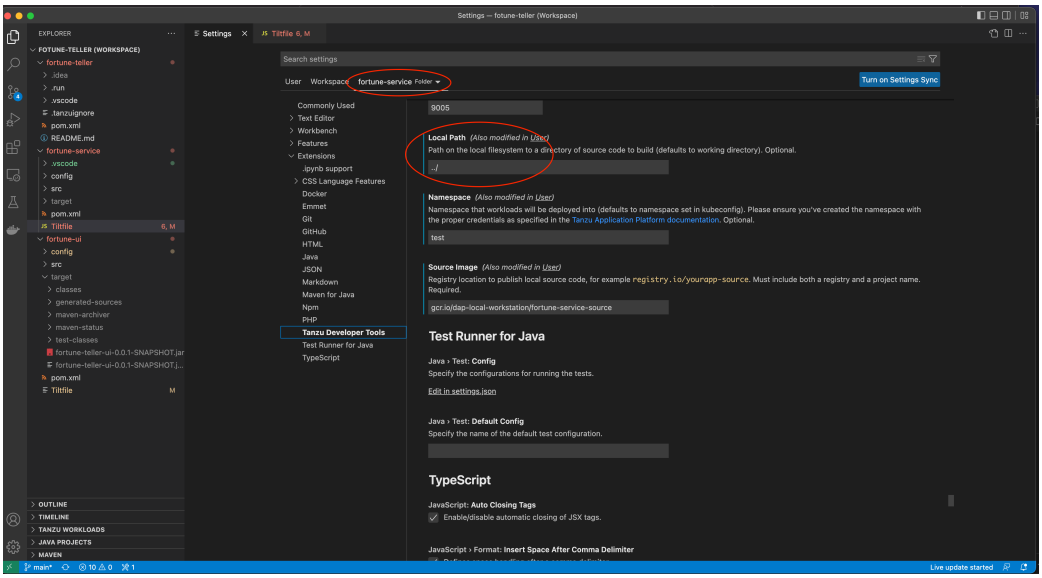
For these projects, make these adjustments:

1. Make `workload.yaml` point to the repository root, not a subfolder. Because submodules have dependencies on code outside of their own subfolder, all source code from the repository must be supplied to the workload builder.
2. Make `workload.yaml` specify additional buildpack arguments through environment variables. They differentiate the submodule that the build is targeting.

   Both of these `workload.yaml` changes are in the following example:

   ```
   apiVersion: carto.run/v1alpha1
   kind: Workload
   metadata:
   name: fortune-ui
   labels:
     apps.tanzu.vmware.com/workload-type: web
     app.kubernetes.io/part-of: fortune-ui
   spec:
   build:
     env:
       - name: BP_MAVEN_BUILD_ARGUMENTS
       value: package -pl fortune-teller-ui -am # indicate which module to build.
       - name: BP_MAVEN_BUILT_MODULE
       value: fortune-teller-ui # indicate where to find the built artefact to de
   ploy.
   source:
     git:
       url: https://github.com/my-user/fortune-teller # repo root
       ref:
       branch: main
   ```

   For more information about these and other `BP_xxx` buildpack parameters, see the Buildpack Documentation.
3. Make the local path preference for each subfolder point to the path of the repository root Because submodules have dependencies on code outside of their own subfolder, all source code from the repository must be supplied to the workload builder.



Changing logging verbosity

The Tanzu Language Server saves logs to `~/tanzu-langserver.log`. You can change the log verbosity in **Preferences** > **Settings** > **Extensions** > **Tanzu Developer Tools** > **Language Server: Log Verbosity**.

Working with Java Native images

Native Image is technology for compiling Java code ahead of time to a binary, which is a native executable file. For more information about Native Image, see the GraalVM documentation.

Native Image requires some changes to your `workload.yaml` files, such as adding new environment variables to the build section of the workload specifications:

```
spec:
  build:
    env:
      - name: BP_NATIVE_IMAGE
        value: "true"
      - name: BP_MAVEN_BUILD_ARGUMENTS
        value: -Dmaven.test.skip=true --no-transfer-progress package -Pnative
      - name: BP_JVM_VERSION
        value: 17 ## only JVM 17 and later versions support native images. Depending o
n your configuration, this might already be the default value.
```

Use native images with Maven

If you are using Maven, you must also add a native profile that includes `native-maven-plugin` for the build phase in `pom.xml`:

```
<profiles>
        <profile>
        <id>native</id>
        <build>
           <plugins>
              <plugin>
                 <groupId>org.graalvm.buildtools</groupId>
                   <artifactId>native-maven-plugin</artifactId>
                </plugin>
            </plugins>
         </build>
```

```
        </profile>
</profiles>
```

Supported Features

There are some differences on supported features when working with Native images:

- You can deploy workloads with native images by running the `Tanzu: Apply Workload` command.
- You can delete workloads with native images by running the `Tanzu: Delete Workload` command.
- Debug and Live Update are not supported when using native images. However you can add an additional `workload.yaml` file that doesn't use a native image to iterate on your development.

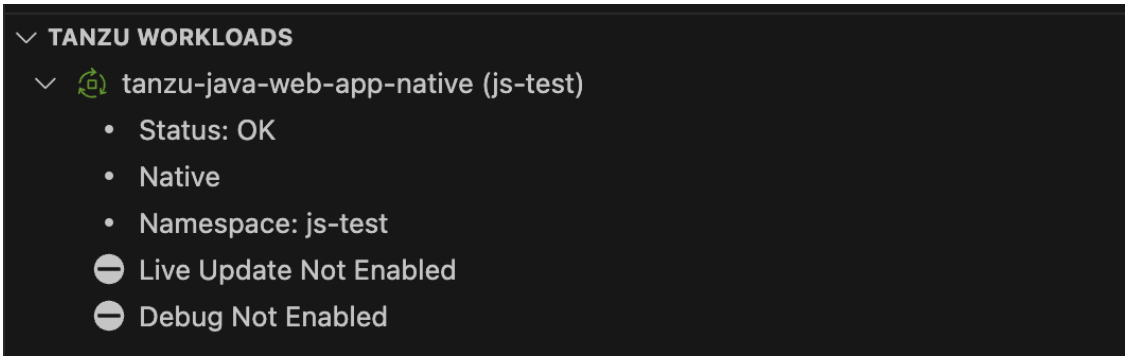
This example `workload.yaml` specification has a native image flag:

```
...
spec:
  build:
    env:
      - name: BP_NATIVE_IMAGE
        value: "true"
...
```

This example `workload.yaml` specification doesn't have a native image flag:

```
...
spec:
  build:
    env:
      #- name: BP_NATIVE_IMAGE
      #  value: "true"
...
```

The Tanzu Workloads panel adds the `Native` label to any workloads that contain native images.



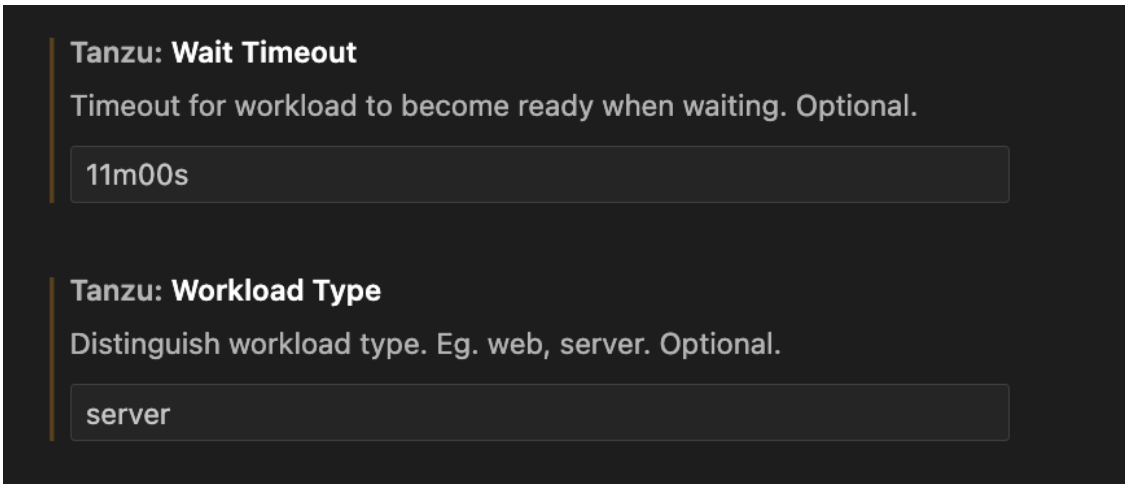
.

Update Workload Apply configurations

The `--wait-timeout` and the `--type` flags can be configured.

For more information, see the Tanzu CLI Command Reference documentation.

To use Telepresence, use `--type server`.



.

Use a `portforward` to access an application locally

You can create a `portforward` by clicking **Tanzu: Portforward** in the pop-up menu in the Tanzu Workloads panel.

A `portforward` enables you to easily access the application, when iterating locally, in the Tanzu Workloads panel from a local URL (via the pop-up menu action) or a Knative URL (for the web type of workloads).

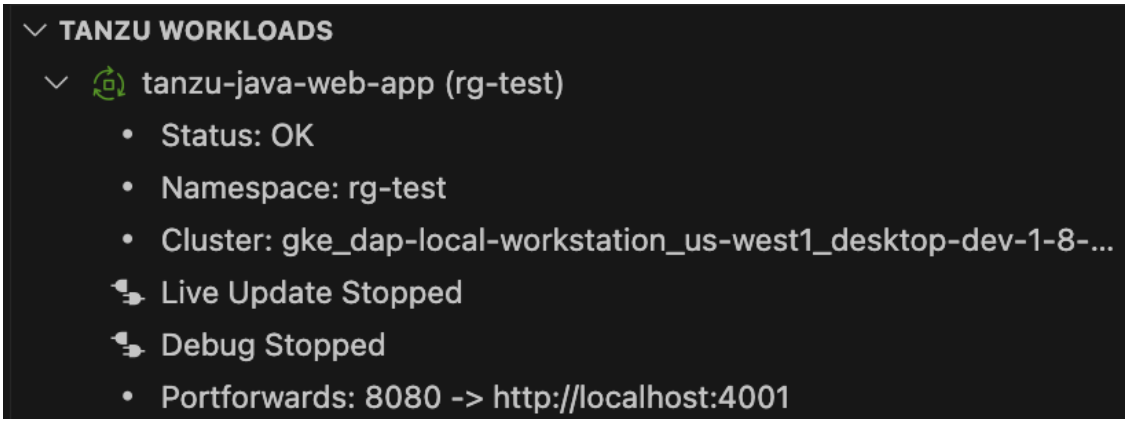
The option to use a `portforward` is only available if containers in your workload have either:

- A `PORT` environment variable
- An entry in the `ports` array that specifies `TCP` as the `protocol`

For example:

```
ports:
- containerPort: 8080
  name: user-port
  protocol: TCP
```

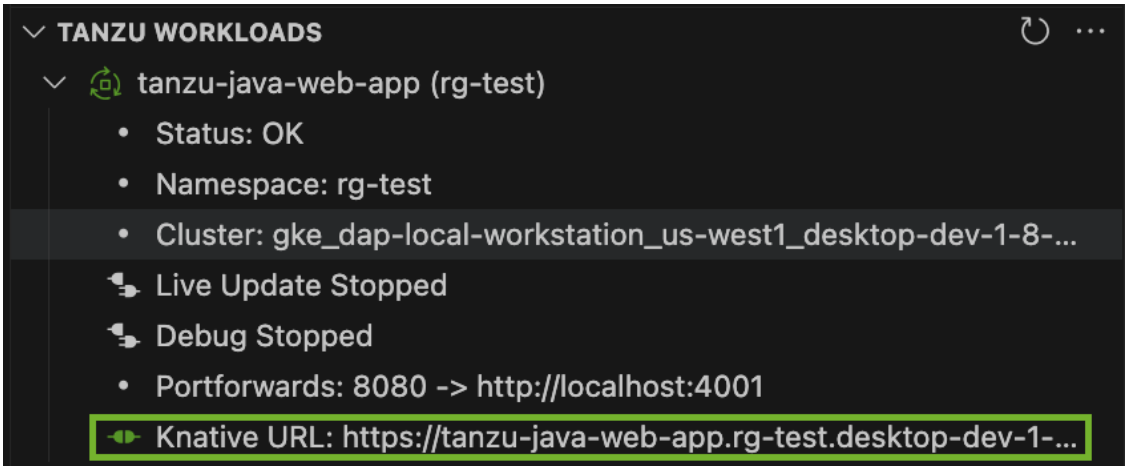
Existing `portforwards` are shown in the Tanzu Workloads panel. You can stop a `portforward` by clicking **Tanzu: Stop Portforward** in the pop-up menu in the Tanzu Workloads panel. The option to stop a `portforward` is only available if there is an existing `portforward`.



.

Viewing the Knative URL

If your workload deploys a Knative service, you can view the Knative URL through the Tanzu Workloads panel.



Use development containers to make a development environment (alpha)

This topic tells you about using development containers (sometimes shortened to dev containers) to make a ready-to-code development environment. This enables you to connect to a pre-configured development container that includes all Tanzu tools and IDE extensions required for development on Tanzu pre-installed.

Caution

Support for development containers is in alpha testing. It is intended for evaluation and test purposes only.

Overview of development containers

A development container enables you to use a container as a full-featured development environment. You can use it to:

- Run an application
- Separate tools, libraries, and runtime environments needed for working with a codebase
- Aid in continuous integration and testing

For more information, see the Development Containers documentation.

Prerequisites

Obtain the following:

- Docker Desktop v2.0 or later or Rancher Desktop on Windows or macOS. If using Docker Desktop, ensure that you meet the system requirements for the VS Code Dev Containers extension.
- The VS Code Dev Containers extension.
- AMD architecture, because ARM, such as Apple M1 Silicon, is not currently supported.

Create a new project or open an existing one

You can start a new project with support for development containers or you can add support for development containers to an existing project:

New project

To set up a new project by using accelerators and development containers:

1. From the Accelerator page in Tanzu Developer Portal, select the Tanzu Java Web App accelerator.
2. Select the options you want.
3. Select the check box for **Include .devcontainer.json (amd64 support only)**.
4. Open a project in VS Code.
5. Follow the VS Code prompts to restart the IDE in `devcontainer` to connect to the development container.

Existing project

To add a development container to an existing project:

1. Open the project with VS Code and ensure that the Tanzu Developer Tools for VS Code plug-in is v1.1.0 or later.
2. Create an empty new file named `devcontainer`.
3. Type `tanzu devcontainer` and press Enter.
4. Rename the file as `.devcontainer.json`.
5. Follow the Visual Studio Code prompts to restart the IDE in `devcontainer` to connect to the development container.

Connect to your cluster

When you start working in your development container for the first time, you must log in and connect to your Tanzu Kubernetes cluster. The method for doing so depends on your cloud provider. For example, for Google Cloud you might run a command similar to:

```
gcloud container clusters get-credentials ${your_cluster_name} --region ${your_region}
\
--project ${your_google_cloud_project_name}
```

For how to connect to a cluster, see the documentation for your specific cloud provider. Examples:

- Azure Kubernetes Service documentation
- Amazon Elastic Kubernetes Service documentation
- Google Kubernetes Engine documentation

Restart the IDE

After you log in to the cluster, restart the IDE for it to detect the new cluster connection. Press CTRL+SHIFT+P (CMD+SHIFT+P on macOS) and click **Developer: Reload Window** in the command palette.

You are now ready to start working on your code, deploy it to your cluster, and monitor your workloads in the Tanzu Panel. To continue your development with Tanzu Developer Tools for VS Code, see Use Tanzu Developer Tools for VS Code.

(Optional) Use local file mounts

Use the `mounts` property in the `.devcontainer.json` file to add a volume bound to any local directory. This is useful for sharing your Kubernetes cluster credentials with the development container, such as a macOS or Linux host.

For example:

```
"mounts": [
        "source=${localEnv:HOME}/.kube/,target=/home/vscode/.kube/,type=bind,consistency=cached"
    ],
```

For more information about using mounts with development containers, see the Visual Studio Code documentation.

VMware General Terms and other legal requirements connected to Tanzu CLI

When the `devcontainer` is created for the first time you are prompted to review and agree with the VMware General Terms and to participate in the Customer Experience Improvement Program (CEIP).

The selections you make are stored and you will not prompted again when you next start `devcontainer`.

Pinniped compatibility

This topic tells you the compatibility details of Pinniped in GitHub.

OAuth

OAuth login is compatible only when both `--skip-browser` and `--skip-listen` flags are not set.

LDAP

LDAP authentication is not compatible with VMware Tanzu Developer Tools for Visual Studio Code.

Integrate Live Hover by using Spring Boot Tools

For more information about this feature, see the **Live application information hovers** section of the Spring Boot Tools Marketplace page.

Prerequisites

To integrate Live Hover by using Spring Boot Tools you need:

- A Tanzu Spring Boot application, such as tanzu-java-web-app
- Spring Boot Extension Pack (includes Spring Boot Dashboard) extension

Activate the Live Hover feature

Activate the Live Hover feature by enabling it in **Code** > **Preferences** > **Settings** > **Extensions** > **Tanzu Developer Tools**.

Deploy a Workload to the Cluster

Follow these steps to deploy the workload for an app to a cluster, making live hovers appear. The examples in some steps reference the sample tanzu-java-web-app.

1. Clone the repository by running:

   ```
   git clone REPOSITORY-ADDRESS
   ```

   Where `REPOSITORY-ADDRESS` is your repository address. For example, `https://github.com/vmware-tanzu/application-accelerator-samples`.

2. Open the project in VS Code, with the Live Hover feature enabled, by running:

   ```
   TAP_LIVE_HOVER=true code ./PROJECT-DIRECTORY
   ```

   Where `PROJECT-DIRECTORY` is your project directory. For example, `./application-accelerator-samples/tanzu-java-web-app`.

3. Verify that you are targeting the cluster on which you want to run the workload by running:

   ```
   kubectl cluster-info
   ```

   For example:

   ```
   $ kubectl cluster-info
   Kubernetes control plane is running at https://...
   CoreDNS is running at https://...

   To further debug and diagnose cluster problems, use 'kubectl cluster-info dum
   p'.
   ```

   Tanzu Developer Tools for VS Code periodically connects to your cluster to search for pods from which live data can be extracted and shown. Tanzu Developer Tools for VS Code uses your current context from `~/.kube/config` to choose which cluster to connect with.

4. If you don't have the workload running yet, run `Tanzu: Apply Workload` from the Command Palette. Tanzu Developer Tools for VS Code periodically searches for pods in your cluster that correspond to the workload configurations it finds in your workspace.

5. The workload takes time to build and then start a running pod. To see if a pod has started running, run:

   ```
   kubectl get pods
   ```

   For example:

   ```
   $ kubectl get pods
   NAME                                                READY   STATUS      REST
   ARTS   AGE
   tanzu-java-web-app-00001-deployment-8596bfd9b4-5vgx2   2/2     Running     0
   20s
   tanzu-java-web-app-build-1-build-pod                0/1     Completed   0
   2m26s
   tanzu-java-web-app-config-writer-fpnzb-pod          0/1     Completed   0
   67s
   ```

   In this example, live data can be extracted from the `...-0001-deployment-...` pod.

6. Open a Java file, such as `HelloController.java`. After a delay of up to 30 seconds, because of a 30-second polling loop, green highlights appear in your code.

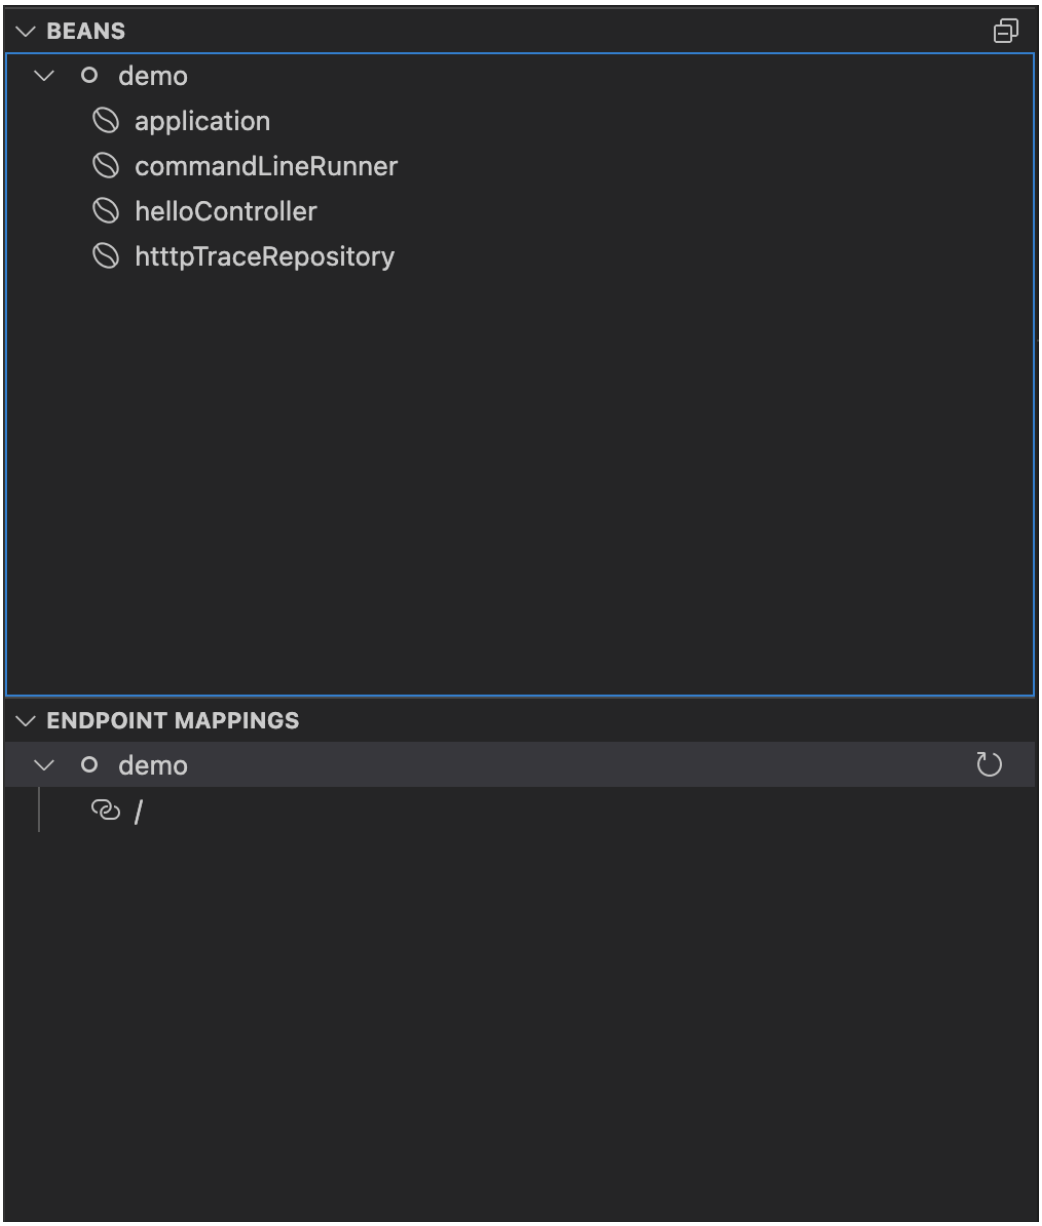
```
@RestController
public class HelloController {

    http://tanzu-java-web-app.my-apps.vipins2appsso.cloudfocused.in/ (Count=1 Total=0.06s Max=0.06s)
    @RequestMapping("/")
    public String index() {

        return "Greetings from Spring Boot + Tanzu + TAP!";
    }

}
```

7. Hover over any of the bubbles to see live information about the corresponding element.
8. The `Live Beans` and `Live Endpoint Mapping` information are displayed in Spring Boot Dashboard. To view the Spring Boot Dashboard, run `View: Show Spring Boot Dashboard` from the Command Palette.



Use Memory View in Spring Boot Dashboard

This topic tells you how to use Spring Boot Dashboard to view memory use.

For more information about Spring Boot Dashboard, see Spring Boot Dashboard.

Prerequisites

To see the Memory View in Spring Boot Dashboard you need:

- A Tanzu Spring Boot application, such as tanzu-java-web-app
- The Spring Boot Extension Pack, which includes Spring Boot Dashboard

Deploy a workload

Deploy the workload for an app to a cluster by following the steps in Deploy a Workload to the Cluster.

View memory use in Spring Boot Dashboard

To view the Spring Boot Dashboard, run `View: Show Spring Boot Dashboard` from the Command Palette.

When the app is running, the Memory View section is displayed in Spring Boot Dashboard. The graphical representation in the memory view highlights the memory use inside the Java virtual machine (JVM). The drop-down menus beneath the graph enable you to switch between different running processes and graphical views.

The heap and non-heap memory regions provide memory insights into the application. The real-time graphs display a stacked overview of the different spaces in memory relative to the total memory used and total memory size.

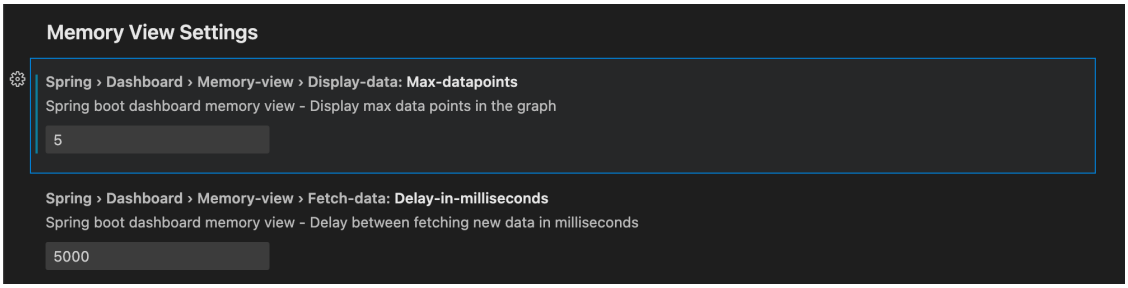
The graphs show only real-time data. You can configure the number of data points to view and the interval by changing the settings. To access the settings on macOS, go to **Code** > **Preferences** > **Settings** > **Extensions** > **Spring Boot Dashboard** > **Memory View Settings**. The navigation path might differ on other operating systems, such as Windows and Linux.



Troubleshoot Tanzu Developer Tools for VS Code

This topic tells you what to do when you encounter issues with VMware Tanzu Developer Tools for Visual Studio Code (VS Code).

Unable to view workloads on the panel when connected to GKE cluster

Symptom

When connecting to Google's GKE clusters, an error appears with the text `WARNING: the gcp auth plugin is deprecated in v1.22+, unavailable in v1.25+; use gcloud instead.`

Cause

GKE authentication was extracted into a separate plug-in and is no longer inside the Kubernetes client or libraries.

Solution

Download and configure the GKE authentication plug-in. For instructions, see the Google documentation.

Live Update fails with `UnsupportedClassVersionError`

Symptom

After live-update has synchronized changes you made locally to the running workload, the workload pods start failing with an error message similar to the following:

```
Caused by: org.springframework.beans.factory.CannotLoadBeanClassException: Error loadi
ng class
[com.example.springboot.HelloController] for bean with name 'helloController' defined
in file
[/workspace/BOOT-INF/classes/com/example/springboot/HelloController.class]: problem wi
th class file
or dependent class; nested exception is
java.lang.UnsupportedClassVersionError: com/example/springboot/HelloController has bee
n compiled by
a more recent version of the Java Runtime (class file version 61.0), this version of t
he
Java Runtime only recognizes class file versions up to 55.0
```

Cause

The classes produced locally on your machine are compiled to target a later Java virtual machine (JVM). The error message mentions `class file version 61.0`, which corresponds to Java 17. The buildpack, however, is set up to run the application with an earlier JVM. The error message mentions `class file versions up to 55.0`, which corresponds to Java 11.

The root cause of this is a misconfiguration of the Java compiler that VS Code uses. The cause might be a suspected issue with the VS Code Java tooling, which sometimes fails to properly configure the compiler source and target compatibility-level from information in the Maven POM.

For example, in the `tanzu-java-web-app` sample application the POM contains the following:

```
<properties>
        <java.version>11</java.version>
```

```
        ...
</properties>
```

This correctly specifies that the app must be compiled for Java 11 compatibility. However, the VS Code Java tooling sometimes fails to take this information into account.

Solution

Force the VS Code Java tooling to re-read and synchronize information from the POM:

1. Right-click the `pom.xml` file.
2. Click **Reload Projects**.

This causes the internal compiler level to be set correctly based on the information from `pom.xml`. For example, Java 11 in `tanzu-java-web-app`.

Timeout error when Live Updating

Symptom

When you attempt to Live Update your workload, the following error message appears in the log:

```
ERROR: Build Failed: apply command timed out after 30s - see }}{{https://docs.tilt.dev/api.html#api.update_settings{{ for how to increase}}
```

Cause

Kubernetes times out on upserts over 30 seconds.

Solution

Add `update_settings (k8s_upsert_timeout_secs = 300)` to the Tiltfile. For more information, see the Tiltfile documentation.

Task-related error when running a Tanzu Debug launch configuration

Symptom

When you attempt to run a Tanzu Debug launch configuration, you see a task-related error message similar to the following:

```
Could not find the task 'tanzuManagement: Kill Port Forward my-app
```

Cause

The task you're trying to run is no longer supported.

Solution

Delete the launch configuration from your `launch.json` file in your `.vscode` directory.

Tanzu Workloads panel workloads only show delete command

Symptom

Some or all workloads in the Tanzu Workloads panel only have describe and delete actions.

Cause

By design, only associated workloads have apply, debug, and Live Update workload actions available.

Solution

Open a project that contains a module that can be associated with your deployed workloads.

Workload actions do not work when in a project with spaces in the name

Symptom

Workload actions and Live Update do not work. The console displays an error message similar to:

```
Error: unknown command "projects/my-app" for "apps workload apply". Process finished w
ith exit code 1
```

Cause

Improper handling of paths that contain spaces causes the shell to misinterpret some commands, such as `tanzu workload apply ...`. This causes anything executing these commands to fail when the name of a project, or any parts of its path on disk, contain spaces.

Solution

1. Close the code editor.
2. Move or rename your project folder on the disk, ensuring that no part of its path contains any spaces.
3. Delete the project settings folder from the project to start with a clean slate. The folder is `.idea` if using IntelliJ and `.vscode` if using VS Code.
4. Open the code editor and then open the project in its new location.

Cannot apply workload because of a malformed kubeconfig file

Symptom

You cannot apply a workload. You see an error message when you attempt to do so.

Cause

Your kubeconfig file (`~/.kube/config`) is malformed.

Solution

Fix your kubeconfig file.

Live Update changes aren't visible when using development containers on Windows

Symptom

Live Update deploys your workload but changes are not visible when using development containers on Windows.

Cause

Monitoring file system changes on Windows directories, while mounted in a Docker container, is very slow and might not work in your specific setup.

Solution

1. Clone the repository inside of a container volume instead of mounting a local directory in the container. This improves I/O performance.
2. Run the `Dev Containers: Clone Repository in Container Volume...` command while the project is open to get started. For more information about this command, see the Visual Studio Code documentation.

You can only store a project in a development container

Symptom

When using a development container, and creating a new project using the Application Accelerator extension in VS Code, the only available location to store the project is inside the development container.

Cause

VS Code is running inside a development container. Therefore the development container file system is the file system made available when creating a new project.

Solution

Use local file mounts to expose additional directories in the host file system to the development container. For more information, see Use Mounts.

Frequent application restarts

Symptom

When an application is applied from VS Code it restarts frequently.

Cause

An application or environment behavior is triggering the application to restart.

Observed trigger behaviors include:

- The application itself writing logs to the file system in the application directory that Live Update is watching
- Autosave being set to a very high frequency in the IDE configuration

Solution

Prevent the trigger behavior. Example solutions include:

- Prevent 12-factor applications from writing to the file system.

- Reduce the autosave frequency to once every few minutes.

Overview of Tanzu Supply Chain

Tanzu Supply Chain is a tool that provides a golden path to production for your teams. Tanzu Supply Chain replaces the supply-chain solution Supply Chain Choreographer, which is based on Cartographer.

> **Caution**
>
> Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

Documentation structure

The Tanzu Supply Chain documentation is organized into the following sections:

- Platform Engineering with Supply Chain: For platform engineers that want to author supply chains that simplify developer cognitive load, and ensure compliant, secure delivery of source to production.
- Developing software with Supply Chain: For developers that want to deliver their software following team and organization standards.
- Reference

Overview of Tanzu Supply Chain

Tanzu Supply Chain is a tool that provides a golden path to production for your teams. Tanzu Supply Chain replaces the supply-chain solution Supply Chain Choreographer, which is based on Cartographer.

> **Caution**
>
> Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

Documentation structure

The Tanzu Supply Chain documentation is organized into the following sections:

- Platform Engineering with Supply Chain: For platform engineers that want to author supply chains that simplify developer cognitive load, and ensure compliant, secure delivery of source to production.
- Developing software with Supply Chain: For developers that want to deliver their software following team and organization standards.

Tanzu Supply Chain for platform engineers

This topic tells you about the Tanzu Supply Chain features that are focused on platform engineering.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

Prepare

Install these CLI tools:

- Install the Tanzu CLI.
- Install the Tanzu Supply Chain CLI plug-ins.

Install and configure Tanzu Supply Chain

- Install Tanzu Supply Chain
- Configure Tanzu Supply Chain

Tutorials

- Build your first SupplyChain
- Install an authored SupplyChain
- Build your first Component
- Add Stages to your SupplyChain

How-to topics: `SupplyChain` Authoring

- Construct a Supply Chain using the Tanzu CLI
- Configure a Supply Chain using the Tanzu CLI

How-to topics: Deploying and Managing Supply Chains

- Manage SupplyChains with GitOps

How-to topics: Starter Supply Chains

- Create Starter SupplyChains

Out of the Box catalog of components

> Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

In this section:

- Build your first SupplyChain
- Install an authored SupplyChain
- Build your first Component
- Add Stages to your SupplyChain

Build your first Supply Chain

This topic tells you how to use the Tanzu Supply Chain CLI plug-in to create a SupplyChain for developers to use.

> **Caution**
>
> Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

This SupplyChain retrieves the source code from a Git repository, and proceeds with building and packaging it as a Carvel package. Subsequently, it initiates a pull request (PR) to transfer the Carvel package to a GitOps repository, facilitating the installation of the built package on the Run clusters. In this tutorial, you will construct a supply chain to build, test, and package Java Maven applications.

Prerequisites

1. Ensure that the Tanzu CLI and Tanzu Supply Chain CLI plug-ins are installed on your local machine.
2. Ensure that Tanzu Supply Chain is installed on the Tanzu Application Platform cluster that you are using to author your first supply chain.

Browse the component catalog

When you have completed the prerequisites, you have the Tanzu Supply Chain controller, Managed Resource Controller, and Component packages installed on the cluster and you are ready to build your first SupplyChain.

1. As a Platform Engineer, you want to know which components are available to use in your SupplyChain. Run:

   ```
   tanzu supplychain component list
   ```

   Example output:

   ```
   Listing components from the catalog
   NAMESPACE                   NAME                                AGE  DESCRIPTION
   alm-catalog                 app-config-server-1.0.0             18h  Generates con
   figuration for a Server application from a Conventions PodIntent.
   alm-catalog                 app-config-web-1.0.0                18h  Generates con
   figuration for a Web application from a Conventions PodIntent.
   alm-catalog                 app-config-worker-1.0.0             18h  Generates con
   figuration for a Worker application from a Conventions PodIntent.
   alm-catalog                 carvel-package-1.0.0                18h  Generates a c
   arvel package from OCI images containing raw YAML files and YTT
                                                                        files.
   alm-catalog                 deployer-1.0.0                      18h  Deploys K8s r
   esources to the cluster.
   alm-catalog                 source-package-translator-1.0.0     18h  Takes the typ
   e source and immediately outputs it as type package.
   conventions-component       conventions-1.0.0                   18h  The Conventio
   ns component analyzes the `image` input as described in the
   git-writer-catalog          git-writer-1.0.0                    18h  Writes carvel
   package config directly to a gitops repository
   git-writer-catalog          git-writer-pr-1.0.0                 18h  Writes carvel
   package config to a gitops repository and opens a PR
   kaniko-catalog              kaniko-build-1.0.0                  18h  Builds an app
   with kaniko
   source-provider             source-git-provider-1.0.0           18h  Source git pr
   ovider retrieves source code and monitors a git repository.
   tbs-catalog                 buildpack-build-1.0.0               18h  Builds an app
   with buildpacks using kpack
   trivy-app-scanning-catalog  trivy-image-scan-1.0.0              18h  Performs a tr
   ivy image scan using the scan 2.0 components

     To view the details of a component, use 'tanzu supplychain component get'
   ```

   Use the `-w/--wide` flag to see a more detailed output including a inputs/outputs of each component.

2. To get more information about each component on the cluster, use the `tanzu supplychain component get` command. For example, to get the information about the `source-git-provider` component, run:

   ```
   tanzu supplychain component get source-git-provider-1.0.0 --show-details
   ```

   Example output:

   ```
     Overview
     name:          source-git-provider-1.0.0
     namespace:     source-provider
     age:           19h
     status:        True
     reason:        Ready
     description:   Source git provider retrieves source code and monitors a git re
   pository.

     Configuration
     source:
       #! Use this object to retrieve source from a git repository.
       #! The tag, commit and branch fields are mutually exclusive, use only one.
   ```

```
    #! Required
    git:
      #! A git branch ref to watch for new source
      #! Example: "main"
      branch: ""
      #! A git commit sha to use
      commit: ""
      #! A git tag ref to watch for new source
      #! Example: "v1.0.0"
      tag: ""
      #! The url to the git source repository
      #! Example: "https://github.com/acme/my-workload.git"
      #! Required
      url: ""
    #! The sub path in the bundle to locate source code
    #! Example: "sub-dir"
    subPath: ""

  Outputs
  git
    ├─ digest: $(resumptions.check-source.results.sha)
    ├─ type: git
    └─ url: $(resumptions.check-source.results.url)
  source
    ├─ digest: $(pipeline.results.digest)
    ├─ type: source
    └─ url: $(pipeline.results.url)

  Pipeline
    ├─ name: source-git-provider
    └─   parameters
      ├─ git-url: $(workload.spec.source.git.url)
      ├─ sha: $(resumptions.check-source.results.sha)
      └─ workload-name: $(workload.metadata.name)

  Resumptions
  - check-source runs source-git-check task every 60s
      Parameters
      ├─ git-branch: $(workload.spec.source.git.branch)
      ├─ git-commit: $(workload.spec.source.git.commit)
      ├─ git-tag: $(workload.spec.source.git.tag)
      └─ git-url: $(workload.spec.source.git.url)

  To generate a supplychain using the available components, use 'tanzu supplych
ain generate'
```

Generate a SupplyChain

1. Now that you know what components are available to create your SupplyChain, start the authoring process. Use the `tanzu supplychain init` command to scaffold the current directory. Run:

   ```
   mkdir myfirstsupplychaingroup
   cd myfirstsupplychaingroup
   tanzu supplychain init --group supplychains.tanzu.vmware.com --description "Thi
   s is my first Supplychain group"
   ```

   Example output:

   ```
   Initializing group supplychains.tanzu.vmware.com
   Creating directory structure
   ├─ supplychains/
   ├─ components/
   ```

```
├─ pipelines/
├─ tasks/
├─ Makefile
├─ README.md
└─ config.yaml

Writing group configuration to config.yaml
```

The `tanzu supplychain init` command creates the following:

- `config.yaml` file that contains the information about the group name, and the description of the SupplyChain group.
- `supplychains`, `components`, `pipelines`, and `tasks` directories which are auto-populated by the authoring wizard later in this tutorial.
- `Makefile` which has the targets to install and uninstall the SupplyChain and related dependencies on any build or full profile clusters.
- `README.md` file which has instructions on how to use the targets in the `Makefile`.

2. Your current directory is now initialized, use the SupplyChain authoring wizard to generate your first SupplyChain. Start the wizard:

```
tanzu supplychain generate --allow-defaults --allow-overrides
```

3. In the wizard prompts that follow, add the following values:

Prompt	Value
What Kind would you like to use as the developer interface?	`MavenAppBuildv1`
Give Supply chain a description?	`Supply chain that pulls the Maven app source code from Git repository, builds it using buildpacks and packages the output as Carvel package.`
Select a component as the first stage of the supply chain?	`source-git-provider-1.0.0`
Select a component as the next stage of the supply chain?	`buildpack-build-1.0.0`
Select a component as the next stage of the supply chain?	`conventions-1.0.0`
Select a component as the next stage of the supply chain?	`app-config-server-1.0.0`
Select a component as the next stage of the supply chain?	`carvel-package-1.0.0`
Select a component as the next stage of the supply chain?	`git-writer-pr-1.0.0`
Select a component as the next stage of the supply chain?	`Done`

After you have selected the components, the wizard creates the required files to deploy your SupplyChain in the current directory. Example output:

```
✓ Successfully fetched all component dependencies
Created file supplychains/mavenappbuildv1.yaml
Created file components/app-config-server-1.0.0.yaml
Created file components/buildpack-build-1.0.0.yaml
Created file components/carvel-package-1.0.0.yaml
Created file components/conventions-1.0.0.yaml
```

```
Created file components/git-writer-pr-1.0.0.yaml
Created file components/source-git-provider-1.0.0.yaml
Created file pipelines/app-config-server.yaml
Created file pipelines/buildpack-build.yaml
Created file pipelines/carvel-package.yaml
Created file pipelines/conventions.yaml
Created file pipelines/git-writer.yaml
Created file pipelines/source-git-provider.yaml
Created file tasks/calculate-digest.yaml
Created file tasks/carvel-package-git-clone.yaml
Created file tasks/carvel-package.yaml
Created file tasks/check-builders.yaml
Created file tasks/fetch-tgz-content-oci.yaml
Created file tasks/git-writer.yaml
Created file tasks/gitops-git-clone.yaml
Created file tasks/prepare-build.yaml
Created file tasks/source-git-check.yaml
Created file tasks/source-git-clone.yaml
Created file tasks/store-content-oci.yaml
```

4. You have now authored your first SupplyChain. View the SupplyChain definition created by the wizard by viewing the manifest created in the `supplychains/` directory. Run:

```
cat supplychains/mavenappbuildv1.yaml
```

Example output

```
apiVersion: supply-chain.apps.tanzu.vmware.com/v1alpha1
kind: SupplyChain
metadata:
    name: mavenappbuildv1
spec:
    defines:
        group: supplychains.tanzu.vmware.com
        kind: MavenAppBuildv1
        plural: mavenappbuildv1s
        version: v1alpha1
    description: Supply chain that pulls the maven app source code from Git rep
ository, builds it using buildpacks and packages the output as Carvel package.
    stages:
        - componentRef:
            name: source-git-provider-1.0.0
          name: source-git-provider
        - componentRef:
            name: buildpack-build-1.0.0
          name: buildpack-build
        - componentRef:
            name: conventions-1.0.0
          name: conventions
        - componentRef:
            name: app-config-server-1.0.0
          name: app-config-server
        - componentRef:
            name: carvel-package-1.0.0
          name: carvel-package
        - componentRef:
            name: git-writer-pr-1.0.0
          name: git-writer-pr
    config:
    #   overrides:
          ...
    #   defaults:
          ...
```

The CLI generated `SupplyChain` manifest has the following information:

- Name of the SupplyChain.
- The Kind definition of the Developer API (Workload) it will create.
- Stages in the SupplyChain. The order of the stages are important as the stages are executed sequentially. Each stage is represented by a component.
- `overrides`: The configuration supplied by a platform engineer for a stage (component) in the SupplyChain that cannot be overridden by developers using the `Workload` (Developer API) created by this SupplyChain.
- `defaults`: The configuration supplied by a platform engineer for a stage (component) in the SupplyChain that can be overridden by developers using the `Workload` (Developer API) created by this SupplyChain. If the developer does not override the configuration, the platform engineer provides the default value.

Configure a SupplyChain to run securely

To configure a SupplyChain to run securely, decide where the SupplyChain stages run, and refine the Developer API (Workload) using overrides and defaults.

Decide where the SupplyChain stages run

Tanzu Supply Chain execute workloads created by developers in accordance with the continuous delivery guidelines established by platform engineers. To ensure compliance and security, platform engineers must supply configurations and sensitive secrets that are not accessible to developers. While supply chains can operate within hardened namespaces to address these concerns, certain elements of a supply chain workload must remain configurable by developers.

Important

Each stage within a supply chain can be configured to operate within either the `supplychain` namespace, where the `Supplychain` will be deployed, or the `developer` namespace, where the `Workload` will be generated by the developer. By default, every stage in a supply chain operates within the `supplychain` namespace. This namespace is secure, restricting developers access to create or view sensitive resources such as secrets. Nevertheless, there are scenarios where developers must provide secrets required by specific stages within the supply chain.

For our generated supply chain, the `source-git-provider` stage operates within the `developer` namespace. Developers need the capability to create a git-secret for their private Git repository where their source code is stored, without requiring involvement from platform engineers. Some stages, such as `buildpack-build` and `git-writer-pr`, should not operate within the developer namespace. The `buildpack-build` stage requires registry credentials for storing the built images, and the `git-writer-pr` stage requires git-secret with write permissions to generate a PR to the GitOps repository. Developers do not have access to provide or view these secrets due to compliance reasons, as they might contain sensitive corporate data.

To do this, update the `source-git-provider` stage of the generated `supplychains/mavenappbuildv1.yaml` file as follows:

```
...
      - componentRef:
          name: source-git-provider-1.0.0
        name: source-git-provider
```

```
        securityContext:
          runAs: workload
...
```

This tells the SupplyChain to run the `source-git-provider` stage in the `developer` namespace where the developer source Git repository secret needed by `source-git-provider` is provided by developers. All other steps run in the `supplychain` namespace where a platform engineer can provide the necessary secrets for the `buildpack-build` stage and the `git-writer-pr` stage during supply chain installation.

Refine the Developer API (Workload) using overrides and defaults

When you generate a supply chain using the `tanzu supplychain generate` command, use the `--allow-defaults` and `--allow-overrides` to generate all the fields that are accessible in the Developer API (Workload) for developers to configure. These fields represent the configurations exposed by the components. Run the `tanzu supplychain component get` command to view the configurations exposed by the components. Inspect the `config.overrides` section of the `supplychains/mavenappbuildv1.yaml` file generated by the CLI to see all the values that developers can specify in a `Workload`.

Some fields, such as `spec.registry`, can only be defined by platform engineers, who can provide the necessary secrets to access those locations in the secure `supplychain` namespace. Developers cannot override these values. This is where the overrides feature becomes relevant. Platform engineers uncomment the fields they want to override and provide the corresponding values at the supply chain level. When these overrides are implemented, these fields are no longer accessible within the `Workload`.

To do this, update the `config.overrides` section of the generated `supplychains/mavenappbuildv1.yaml` file as follows:

```
...
  config:
    overrides:
        # Platform Engineer provided registry overrides
        - path: spec.registry.repository
          value: "YOUR-REGISTRY-REPO"
        - path: spec.registry.server
          value: "YOUR-REGISTRY-SERVER"

        # Platform Engineer provided build overrides
        - path: spec.build.builder.kind
          value: clusterbuilder
        - path: spec.build.builder.name
          value: default
        - path: spec.build.cache.enabled
          value: false
        - path: spec.build.cache.image
          value: ""
        - path: spec.build.serviceAccountName
          value: default

        # Platform Engineer provided carvel package component overrides
        - path: spec.carvel.caCertData
          value: ""
        - path: spec.carvel.iaasAuthEnabled
          value: false
        - path: spec.carvel.packageDomain
          value: "default.tap"
        - path: spec.carvel.serviceAccountName
          value: "default"
        - path: spec.carvel.valuesSecretName
          value: ""
```

```
        # Platform Engineer provided GitOps repo overrides
        - path: spec.gitOps.baseBranch
          value: main
        - path: spec.gitOps.branch
          value: main
        - path: spec.gitOps.subPath
          value: "YOUR-GITOPS-REPO-SUBPATH"
        - path: spec.gitOps.url
          value: "YOUR-GITOPS-REPO-URL"
...
```

Review our SupplyChain

Here is an example of what a `SupplyChain` looks like when the configuration is complete:

```
apiVersion: supply-chain.apps.tanzu.vmware.com/v1alpha1
kind: SupplyChain
metadata:
    name: mavenappbuildv1
spec:
    defines:
        group: supplychains.tanzu.vmware.com
        kind: MavenAppBuildv1
        plural: mavenappbuildv1s
        version: v1alpha1
    description: Supply chain that pulls the maven app source code from Git repositor
y, builds it using buildpacks and packages the output as Carvel package.
    stages:
        - componentRef:
            name: source-git-provider-1.0.0
          name: source-git-provider
          securityContext:
            runAs: workload
        - componentRef:
            name: buildpack-build-1.0.0
          name: buildpack-build
        - componentRef:
            name: conventions-1.0.0
          name: conventions
        - componentRef:
            name: app-config-server-1.0.0
          name: app-config-server
        - componentRef:
            name: carvel-package-1.0.0
          name: carvel-package
        - componentRef:
            name: git-writer-pr-1.0.0
          name: git-writer-pr

    config:
      overrides:
        # Platform Engineer provided registry overrides
        - path: spec.registry.repository
          value: "YOUR-REGISTRY-REPO"
        - path: spec.registry.server
          value: "YOUR-REGISTRY-SERVER"

        # Platform Engineer provided build overrides
        - path: spec.build.builder.kind
          value: clusterbuilder
        - path: spec.build.builder.name
          value: default
        - path: spec.build.cache.enabled
```

```
      value: false
    - path: spec.build.cache.image
      value: ""
    - path: spec.build.serviceAccountName
      value: default

    # Platform Engineer provided carvel package component overrides
    - path: spec.carvel.caCertData
      value: ""
    - path: spec.carvel.iaasAuthEnabled
      value: false
    - path: spec.carvel.packageDomain
      value: "default.tap"
    - path: spec.carvel.serviceAccountName
      value: "default"
    - path: spec.carvel.valuesSecretName
      value: ""

    # Platform Engineer provided GitOps repo overrides
    - path: spec.gitOps.baseBranch
      value: main
    - path: spec.gitOps.subPath
      value: "YOUR-GITOPS-REPO-SUBPATH"
    - path: spec.gitOps.url
      value: "YOUR-GITOPS-REPO-URL"
```

Next Steps

Deploy the `SupplyChain` to your Tanzu Application Platform cluster. For instructions, see Install an authored Supply Chain.

Install an authored Supply Chain

This topic tells you how to install a `SupplyChain` authored using the Tanzu Supply Chain CLI plug-in.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

Prepare

- Ensure that you created a `SupplyChain` by following the tutorial Build your first SupplyChain.
- The `make install` command requires the `kapp` CLI to be installed on your computer. Install kapp CLI.

Install

To install an authored Supply Chain:

1. Create a namespace where you want to install the `SupplyChain`:

```
kubectl create namespace mysupplychains
```

2. The `Makefile` was generated in the Build your first Supply Chain tutorial. Use the `Makefile` to install the `SupplyChain` with required `Components` and Tekton resources, such as `Pipelines` and `Tasks` to execute the logic of the components. Run:

```
NAMESPACE=mysupplychains make install

...

Next Steps

Create your first `Component` to add to your `SupplyChain`. For instructions, see Build your first component.

Build your first component

This topic tells you how to use Tanzu Supply Chain to build a component.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

Prepare

Build a `SupplyChain` resource if you do not already have one. For how to build one, see Build your first SupplyChain.

Get started

In Build your first Supply Chain, you built a `SupplyChain` resource that retrieves the source code from a Git repository, and builds and packages it as a Carvel package. The `SupplyChain` resource then initiates a pull request to transfer the Carvel package to a GitOps repository, which enables the installation of the built package on the Run clusters.

This topic tells you how to create a component that you can use in your `SupplyChain` resource for unit-testing your Maven apps. You will create a component called `maven-unit-tester`, which will run unit tests on the source pulled by the `source-git-provider` stage.

```
tanzu supplychain component get source-git-provider-1.0.0 --show-details
```

Example:

```
...
  Outputs
   git
    ├─ digest: $(resumptions.check-source.results.sha)
    ├─ type: git
    └─ url: $(resumptions.check-source.results.url)
   source
    ├─ digest: $(pipeline.results.digest)
    ├─ type: source
    └─ url: $(pipeline.results.url)
...
```

Create a Tekton `Pipeline`

The first step for creating a `Component` resource is to make a Tekton `Pipeline` resource that includes the logic the component uses. In this case, `maven-unit-tester`:

- Obtains the source code extracted by the `source-git-provider` component.
- Uses the source code as input.
- Runs the unit test command on the source repository.

Tekton `Pipeline`:

- Defines `parameters` that a developer can provide by using the workload.
- Creates a shared `workspace` to store intermediate files, such as the source code from the `source-git-provider` stage.
- Provides tasks that run the unit-testing logic.

To create a Tekton `Pipeline`:

1. Define `parameters` as shown in the following YAML:

```
---
apiVersion: tekton.dev/v1
kind: Pipeline
metadata:
    name: maven-unit-tester-1.0.0
spec:
    description: Test maven application using mvn test command
    params:
      - description: url of source registry image
        name: source-url
        type: string
      - description: sub directory in source to become root dir for build
        name: sub-path
        default: "."
        type: string
      - description: The test command to run in my task
        name: testcmd
        type: string
      - description: The test command to run in my task
        name: workload-name
        type: string
```

2. Define a Tekton workspace as shown in the following YAML:

```
    workspaces:
      - name: shared-data
```

3. Add two tasks to the `Pipeline` resource. Task 1 pulls the output from `source-git-provider` and puts it in the workspace `shared-data` that was defined in the `Pipeline` resource earlier. Task 2 runs the unit tests and records the output as a Tekton Result.

   See the following example YAML:

```
    tasks:
      # task 1 pulls the output from source-git-provider and puts it in a works
pace called shared-data
      - name: fetch-source
        params:
          - name: url
            value: $(params.source-url)
        taskRef:
          kind: Task
          name: fetch-tgz-content-oci
        workspaces:
          - name: store
            workspace: shared-data

      # task 2 runs the unit tests
      - name: test
        runAfter:
          - fetch-source
        params:
```

```
          - name: sub-path
            value: $(params.sub-path)
          - name: testcmd
            value: $(params.testcmd)
          - name: workload-name
            value: $(params.workload-name)
        taskSpec:
          params:
            - name: sub-path
            - name: testcmd
            - name: workload-name
          results:
            - description: Error message if things failed
              name: message
              type: string
          steps:
            - name: test
              image: maven
              env:
                - name: HOME
                  value: /tekton/home/
              script: |-
                #!/usr/bin/env sh
                set -eu
                ls -al $(workspaces.store.path)
                cd $(workspaces.store.path)/$(params.sub-path)

                set +e
                $(params.testcmd)
                testval=$?
                set -e

                if [ $testval -ne 0 ]; then
                  echo "Unit tests stage failed. Please run 'tanzu workload log
s $(params.workload-name)' to see the run logs for more details." | tee "$(resu
lts.message.path)"
                  exit $testval
                fi
          stepTemplate:
              computeResources: {}
              securityContext:
                  allowPrivilegeEscalation: false
                  capabilities:
                      drop:
                          - ALL
                  runAsNonRoot: true
                  runAsUser: 1001
                  seccompProfile:
                      type: RuntimeDefault
        workspaces:
          - name: store
            workspace: shared-data
```

4. Add the version of the pipeline in the name of the YAML file and the name of the pipeline. This enables you to create new versions of the pipelines without interfering with the old one.
5. Store the `Pipeline` resource in the `pipelines` directory created by the CLI as `maven-unit-tester-1.0.0.yaml`, as shown in the following YAML:

```
---
apiVersion: tekton.dev/v1
kind: Pipeline
metadata:
    name: maven-unit-tester-1.0.0
```

```
spec:
    description: Test maven application using mvn test command
    params:
      - description: url of source registry image
        name: source-url
        type: string
      - description: sub directory in source to become root dir for build
        name: sub-path
        default: "."
        type: string
      - description: The test command to run in my task
        name: testcmd
        type: string
      - description: The test command to run in my task
        name: workload-name
        type: string
    workspaces:
      - name: shared-data
    # My tasks starts here
    tasks:
      # task 1 pulls the output from source-git-provider and puts it in a works
pace called shared-data
      - name: fetch-source
        params:
          - name: url
            value: $(params.source-url)
        taskRef:
          kind: Task
          name: fetch-tgz-content-oci
        workspaces:
          - name: store
            workspace: shared-data

      # task 2 runs the unit tests
      - name: test
        runAfter:
          - fetch-source
        params:
          - name: sub-path
            value: $(params.sub-path)
          - name: testcmd
            value: $(params.testcmd)
          - name: workload-name
            value: $(params.workload-name)
        taskSpec:
          params:
            - name: sub-path
            - name: testcmd
            - name: workload-name
          results:
            - description: Error message if things failed
              name: message
              type: string
          steps:
            - name: test
              image: maven
              env:
                - name: HOME
                  value: /tekton/home/
              script: |-
                #!/usr/bin/env sh
                set -eu
                ls -al $(workspaces.store.path)
                cd $(workspaces.store.path)/$(params.sub-path)

                set +e
```

```
                $(params.testcmd)
                testval=$?
                set -e

                if [ $testval -ne 0 ]; then

        workspaces:
          - name: store
            workspace: shared-data
```

Create a `SupplyChain` `Component`

The section describes how to write a `Component` manifest that defines the following:

- Configuration for a `Component` that is exposed as part of the Developer API. This is the configuration that a platform engineer can override at a `SupplyChain` level or that a developer can provide by using the `Workload` if a platform engineer does not override it at the `SupplyChain` level.
- `Inputs`, which is a list of named `Outputs` from a previous stage in a `SupplyChain` resource that the current `Component` resource depends on.
- `Outputs`, which are named outputs from this component another `Component` resource can use as `Inputs`.
- The Pipeline Run Definition section, which defines the work performed by this component. `spec.pipelineRun` is used to create a Tekton `PipelineRun` and has many similarities.
- Define the `Component` resource configuration as shown in the following YAML:

```
---
apiVersion: supply-chain.apps.tanzu.vmware.com/v1alpha1
kind: Component
metadata:
    name: maven-unit-tester-1.0.0
spec:
    description: Execute a maven unit test command using the mvn CLI
    config:
        - path: spec.test.cmd
          schema:
            description: |
                Unit testing mvn command to run
            required:
                - cmd
            type: string
            default: "mvn test"
            example: "mvn test"
```

- Define `Component` inputs and outputs. In this case, the output of the `source-git-provider` component is used as an input for the `maven-unit-tester` component.

```
    inputs:
      - name: source
        type: source
```

- Define `Component PipelineRun` details. The `Pipeline` resource created earlier is referenced here. The values are passed from the `Workload` and `Inputs` to satisfy the parameters for the `Pipeline` resource. See the following example YAML:

```
    pipelineRun:
        params:
            - name: source-url
              value: $(inputs.source.url)
            - name: sub-path
              value: $(workload.spec.source.subPath)
            - name: testcmd
              value: $(workload.spec.test.cmd)
            - name: workload-name
              value: $(workload.metadata.name)
        pipelineRef:
            name: maven-unit-tester-1.0.0
        taskRunTemplate:
            podTemplate:
                securityContext:
                    fsGroup: 1000
                    runAsGroup: 1000
                    runAsUser: 1001
        workspaces:
            - name: shared-data
              volumeClaimTemplate:
                spec:
                    accessModes:
                        - ReadWriteOnce
                    resources:
                        requests:
                            storage: 1Gi
```

- Store the `Component` resource in the `components` directory created by the CLI as `maven-unit-tester-1.0.0.yaml`. See the following example YAML:

```
---
apiVersion: supply-chain.apps.tanzu.vmware.com/v1alpha1
kind: Component
metadata:
    name: maven-unit-tester-1.0.0
spec:
    description: Execute a maven unit test command using the mvn CLI
    inputs:
      - name: source
        type: source
    config:
        - path: spec.test.cmd
          schema:
            description: |
                Unit testing mvn command to run
            required:
                - cmd
            type: string
            default: "mvn test"
            example: "mvn test"
    pipelineRun:
        params:
```

```
            - name: source-url
              value: $(inputs.source.url)
            - name: sub-path
              value: $(workload.spec.source.subPath)
            - name: testcmd
              value: $(workload.spec.test.cmd)
            - name: workload-name
              value: $(workload.metadata.name)
        pipelineRef:
            name: maven-unit-tester-1.0.0
        taskRunTemplate:
            podTemplate:
                securityContext:
                    fsGroup: 1000
                    runAsGroup: 1000
                    runAsUser: 1001
        workspaces:
            - name: shared-data
              volumeClaimTemplate:
                spec:
                    accessModes:
                        - ReadWriteOnce
                    resources:
                        requests:
                            storage: 1Gi
```

Install the component

You can now use the `make install` target created by the `tanzu supplychain` CLI to install the new `Component` and `Pipeline` resources to see if they reconcile.

Install the component by running:

```
NAMESPACE=mysupplychains make install
```

This command also displays any errors that Tekton throws.

Next Steps

Add your new `Component` to a `SupplyChain`. For instructions, see Add stages to your Supply Chain.

Useful links

- Component API Reference
- Component Catalog

Add stages to your Supply Chain

This topic tells you how to add a stage to a `SupplyChain` resource.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

Preparation

You must have:

- A `SupplyChain` resource. For how to build one, see Build your first SupplyChain.
- A component. For how to build one, see Build your first component.

Add a stage to an existing `SupplyChain`

This section describes how to add a stage to an existing `SupplyChain` resource if the `SupplyChain` resource has not been deployed to clusters used by developers.

Important

If the `SupplyChain` resource is in use by developers with existing running workloads, do not add a stage. Instead, create a new `SupplyChain` resource with an updated version in the name, such as `MavenAppBuildv2`.

Creating a new `SupplyChain` resource with every breaking Workload API change provides developers with a migration path and a chance to test their app on the new `SupplyChain` resource.

To add a stage:

1. Add a component to the `SupplyChain` resource by adding the following YAML snippet between `source-git-provider` and the `buildpack-build` stage in your `SupplyChain` resource:

   ```
       - componentRef:
           name: COMPONENT-NAME
         name: unit-testing
   ```

   Where `COMPONENT-NAME` is the component name. For example, `maven-unit-tester-1.0.0`.

2. Update the `SupplyChain` resource by running:

   ```
   NAMESPACE=mysupplychains make install
   ```

Install the Tanzu Supply Chain CLI plug-ins

This topic tells you how to install the Tanzu Supply Chain, and Tanzu Workload CLI plug-ins.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

To start working with Tanzu Supply Chain, there are two Tanzu CLI plug-ins that you must install:

1. The Tanzu Supply Chain CLI plug-in is used to author and manage SupplyChains and Components.
2. The Tanzu Workload CLI plug-in is used by developers to discover and use the Workloads that you authored with the Tanzu Supplychain CLI plug-in.

Important The Tanzu Supply Chain beta release does not include the installation of the Tanzu Workload and Supply Chain` CLI plug-ins as part of the plug-in group.

Prerequisites

Ensure that you installed or updated the core Tanzu CLI. For more information, see Install Tanzu CLI.

1. Install the Tanzu CLI plug-ins by running:

   ```
   tanzu plugin install supplychain
   tanzu plugin install workload
   ```

2. Verify that the plug-ins are installed correctly by running:

   ```
   tanzu supplychain version
   tanzu workload version
   ```

Uninstall Tanzu Supply Chain CLI plug-ins

Run:

```
tanzu plugin delete supplychain
tanzu plugin delete workload
```

Install Tanzu Supply Chain

This section tells you how to install Tanzu Supply Chain.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

There are two ways to install Tanzu Supply Chain:

- Install with the 'authoring' profile (Recommended)
- Installing manually on a Full or Build profile

After you have installed Tanzu Supply Chain, you must configure your system.

- Post-install configuration

Install Tanzu Supply Chain with the authoring profile (recommended)

This topic describes the recommended method for installing Tanzu Supply Chain using the Authoring profile (beta). This profile installs all the required packages.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

The Authoring profile has the following additional packages that the Iterate profile does not have:

Packages

- Tanzu Supply Chain packages
    - `supply-chain.apps.tanzu.vmware.com`
    - `supply-chain-catalog.apps.tanzu.vmware.com`
    - `managed-resource-controller.apps.tanzu.vmware.com`
- Catalog Component packages
    - `alm-catalog.component.apps.tanzu.vmware.com`
    - `buildpack-build.component.apps.tanzu.vmware.com`
    - `conventions.component.apps.tanzu.vmware.com`
    - `git-writer.component.apps.tanzu.vmware.com`
    - `source.component.apps.tanzu.vmware.com`

    - `trivy.app-scanning.component.apps.tanzu.vmware.com`
- App Scanning package
    - `app-scanning.apps.tanzu.vmware.com`

Install Tanzu Supply Chain

1. Update your `tap-values.yaml` file to contain:

    ```
    profile: authoring
    ```

2. Confirm that the required packages are installed and reconciled successfully by running:

    ```
    kubectl get pkgi -A
    ```

    Example output

    ```
    NAMESPACE     NAME                                PACKAGE NAME
    PACKAGE VERSION                        DESCRIPTION           AGE
    tap-install   alm-catalog-component               alm-catalog.component.apps.tan

    ps.tanzu.vmware.com     0.1.2                                Reconcile succeed
    ed   15d
    ...
    tap-install   namespace-provisioner               namespace-provisioner.apps.tan
    zu.vmware.com           0.6.2                                Reconcile succeed
    ed   15d
    ...
    tap-install   source-component                    source.component.apps.tanzu.vm
    ware.com                0.0.1                                Reconcile succeed
    ed   15d
    ...
    tap-install   supply-chain                        supply-chain.apps.tanzu.vmwar
    e.com                    0.1.16                               Reconcile succee
    ded   15d
    tap-install   supply-chain-catalog                supply-chain-catalog.apps.tanz
    u.vmware.com            0.1.1                                Reconcile succeed
    ed   15d
    ...
    tap-install   trivy-app-scanning-component        trivy.app-scanning.component.a
    pps.tanzu.vmware.com    0.0.1-alpha.build.40376886+b5f4e614   Reconcile succeed
    ed   15d
    ...
    ```

Note

> As the Authoring profile adds additional packages in addition to what is already installed with the Iterate profile, the `tap-values.yaml` file for both profiles can look the same except for the `profile` value.

Next step

Configure Tanzu Supply Chain.

Install Tanzu Supply Chain manually (not recommended)

This topic tells you how to install Tanzu Supply Chain manually. This installation method is not recommended.

> **Caution**
>
> Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

To install Tanzu Supply Chain manually, you must install additional packages that are not bundled with existing installation profiles.

The following Supply Chain packages are required.

- `supply-chain.apps.tanzu.vmware.com`
- `supply-chain-catalog.apps.tanzu.vmware.com`
- `managed-resource-controller.apps.tanzu.vmware.com`

The following Component packages are required if you're authoring a supply chain:

- `source.component.apps.tanzu.vmware.com`
- `conventions.component.apps.tanzu.vmware.com`
- `buildpack-build.component.apps.tanzu.vmware.com`
- `alm-catalog.component.apps.tanzu.vmware.com`
- `git-writer.component.apps.tanzu.vmware.com`
- `trivy-scanning.component.apps.tanzu.vmware.com`

1. To install these packages, run the following script:

```
export SUPPLY_CHAIN_VERSION=$(kubectl get package -n tap-install -o=jsonpath
='{.items[?(@.spec.refName=="supply-chain.apps.tanzu.vmware.com")].spec.versio
n}')
echo $SUPPLY_CHAIN_VERSION

tanzu package install supply-chain \
-p supply-chain.apps.tanzu.vmware.com \
-v $SUPPLY_CHAIN_VERSION \
-n tap-install

export SUPPLY_CHAIN_CATALOG_VERSION=$(kubectl get package -n tap-install -o=jso
npath='{.items[?(@.spec.refName=="supply-chain-catalog.apps.tanzu.vmware.co
m")].spec.version}')
echo $SUPPLY_CHAIN_CATALOG_VERSION
```

```
tanzu package install supply-chain-catalog \
-p supply-chain-catalog.apps.tanzu.vmware.com \
-v $SUPPLY_CHAIN_CATALOG_VERSION \
-n tap-install

export MANAGED_RESOURCE_VERSION=$(kubectl get package -n tap-install -o=jsonpat
h='{.items[?(@.spec.refName=="managed-resource-controller.apps.tanzu.vmware.co
m")].spec.version}')
echo $MANAGED_RESOURCE_VERSION

tanzu package install managed-resource-controller \
-p managed-resource-controller.apps.tanzu.vmware.com \
-v $MANAGED_RESOURCE_VERSION \
-n tap-install

export SOURCE_COMPONENT_VERSION=$(kubectl get package -n tap-install -o=jsonpat
h='{.items[?(@.spec.refName=="source.component.apps.tanzu.vmware.com")].spec.ve
rsion}')
echo $SOURCE_COMPONENT_VERSION

tanzu package install source-component \
-p source.component.apps.tanzu.vmware.com \
-v $SOURCE_COMPONENT_VERSION \
-n tap-install

export CONVENTIONS_COMPONENT_VERSION=$(kubectl get package -n tap-install -o=js
onpath='{.items[?(@.spec.refName=="conventions.component.apps.tanzu.vmware.co
m")].spec.version}')
echo $CONVENTIONS_COMPONENT_VERSION

tanzu package install conventions-component \
-p conventions.component.apps.tanzu.vmware.com \
-v $CONVENTIONS_COMPONENT_VERSION \
-n tap-install

export BUILDPACK_COMPONENT_VERSION=$(kubectl get package -n tap-install -o=json
path='{.items[?(@.spec.refName=="buildpack-build.component.apps.tanzu.vmware.co
m")].spec.version}')
echo $BUILDPACK_COMPONENT_VERSION

tanzu package install buildpack-build-component \
-p buildpack-build.component.apps.tanzu.vmware.com \
-v $BUILDPACK_COMPONENT_VERSION \
-n tap-install

export ALM_CATALOG_COMPONENT_VERSION=$(kubectl get package -n tap-install -o=js
onpath='{.items[?(@.spec.refName=="alm-catalog.component.apps.tanzu.vmware.co
m")].spec.version}')
echo $ALM_CATALOG_COMPONENT_VERSION

tanzu package install alm-catalog-component \
-p alm-catalog.component.apps.tanzu.vmware.com \
-v $ALM_CATALOG_COMPONENT_VERSION \
-n tap-install

export GIT_WRITER_COMPONENT_VERSION=$(kubectl get package -n tap-install -o=jso
npath='{.items[?(@.spec.refName=="git-writer.component.apps.tanzu.vmware.co
m")].spec.version}')
echo $GIT_WRITER_COMPONENT_VERSION

tanzu package install git-writer-component \
-p git-writer.component.apps.tanzu.vmware.com \
-v $GIT_WRITER_COMPONENT_VERSION \
-n tap-install
```

```
export TRIVY_SCANNING_COMPONENT_VERSION=$(kubectl get package -n tap-install -o
=jsonpath='{.items[?(@.spec.refName=="trivy-scanning.component.apps.tanzu.vmwar
e.com")].spec.version}')
echo $TRIVY_SCANNING_COMPONENT_VERSION

tanzu package install trivy-scanning-component \
-p trivy-scanning.component.apps.tanzu.vmware.com \
-v $TRIVY_SCANNING_COMPONENT_VERSION \
-n tap-install
```

2. Confirm that the required packages are installed and reconciled successfully by running:

```
kubectl get pkgi -A
```

Example output:

```
NAMESPACE     NAME                                PACKAGE NAME
PACKAGE VERSION                        DESCRIPTION           AGE
tap-install   alm-catalog-component               alm-catalog.component.apps.tan

ed   15d
...
```

Configure Tanzu Supply Chain

This topic tells you what to configure to complete your Tanzu Supply Chain installation.

Caution

> Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

After you install Tanzu Supply Chain, use Namespace Provisioner to configure service accounts and permissions.

VMware recommended that you use Namespace Provisioner to configure the following:

OCI Store configuration: Supply Chains persist data between stages by reading and writing to an OCI repository. The location of the OCI repository is configured by a Kubernetes Secret named `oci-store` that exists within the developer namespace. Access to this repository is controlled by a Tekton annotated secret that can have any name with the `tekton.dev/docker-0` annotation pointing to the OCI repository.

Permissions for the `buildpack-build` component and Cluster Builders: You must add some additional permissions to use the `buildpack-build` component to create images with Tanzu Build Service configured with `ClusterBuilders.

Configure Tanzu Supply Chain using Namespace Provisioner

1. Create a `Secret` in the `tap-install` namespace that has the location and credentials for the `oci-store` as follows:

```
cat << EOF | kubectl apply -f -
apiVersion: v1
kind: Secret
metadata:
  name: supply-chain-oci-store-credentials
  namespace: tap-install
type: Opaque
stringData:
  ocistore.yaml: |
    tanzusupplychain:
      ocistore:
        username: REGISTRY-USERNAME
        password: REGISTRY-PASSWORD
        server: REGISTRY-SERVER
        repository: REGISTRY-REPO
EOF
```

2. Configure Namespace Provisioner to use the accelerator sample. This creates the required resources for configuring `oci-store` and `buildpack-build` permissions. Update the `namespace_provisioner` section of your `tap-values.yaml` file as follows:

```
namespace_provisioner:
  additional_sources:
  - git:
      ref: origin/main
      subPath: ns-provisioner-samples/tanzu-supply-chain
      url: https://github.com/vmware-tanzu/application-accelerator-samples.git
  import_data_values_secrets:
  - name: supply-chain-oci-store-credentials
    namespace: tap-install
    create_export: true
  default_parameters:
    supply_chain_service_account:
```

```
      secrets:
      - oci-store-credentials
```

Namespace Provisioner creates the required secrets and role bindings in your developer namespace.

Create Developer Namespaces

```
kubectl create namespace dev
kubectl label namespaces dev apps.tanzu.vmware.com/tap-ns=""
```

Configure Namespace Provisioner to support custom Supply Chains

If there is a requirement for injecting additional secrets to the Service Account such as `git-secret`, for all Developer namespaces managed by Namespace Provisioner, update the `namespace_provisioner` section of `tap-values.yaml` as follows:

```
namespace_provisioner:
  ...
  default_parameters:
    supply_chain_service_account:
      secrets:
      # Add secrets here
      - git-secret
```

- Single Namespace using annotation:

```
kubectl annotate ns DEVELOPER-NAMESPACE param.nsp.tap/delivery_service_account.secrets
='["git-secret"]'
```

How to Author a Supply Chain

This section contains guides for platform engineers about authoring SupplyChain resources.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

In this section:

- Construct a Supply Chain using the CLI
- Configure a Supply Chain using the Tanzu CLI

Construct a Supply Chain using the Tanzu CLI

This topic tells you how to construct a SupplyChain resource by using the Tanzu Supply Chain CLI plug-in.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

Prerequisites

1. Ensure that the Tanzu CLI, and Tanzu Supply Chain CLI plug-in are installed on your local machine.
2. Ensure that Tanzu Supply Chain packages and Catalog Component packages are installed on the Tanzu Application Platform cluster that you are using to author your first supply chain.
3. If you Install Tanzu Supply Chain with the authoring profile (recommended), these packages are automatically installed.
4. If you Install Tanzu Supply Chain manually (not recommended), you must install the packages individually.

SupplyChain authoring

Deploy SupplyChain authoring resources such as `SupplyChain`, `Component`, and the Tekton `Pipeline`/`Task` to clusters through a Git repository by using the GitOps source promotion methodology.

For a Platform Engineer, the recommended approach is:

- Author the `SupplyChain` by using a set of YAML files within a Git-backed file system.
- Test and debug by pushing all files to a single namespace on the `authoring` profile cluster.
- When you are satisfied with the new or modified `SupplyChain`, use a pull request to commit to Git.

Managing a potentially large number of YAML manifests manually can be error-prone. Platform Engineers can use the Tanzu Supplychain CLI plug-in to streamline the authoring process for `SupplyChains` tailored to their developers.

Initialize the local directory

First use the `tanzu supplychain init` command to initialize the local directory for the `tanzu supplychain generate` command. Run:

```
tanzu supplychain init --group supplychains.tanzu.vmware.com --description "MY-SUPPLYC
HAIN-GROUP"
```

Where

- `--group`: (Optional) Group of the supplychains. The default is `supplychains.tanzu.vmware.com`. Used for auto-populating `spec.defines.group` of the SupplyChain API.
- `--description`: (Optional) Description of the Group. The default is "".

The `tanzu supplychain init` command creates:

- `config.yaml` file that contains the information about the group name, and the description of the Supplychain group.
- `supplychains`, `components`, `pipelines`, and `tasks` directories which are auto-populated by the authoring wizard later in this tutorial.

- `Makefile` which has the targets to install or uninstall the SupplyChain and related dependencies on any Build or Full profile clusters.
- `README.md` file which has instructions on how to use the targets in the `Makefile`.

Important

After being set up with the designated `group`, the local directory becomes a hub for shipping one or more `SupplyChains`. Within this local directory, every `SupplyChain` shares the same `group`, and this group information is stored in the `config.yaml` file. Conversely, in your GitOps repository, multiple directories can exist, each initialized with distinct groups such as `hr.supplychains.company.biz`, `finance.supplychains.company.biz`, and so on. Each of these directories is capable of accommodating multiple `SupplyChains` tailored to their respective groups.

Example output from `tanzu supplychain init` command:

```
Initializing group supplychains.tanzu.vmware.com
Creating directory structure
 ├─ supplychains/
 ├─ components/
 ├─ pipelines/
 ├─ tasks/
 ├─ Makefile
 ├─ README.md
 └─ config.yaml

Writing group configuration to config.yaml
```

Inspecting Components available to author Supply Chains

1. As a Platform Engineer, you want to know which components are available to use in your SupplyChain. Run:

   ```
   tanzu supplychain component list
   ```

   Example output

   ```
   Listing components from the catalog
     NAME                              INPUTS
   OUTPUTS                                                    AGE
     app-config-server-1.0.0           conventions[conventions]
   oci-yaml-files[oci-yaml-files], oci-ytt-files[oci-ytt-files]  14d
     app-config-web-1.0.0              conventions[conventions]
   oci-yaml-files[oci-yaml-files], oci-ytt-files[oci-ytt-files]  14d
     app-config-worker-1.0.0           conventions[conventions]
   oci-yaml-files[oci-yaml-files], oci-ytt-files[oci-ytt-files]  14d
     carvel-package-1.0.0              oci-yaml-files[oci-yaml-files], oci-ytt-file
   s[oci-ytt-files]  package[package]
   14d
     deployer-1.0.0                    package[package]
   <none>                                                     14d
     source-package-translator-1.0.0   source[source]
   package[package]                                           14d
     conventions-1.0.0                 image[image]
   conventions[conventions]                                   14d
     app-config-web-1.0.0              conventions[conventions]
   oci-yaml-files[oci-yaml-files], oci-ytt-files[oci-ytt-files]  14d
     git-writer-1.0.0                  package[package]
   <none>                                                     14d
   ```

```
  git-writer-pr-1.0.0              package[package]
git-pr[git-pr]                                          14d
  source-git-provider-1.0.0        <none>
source[source], git[git]                                14d
  buildpack-build-1.0.0            source[source], git[git]
image[image]                                            14d
  trivy-image-scan-1.0.0           image[image], git[git]
<none>                                                  14d

  To view the details of a component, use 'tanzu supplychain component get'
```

Use the `-w/--wide` flag to see a more detailed output including a description of each component.

Important

The `tanzu supplychain component list` command scans for `Component` custom resources labeled with `supply-chain.apps.tanzu.vmware.com/catalog`. Those `Component` custom resources possessing this label are the ones taken into account for authoring `SupplyChains` with the Tanzu CLI. Notably, the `Components` installed during the SupplyChain installation lack this label. This labeling distinction serves as the basis for differentiating between “Cataloged” and “Installed” `Components` in the CLI.

2. To get more information about each component on the cluster, run the `tanzu supplychain component get` command. For example, to get information about the `source-git-provider` component, run:

```
tanzu supplychain component get source-git-provider-1.0.0 -n source-provider --
show-details
```

Example output

```
  Overview
  name:         source-git-provider-1.0.0
  namespace:    source-provider
  age:          14d
  status:       True
  reason:       Ready
  description:  Monitors a git repository

  Configuration
  source:
    #! Use this object to retrieve source from a git repository.
    #! The tag, commit, and branch fields are mutually exclusive, use only one.
    #! Required
    git:
      #! A git branch ref to watch for new source
      branch: "main"
      #! A git commit sha to use
      commit: ""
      #! A git tag ref to watch for new source
      tag: "v1.0.0"
      #! The url to the git source repository
      #! Required
      url: "https://github.com/acme/my-workload.git"
    #! The sub path in the bundle to locate source code
    subPath: ""

  Outputs
```

```
  git
    ├─ digest: $(resumptions.check-source.results.sha)
    ├─ type: git
    └─ url: $(resumptions.check-source.results.url)
  source
    ├─ digest: $(pipeline.results.digest)
    ├─ type: source
    └─ url: $(pipeline.results.url)

  Pipeline
    ├─ name: source-git-provider
    └─   parameters
      ├─ git-url: $(workload.spec.source.git.url)
      ├─ sha: $(resumptions.check-source.results.sha)
      └─ workload-name: $(workload.metadata.name)

  Resumptions
  - check-source runs source-git-check task every 300s
      Parameters
      ├─ git-branch: $(workload.spec.source.git.branch)
      ├─ git-commit: $(workload.spec.source.git.commit)
      ├─ git-tag: $(workload.spec.source.git.tag)
      └─ git-url: $(workload.spec.source.git.url)

  To generate a supplychain using the available components, use 'tanzu supplych
ain generate'
```

Generate the SupplyChain

The Tanzu Supply Chain CLI plug-in supports two modes of operation for generating SupplyChains.

- Interactive: Use a guided wizard.
- Non-Interactive: Use flags.

Interactive

Start the wizard:

```
tanzu supplychain generate
```

The wizard prompts for the following:

Prompt	Example value
What Kind would you like to use as the developer interface?	`AppBuildV1` (This value is used for auto-populating the `spec.defines` section of the SupplyChain API)
Give Supply chain a description?	`Supply chain that pulls the source code from Git repository, builds it using buildpacks and package the output as Carvel package.`
Select a component as the first stage of the supply chain?	`source-git-provider-1.0.0`
Select a component as the first stage of the supply chain?	`buildpack-build-1.0.0`
Select a component as the first stage of the supply chain?	`conventions-1.0.0`
Select a component as the first stage of the supply chain?	`app-config-server-1.0.0`
Select a component as the first stage of the supply chain?	`carvel-package-1.0.0`

Prompt	Example value
Select a component as the first stage of the supply chain?	`git-writer-pr-1.0.0`
Select a component as the first stage of the supply chain?	`Done`

The Tanzu Supply Chain CLI knows what stages are already part of the SupplyChain and removes them from the list of stages to add.

Non-interactive

Generate the Supply chain by using flags:

```
tanzu supplychain generate \
--kind AppBuildV1 \
--description "Supply chain that pulls the source code from git repo, builds it usin
g buildpacks and package the output as Carvel package." \
--component "source-git-provider-1.0.0" \
--component "buildpack-build-1.0.0" \
--component "conventions-1.0.0" \
--component "app-config-server-1.0.0" \
--component "carvel-package-1.0.0" \
--component "git-writer-pr-1.0.0"
```

When you have selected the components, the Tanzu Supply Chain CLI plug-in creates the required files to deploy your SupplyChain in the current directory

For example:

```
✓ Successfully fetched all component dependencies
Created file supplychains/appbuildv1.yaml
Created file components/app-config-server-1.0.0.yaml
Created file components/buildpack-build-1.0.0.yaml
Created file components/carvel-package-1.0.0.yaml
Created file components/conventions-1.0.0.yaml
Created file components/git-writer-pr-1.0.0.yaml
Created file components/source-git-provider-1.0.0.yaml
Created file pipelines/app-config-server.yaml
Created file pipelines/buildpack-build.yaml
Created file pipelines/carvel-package.yaml
Created file pipelines/conventions.yaml
Created file pipelines/git-writer.yaml
Created file pipelines/source-git-provider.yaml
Created file tasks/calculate-digest.yaml
Created file tasks/carvel-package-git-clone.yaml
Created file tasks/carvel-package.yaml
Created file tasks/check-builders.yaml
Created file tasks/fetch-tgz-content-oci.yaml
Created file tasks/git-writer.yaml
Created file tasks/gitops-git-clone.yaml
Created file tasks/prepare-build.yaml
Created file tasks/source-git-check.yaml
Created file tasks/source-git-clone.yaml
Created file tasks/store-content-oci.yaml
```

Enforce proper ordering of Components in the SupplyChain

Components have zero or more inputs and outputs. The inputs for a component must be fulfilled by a preceding component in the SupplyChain. If not, there will be a component at a stage in a

SupplyChain that will not run. Proper ordering is handled differently depending on whether you are authoring using the interactive or non-interactive method.

Interactive
The entries that get populated for stage selection already take the ordering logic into account. The CLI only shows components for selection if the inputs for that component are already satisfied by another component in the SupplyChain.

Non-interactive
The SupplyChain returns an error if a component expects an input that has not been output by a previous stage. For example:

```
$ tanzu supplychain generate \
--kind AppBuildV1 \
--description "Supply chain that pulls the source code from Git repository, builds i
t using buildpacks and packages the output as Carvel package." \
--component "buildpack-build-1.0.0" \
--component "conventions-1.0.0" \
--component "app-config-server-1.0.0" \
--component "carvel-package-1.0.0" \
--component "git-writer-pr-1.0.0"
```

Example error output:

```
Error: unable to find the component buildpack-build-1.0.0 or the component buildpack
-build-1.0.0 does not match expected input value
```

For detailed information about the API specification for SupplyChain, see the SupplyChain API reference documentation.

Ensure that your Components and Supply Chains adhere to version constraints

For information about versioning SupplyChains and Components to avoid delivery failures of your SupplyChain resources to your Build clusters, see Supply Chains enforce immutability.

Configure a Supply Chain using the Tanzu CLI

This topic tells you how to construct a SupplyChain configuration.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

Prerequisites

1. Ensure that the Tanzu CLI, and Tanzu Supply Chain CLI plug-in are installed on your local machine.
2. Ensure that Tanzu Supply Chain packages and Catalog Component packages are installed on the Tanzu Application Platform cluster that you are using to author your supply chain.

- If you Install Tanzu Supply Chain with the authoring profile (recommended), these packages are automatically installed.
- If you Install Tanzu Supply Chain manually (not recommended), you must install the packages individually.

SupplyChain configuration

SupplyChains can be configured to supply default and override values for each component. This allows a platform engineer to either pre-populate common default values for a component or override values to always be some value that the developer cannot modify.

Generate SupplyChain with overrides

Platform engineers generate SupplyChains with overrides to allow them to define values that cannot be changed by developers using the `Workload` (Developer API). By configuring overrides for each component in the SupplyChain, the generated `Workload` will not contain values that have been overriden.

Overrides consist of:

- `path`: The path to the configuration value, formatted as either:
    1. The full path to the field you want to set.
    2. The path to any structure where all desired child fields must be set.
- `value`: A string or YAML structured value.

Overrides use case

As a platform engineer, I want all built images to be accessible only through my organizations QA registry.

1. Generate the SupplyChain by supplying the `--allow-overrides` flag:

```
tanzu supplychain generate \
    --kind AppBuildV1 \
    --description "Supply chain that pulls the source code from git repo, build
s it using buildpacks and package the output as Carvel package." \
    --component "source-git-provider-1.0.0" \
    --component "buildpack-build-1.0.0" \
```

```
    --component "conventions-1.0.0" \
    --component "app-config-server-1.0.0" \
    --component "carvel-package-1.0.0" \
    --component "git-writer-pr-1.0.0" \
    --allow-overrides
```

The Tanzu Supply Chain CLI plug-in creates the required files to deploy your SupplyChain in the current directory:

```
✓ Successfully fetched all component dependencies
Created file supplychains/appbuildv1.yaml
...
```

2. To configure overrides, open `supplychains/appbuildv1.yaml` in your editor and navigate to the following section:

```
...
config:
  overrides:
      # Platform Engineer provided registry overrides
      - path: spec.registry.repository
        value: "YOUR-REGISTRY-REPO"
      - path: spec.registry.server
        value: "YOUR-REGISTRY-SERVER"

      # Platform Engineer provided build overrides
      - path: spec.build.builder.kind
        value: clusterbuilder
      - path: spec.build.builder.name
        value: default
      - path: spec.build.cache.enabled
        value: false
      - path: spec.build.cache.image
        value: ""
      - path: spec.build.serviceAccountName
        value: default

      # Platform Engineer provided carvel package component overrides
      - path: spec.carvel.caCertData
        value: ""
      - path: spec.carvel.iaasAuthEnabled
        value: false
      - path: spec.carvel.packageDomain
        value: "default.tap"
      - path: spec.carvel.serviceAccountName
        value: "default"
      - path: spec.carvel.valuesSecretName
        value: ""

      # Platform Engineer provided GitOps repo overrides
      - path: spec.gitOps.baseBranch
        value: main
      - path: spec.gitOps.branch
        value: main
      - path: spec.gitOps.subPath
        value: "YOUR-GITOPS-REPO-SUBPATH"
      - path: spec.gitOps.url
        value: "YOUR-GITOPS-REPO-URL"
```

3. Configure overrides using either a full path to the field you want to set or a path to any structure where all desired child fields must be set. For example:

Full path

Example path `spec.registry.repository`. As this example does not provide a value for `spec.registry.server`, it will not be available to modify in the `Workload`.

```
config:
  overrides:
    - path: spec.registry.repository
      value: "https://my-registry.url.com"
```

Path to any key representing a YAML object
Examples:

1. Path `spec.registry`:

   ```
   config:
     overrides:
       - path: spec.registry
         value:
           repository: "https://my-registry.url.com"
   ```

2. Path `spec`. In this example, there is no value for `spec.registry.server`, it will not be available to modify in the `Workload`.

   ```
   config:
     overrides:
       - path: spec
         value:
           registry:
             repository: "https://my-registry.url.com"
   ```

3. Path `spec` with empty value. This example results in a `Workload` without a spec.

   ```
   config:
     defaults:
       - path: spec
         value: {}
   ```

Generate SupplyChain with defaults

Platform engineers generate SupplyChains with defaults to allow them to define default values that can be changed by developers using the `Workload` (Developer API). By configuring defaults for each component in the SupplyChain, the generated `Workload` will contain default values.

Defaults consist of:

- `path`: path to the configuration value, formatted as either:
  1. The full path to the field you want to set.
  2. The path to any structure where all desired child fields must be set.
- `value`: String or YAML structured value.

Defaults use case

1. Generate the SupplyChain by supplying the `--allow-defaults` flag:

   ```
   tanzu supplychain generate \
       --kind AppBuildV1 \
       --description "Supply chain that pulls the source code from git repo, build
   s it using buildpacks and package the output as Carvel package." --component "s
   ource-git-provider-1.0.0" --component "buildpack-build-1.0.0" --component "conv
   entions-1.0.0" \
   ```

```
    --component "app-config-server-1.0.0" \
    --component "carvel-package-1.0.0" \
    --component "git-writer-pr-1.0.0" \
    --allow-defaults
```

The Tanzu Supply Chain CLI plug-in creates the required files to deploy your SupplyChain in the current directory:

```
✓ Successfully fetched all component dependencies
Created file supplychains/appbuildv1.yaml
...
```

2. To configure defaults, open the `supplychains/appbuildv1.yaml` file in your editor and navigate to the following section:

```
  ...
  config:
    defaults:
        # Platform Engineer provided registry defaults
        - path: spec.registry.repository
        value: "YOUR-REGISTRY-REPO"
        - path: spec.registry.server
        value: "YOUR-REGISTRY-SERVER"

        # Platform Engineer provided build defaults
        - path: spec.build.builder.kind
          value: clusterbuilder
        - path: spec.build.builder.name
          value: default
        - path: spec.build.cache.enabled
          value: false
        - path: spec.build.cache.image
          value: ""
        - path: spec.build.serviceAccountName
          value: default

        # Platform Engineer provided carvel package component defaults
        - path: spec.carvel.caCertData
          value: ""
        - path: spec.carvel.iaasAuthEnabled
          value: false
        - path: spec.carvel.packageDomain
          value: "default.tap"
        - path: spec.carvel.serviceAccountName
          value: "default"
        - path: spec.carvel.valuesSecretName
          value: ""

        # Platform Engineer provided GitOps repo defaults
        - path: spec.gitOps.baseBranch
          value: main
        - path: spec.gitOps.branch
          value: main
        - path: spec.gitOps.subPath
          value: "YOUR-GITOPS-REPO-SUBPATH"
        - path: spec.gitOps.url
          value: "YOUR-GITOPS-REPO-URL"
```

3. Configure defaults using either a full path to the field you want to set or a path to any structure where all desired child fields must be set.

Full path
Example path `spec.registry.repository`:

```
config:
  defaults:
    - path: spec.registry.repository
      value: "https://my-default-registry.url.com"
```

Path to any key representing a YAML object

Examples

1. Path `spec.registry`:

   ```
   config:
     defaults:
       - path: spec.registry
         value:
           repository: "https://my-default-registry.url.com"
   ```

2. Path `spec`:

   ```
   config:
     defaults:
       - path: spec
         value:
           registry:
             repository: "https://my-default-registry.url.com"
   ```

Deploy and Manage Supply Chains

This section contains guides for platform engineers about deploying and managing SupplyChain resources.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

In this section:

- GitOps managed SupplyChains

Manage Supply Chains with GitOps

This topic tells you how to manage SupplyChains using GitOps.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

SupplyChains, especially the authoring resources SupplyChain, Component, and Tekton Pipeline/Tekton Task, are delivered to clusters using a Git repository and GitOps source promotion style.

The expected flow is as follows:

1. Author the SupplyChain as a collection of YAML files in a file system backed by Git.
2. Test and debug by pushing all the files to a single namespace.
3. When you're happy with your new or modified SupplyChain, commit it to Git and create a pull request.
4. Using continuous integration, test, and approve the pull request.
5. Using continuous deployment, deliver your edits to build clusters.

Note

Both the integration and deployment of your SupplyChains should be managed by SupplyChains. VMware will release examples of integration and delivery SupplyChains for SupplyChains in a future release.

Create starter Supply Chains

This topic gives you recipes for authoring useful, minimal Supply Chains to get started with.

Build and deploy an application recipe

This Supply Chain builds and deploys an application from source.

It performs the following actions:

- Pulls the application source from Git.
- Builds a container image using Buildpacks.
- Generates a runtime definition with the image.
- Generates a Kubernetes Deployment and Service.
- Generates a Carvel package to make the application deployable.
- Deploys the application.

Complete the following steps:

1. Ensure that you have first initialized a working directory by running tanzu supplychain init.
2. Generate the Supply Chain by running:

```
tanzu supplychain generate \
  --kind WebApp \
  --description "Build and deploy an application from Git" \
  --component source-git-provider-1.0.0 \
  --component buildpack-build-1.0.0 \
  --component conventions-1.0.0 \
  --component app-config-web-1.0.0 \
  --component carvel-package-1.0.0 \
  --component deployer-1.0.0
```

Note

To deploy other workload types, replace the `app-config-web-1.0.0` component with another option such as `app-config-server-1.0.0`, or `app-config-worker-1.0.0`.

Build an application and store the artifact in a Git recipe

This Supply Chain builds a Carvel package from the application source and stores it in a Git repository for deployment to a runtime environment.

It performs the following actions:

- Pulls the application source from Git.
- Builds a container image using Buildpacks.
- Generates a runtime definition with the image.
- Generates a Knative service.
- Generates a Carvel package to make the application deployable.
- Creates a pull request against a Git repository with the Carvel package contents.

Complete the following steps:

1. Ensure that you have initialized a working directory by running tanzu supplychain init.
2. Generate the Supply Chain by running:

```
tanzu supplychain generate \
  --kind CarvelPackage \
  --description "Build an application from source and store the Carvel package
in Git" \
  --component source-git-provider-1.0.0 \
  --component buildpack-build-1.0.0 \
  --component conventions-1.0.0 \
  --component app-config-web-1.0.0 \
  --component carvel-package-1.0.0 \
  --component git-writer-pr-1.0.0
```

Note

To write directly to a Git repository without creating a pull request, replace the `git-writer-pr-1.0.0` component with `git-writer-1.0.0`.

Deploy an application package from a Git recipe

This Supply Chain deploys a Carvel package from a Git repository.

It performs the following actions:

- Pulls the application package from Git.
- Translates the Carvel package to a deployable package.
- Deploys the application.

Complete the following steps:

1. Ensure that you have initialized a working directory by running tanzu supplychain init.
2. Generate the Supply Chain by running:

```
tanzu supplychain generate \
  --kind PackageDeploy \
  --description "Deploy a Carvel package from Git" \
  --component source-git-provider-1.0.0 \
  --component source-package-translator-1.0.0 \
  --component deployer-1.0.0
```

Supply Chain Choreographer

The recipes in this topic are analogous to out of the box supply chains, and profile experiences in Supply Chain Choreographer. Use this mapping to help decide which recipe to start with. These recipes do not provide exact parity with out of the box supply chains.

- Iterate Profile: Use Build and deploy an application recipe.
- Supply Chain Basic: Use Build an application and store the artifact in a Git recipe.
- Delivery Basic: Use Deploy an application package from a Git recipe.

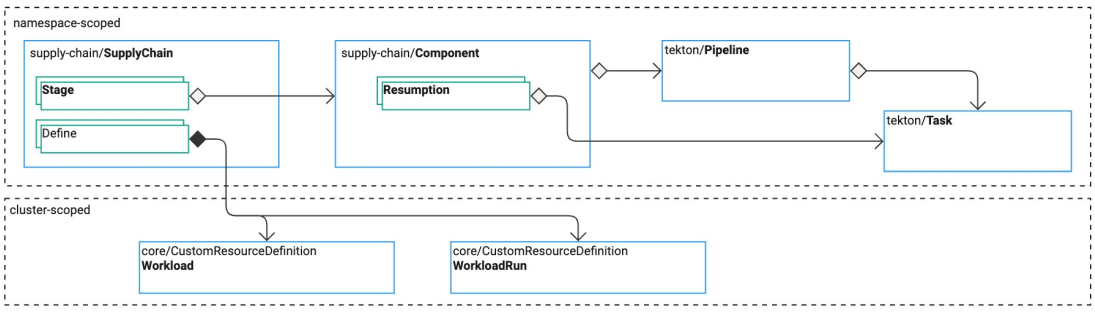
Explanations for platform engineers

This topic tells you about the core architectural concepts of Tanzu Supply Chain. This topic focuses on authoring a platform for application development.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

Tanzu Supply Chain enables platform engineers to author a seamless experience for development work without expertise in Kubernetes.



About the primitives of Tanzu Supply Chain

Tanzu Supply Chain has the following primitives:

- `SupplyChain` defines the `Workload` kind and the components to use.
- `Workload` provides a developer API.
- `WorkloadRun` provides a record of each progression through a supply chain.
- `Component` provides an abstraction for a piece of work and reasons to trigger new runs.
- `Resumptions` provide a process for defining the triggering of new runs.

Overview of the Tanzu Supply Chain system

Each `SupplyChain` resource combines multiple `Component` resources in `stages`. `SupplyChain` resources define a process for converting configuration workloads into final artifacts. They are similar to pipelines in other CI/CD systems, but with some key differences:

- The `SupplyChain` defines a `Workload` custom resource definition (CRD), and the `Workload` becomes the interface that users, typically developers, consume to have work performed.
- Users are typically unaware of the inner workings of the `SupplyChain` and `Component` resources.
- `Component` resources encapsulate the work of generating a final or intermediate artifact and, importantly, the work of discovering new work to be performed.

The flow of operations is as follows:

1. Apply a valid `SupplyChain`, `Components`, and accompanying Tekton `Tasks` and `Pipelines`.
2. Tanzu Supply Chain generates a `Workload` CRD as defined by the `SupplyChain`.
3. A developer uses the Tanzu CLI to see the `Workload` kinds available to them.
4. The developer generates a `Workload` and fills in the required configuration.
5. Tanzu Supply Chain applies the `Workload`.
6. Tanzu Supply Chain starts the first `WorkloadRun`.
7. Tanzu Supply Chain captures the progress and artifacts of the first `WorkloadRun`.
8. Tanzu Supply Chain monitors `Component` resources that have `Resumptions` to detect if it must generate new runs. Tanzu Supply Chain generates new runs if:
    - There is new configuration in the `Workload`
    - There is new source code, base images, or other triggers from `Resumptions`
9. The developer observes the progress of runs using the Tanzu CLI.

Managing SupplyChains with GitOps

`SupplyChain` resources, such as the authoring resources `SupplyChain`, `Component`, Tekton `Pipeline`, and Tekton `Task`, are delivered to clusters through a Git repository and GitOps source promotion style.

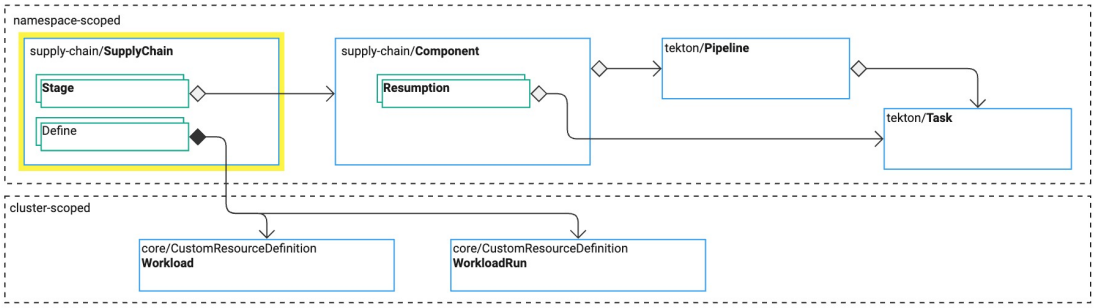
For more information, see Manage SupplyChains with GitOps.

Overview of SupplyChain

This topic tells you about the `SupplyChain` primitive in Tanzu Supply Chain. The `SupplyChain` primitive unifies the Tanzu Supply Chain operation. For reference information, see SupplyChain.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.



`SupplyChain` describes a process with stages

In physical manufacturing a supply chain is the process that delivers an end product to customers, starting with the raw materials. In software, a supply chain delivers an operational end product to customers, starting with source code. VMware refers to this as the golden path to production.

Tanzu Supply Chain provides a primitive called `SupplyChain`, which is a Kubernetes custom resource that you use to define all, or portions of, your software supply chain.

This section describes typical uses of the `SupplyChain` primitive for Tanzu Supply Chain.

`SupplyChain` describes a build process

A `SupplyChain` primitive can describe the process of converting source code into a runnable or deployable package.

Typical stages in this process are:

- Build:
  - Compile a binary from source.
  - Create an OCI image from the binary.
- Configure:
  - Create deployment artifacts, such as Kubernetes Pod definitions.
- Package:
  - Create packaging artifacts, such as a Carvel package or a Helm Chart.

`SupplyChain` defines a configuration resource

A `SupplyChain` primitive brings together the API for a user to apply to the cluster by:

- Defining a group and kind for a resource called a `Workload`. For reference information, see spec.defines.
- Specifying components used in the stages of the `SupplyChain`. For reference information, see spec.stages[].

By selecting components, `SupplyChain` aggregates each configuration for each component as a single API specification for the `Workload`.

Note

`Workload` might be renamed in a later Tanzu Application Platform version.

`SupplyChain` enforces immutability

The version of your `SupplyChain` primitive that is embedded in the name must adhere to the rules described in this section.

A patch update is required to update `SupplyChain` without an API change. The controller ensures taht this rule cannot be broken when comparing `SupplyChain` primitives on the cluster.

For example, you can apply to a cluster:

- A `SupplyChain` primitive with the name `serverappv1s.example.com-1.0.0` and the kind `ServerAppV1s`
- A `SupplyChain` primitive with the name `serverappv1s.example.com-1.0.1` and the kind `ServerAppV1s`

If the generated API for the kind is unchanged, then the later version is accepted. If there is a change, the `SupplyChain` primitive that was applied first succeeds, and the others reflect the error in their statuses. This rule ensures that you cannot accidentally break the kind API that is running.

These rules ensure that potentially thousands of `Workload` and `Run` resources on the cluster do not break.

Recommended version practices:

- If the API and general behavior are unchanged by a change to the `spec.stages`:
  - Use a patch update, such as `1.2.5` to `1.2.6`
  - Keep the same kind, such as `ServerAppV1`
- If the API is unchanged, but something significantly different occurs because of changes to the `spec.stages`, consider doing:
  - An update to the minor or major version, such as `1.2.5` to `1.3.0`
  - An update to the kind, such as `ServerAppV2`
  - A change of kind, such as `ServerAppWithApprovalV1`
- If the API changes, consider doing:
  - An update to the minor or major version, such as `1.2.5` to `1.3.0`
  - An update to the kind, such as `ServerAppV2`

This ensures effective communication to your users. New kind versions typically indicate that the user must migrate their resources to the new API.

Integrity validation

A `SupplyChain` primitive is not valid if:

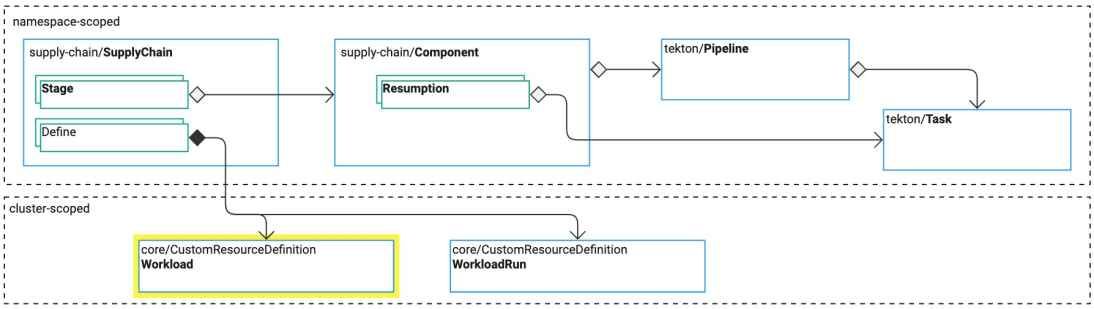
- A required field is missing.
- The `Component` resources referenced are not in the same namespace.
- The `Component` resources referenced contain values that are not satisfied by their position in `spec.stages`.
- The name does not match the `spec.defines` section.
- `SupplyChain` breaks the versioning rules.

For more information, see status.conditions[].

Overview of Workloads

This topic tells you about the `Workload` resource in Tanzu Supply Chain. For reference information, see Workload CRD.

> **Caution**
>
> Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

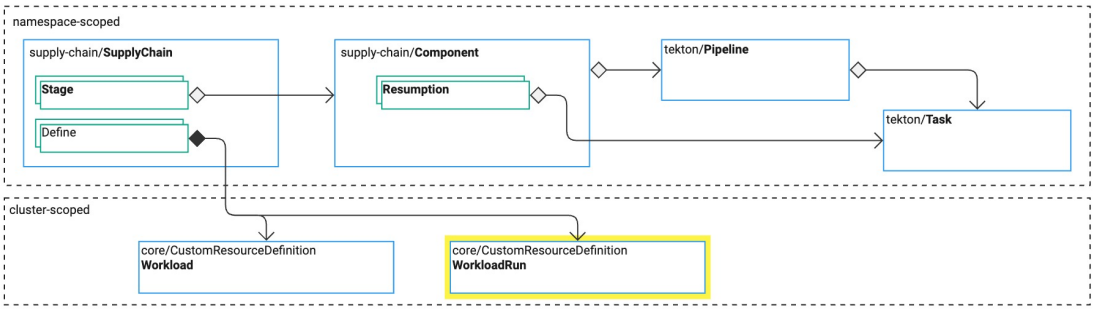


The `SupplyChain` resource defines the `Workload` custom resource definition (CRD).

Overview of WorkloadRun

This topic tells you about the `WorkloadRun` resource in Tanzu Supply Chain. For reference information, see WorkloadRun CRD.

> **Caution**
>
> Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.



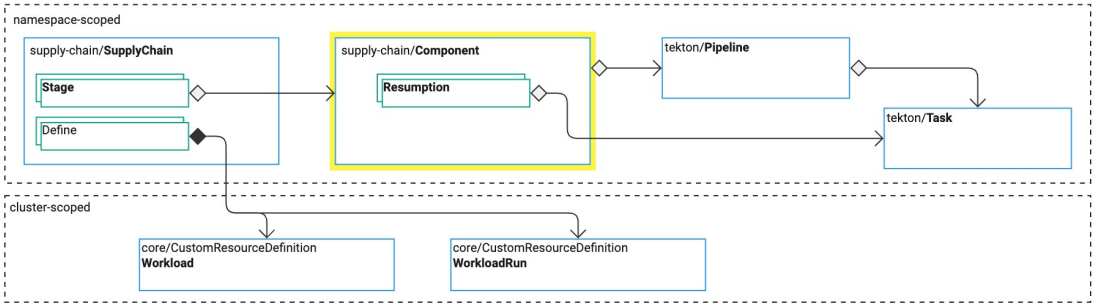
The `SupplyChain` resource defines the `WorkloadRun` custom resource definition (CRD).

Overview of Components

This topic tells you about the `Component` resource in Tanzu Supply Chain. For reference information, see Component API.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.



Components encapsulate the work to be performed in composable and reusable pieces. Components are analogous to steps, stages, jobs, and tasks in other CI/CD offerings. Components are different to other CI/CD offerings in three distinct ways:

- Component configuration requirements are declared, static, and enforced. The configuration is used to build a `Workload` resource that is strongly-typed and well-documented.
- Components are observed by users through a strict error-reporting API.
- Components can exhibit reentrant behavior. If you define a resumption for a component, the resumption can trigger new workload runs. This keeps the stored information about the component in transient dependencies within the component. For more information, see Resumptions.

These design constraints exist to:

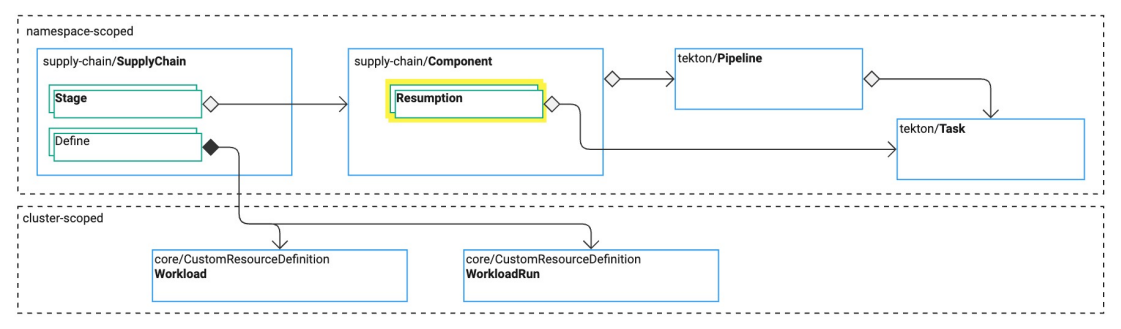
- Simplify the end-user experience by providing a single, well-defined API and a way of mitigating errors if they arise.
- Simplify the authoring experience by requiring only minimal Kubernetes experience to construct supply chains that meet your organization's needs.

Overview of Resumptions

This topic tells you about the concept of resumptions in Tanzu Supply Chain. For reference information about resumptions, see Component API.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.



Resumptions are an important part of the Tanzu Supply Chain `Component` resource.

The `Component` resource deals with the configuration to pass to resumptions and pipelines, or the pipeline to run when the `Component` stage is reached in the supply chain. Resumptions are focused on the reasons to run again.

Resumptions are executed on a timer that is specified in the `resumptions` array of the component. When resumptions trigger they execute a Tekton `TaskRun` to detect new values. These are common for detecting changes to source repositories, image repositories, and new versions of binaries.

If a run reaches a stage with a resumption, the system generates a `resumptionKey` based on the value of the parameters that are passed to the resumption. If a resumption has already been executed with the same parameters, the result of that resumption is used. This allows hundreds or thousands of workloads to reuse the same common inputs from resumptions without needing to run another resumption.

After the last completion of a resumption `TaskRun`, resumptions wait for the period specified in `resumptions[].trigger.runAfter` before running it again.

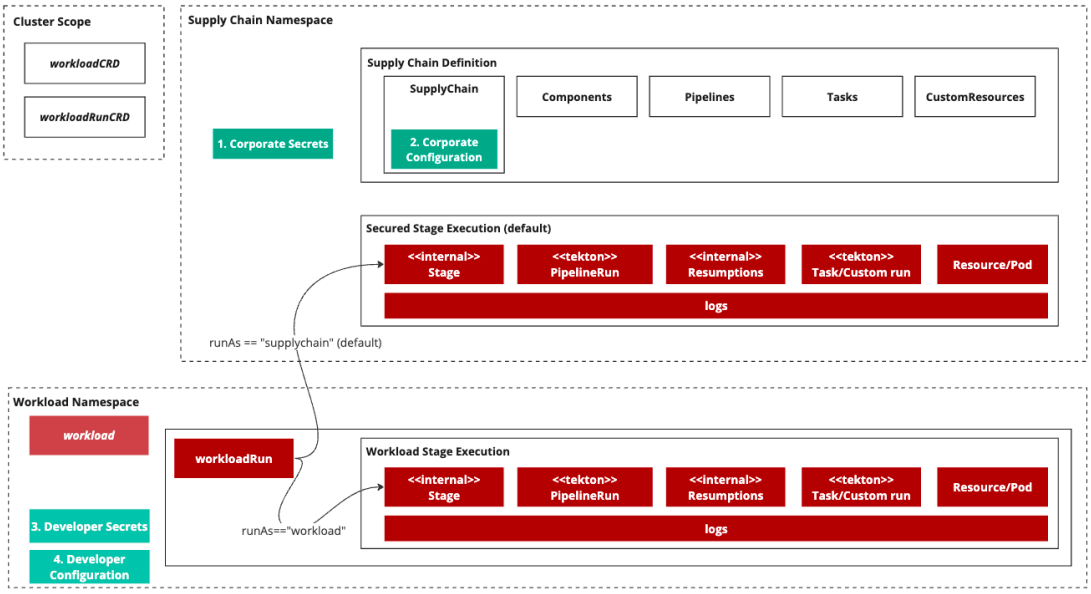
When a result for a resumption changes, all the `WorkloadRun` resources with the same `resumptionKey` are cloned, truncated back to the stage of the resumption, and progress starts from there. This is the mechanism for resumptions triggering a new `WorkloadRun`.

Security Model

This topic tells you about the security model for Tanzu Supply Chain. This security model is for executing stages of a Supply Chain where workloads exist in a separate namespace to the Supply Chain.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.



Runs for associated workloads are created in the same namespace as the workload.

`Stages`, `Resumptions`, `TaskRuns`, and `PipelineRuns` are created by default in the Supply Chain namespace. This gives the components in these stages visibility over platform secrets in the Supply Chain namespace.

If you want a stage of a pipeline to execute in the workload namespace, use the `securityContext.runAs` setting. For example, you can allow a source component to retrieve the source from a developer-controlled repository by using secrets that the developer provides in the workload namespace.

For more information, see the `securityContext` specification in the `SupplyChain` API topic.

Tanzu Supply Chain for Developers

This section contains the developer-focused features of Tanzu Supply Chain.

> **Caution**
>
> Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

Prerequisites

Start using Tanzu Supply Chain by installing these CLI tools:

- Install the Tanzu CLI
- Install the Tanzu Workload CLI plug-in

Getting Started with Tutorials

- Deploy your first Workload

How to Guides

- Work with Workloads

Tutorials for Developers

This section contains tutorials for developers about how to use Tanzu Supply Chain.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

In this section:

- Deploy your first workload

Tutorial: Deploy your first workload

This topic tells you how to use the Tanzu Workload CLI plug-in to create your first `Workload`.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

In this tutorial, the platform engineer has already created some Supply Chains for you to use. The Supply Chains can pull the source code from the source repository and build it. The built artifact is then pushed to a GitOps repository that the platform engineer selected.

Prepare

Install:

- Tanzu CLI
- Tanzu Workload CLI plug-in

Deploy a workload

To get started:

1. See which `SupplyChain` resources are available to you, and which kinds of `Workload` resources you can create by using those `SupplyChain` resources, by running:

   ```
   tanzu workload kind list
   ```

   Example output:

   ```
   $ tanzu workload kind list

    KIND                                        VERSION   DESCRIPTION
    appbuildv1s.supplychains.tanzu.vmware.com   v1alpha1  Supply chain that pulls t
   he source code from git repo, builds it using
                                                         buildpacks and package th
   e output as Carvel package.
   ```

```
  To generate a workload for one of these kinds, use 'tanzu workload generate'
```

The command output shows that you have a `appbuildv1s.supplychains.tanzu.vmware.com` kind that you can use to generate the workload. The Tanzu CLI also shows a hint about the next command to use in the process.

2. For this tutorial, build your workload by using the tanzu-java-web-app sample application.

   Use the `tanzu workload generate` command to create a `Workload` of the kind `AppBuildV1`. A selector is displayed if multiple kinds are available. If a single kind is available, it is used to generate the scaffold of the `Workload`. Run:

   ```
   tanzu workload generate tanzu-java-web-app
   ```

   Example output:

   ```
   apiVersion: supplychains.tanzu.vmware.com/v1alpha1
   kind: AppBuildV1
   metadata:
    name: tanzu-java-web-app
   spec:
    #! Configuration for the generated Carvel Package
    carvel:
      ...
    gitOps:
      ...
    #! Configuration for the registry to use
    registry:
      ...
    source:
      ...
    #! Kpack build specification
    build:
      ...
   ```

3. Pipe the output into a `workload.yaml` file. If you have more than one kind available in the cluster, you must provide a `--kind` flag. The `--kind` flag supports tab auto-completion. Run:

   ```
   tanzu workload generate tanzu-java-web-app --kind appbuildv1s.supplychains.tanz
   u.vmware.com > workload.yaml
   ```

4. Add the appropriate values in the `workload.yaml` file for each required entry. For example:

   ```
   apiVersion: supplychains.tanzu.vmware.com/v1alpha1
   kind: AppBuildV1
   metadata:
     name: tanzu-java-web-app
   spec:
     gitOps:
       baseBranch: "main"
       subPath: "packages"
       url: GITOPS-REPO-PATH
     registry:
       repository: REPOSITORY-PATH
       server: REGISTRY-SERVER
     source:
       git:
         branch: "main"
         url: "https://github.com/vmware-tanzu/application-accelerator-samples.gi
   t"
       subPath: "tanzu-java-web-app"
     carvel:
   ```

```
    packageName: "tanzu-java-web-app"
    packageDomain: "tanzu.vmware.com"
```

Caution

The beta version of the Tanzu Supply Chain does not support platform engineer-level overrides and defaults. Therefore, the `Workload` generate command also shows the entries that a platform engineer is supposed to set, such as the registry details.

When the overrides feature is available, a platform engineer can set platform-level values, such as the registry details. These entries are not part of the `generate` command output because that is something a platform engineer does not want a developer to override.

This results in a much smaller `Workload` spec and one that only has values that a developer can provide for the `SupplyChain`. This helps to keep the platform engineering role and the developer role separate.

5. Use the `tanzu workload apply` command to apply your `AppBuildV1` workload to the cluster. If your workload YAML file is not named `workload.yaml`, use the `-f` flag to point to it. For this tutorial, use the `dev` namespace. Run:

```
tanzu workload apply
```

Example output:

```
  Creating workload:
     1 + |---
     2 + |apiVersion: supplychains.tanzu.vmware.com/v1alpha1
     3 + |kind: AppBuildV1
     4 + |metadata:
     5 + |  name: tanzu-java-web-app
     6 + |  namespace: dev
     7 + |spec:
     8 + |  carvel:
     9 + |    packageDomain: tanzu.vmware.com
    10 + |    packageName: tanzu-java-web-app
    11 + |  gitOps:
    12 + |    baseBranch: main
    13 + |    subPath: packages
    14 + |    url: GITOPS-REPO-PATH
    15 + |  registry:
    16 + |    repository: REPOSITORY-PATH
    17 + |    server: REGISTRY-SERVER
    18 + |  source:
    19 + |    git:
    20 + |      branch: main
    21 + |      url: https://github.com/vmware-tanzu/application-accelerator-sam
ples.git
    22 + |    subPath: tanzu-java-web-app
Create workload tanzu-java-web-app from workload.yaml? [yN]: y
✓ Successfully created workload tanzu-java-web-app
```

6. See all the workloads of each kind running in your namespace by running:

```
tanzu workload list
```

Example output:

```
Listing workloads from the dev namespace

 NAME                KIND                                          VERSION   AGE
 tanzu-java-web-app  appbuildv1s.supplychains.tanzu.vmware.com  v1alpha1  30m

  To see more details about a workload, use 'tanzu workload get workload-name -
-kind workload-kind'
```

7. See all the workloads running in all namespaces by running:

```
tanzu workload list -A
```

8. See how the `tanzu-java-web-app` workload in the workload list is progressing by running:

```
tanzu workload get tanzu-java-web-app
```

Example output:

```
  Overview
  name:       tanzu-java-web-app
  kind:       appbuildv1s.supplychains.tanzu.vmware.com/tanzu-java-web-app
  namespace:  dev
  age:        15m

  Runs:
  ID                           STATUS   DURATION  AGE
  tanzu-java-web-app-run-454m5  Running  2m        2m

  To view a run information, use 'tanzu workload run get run-id'
```

From the output, you see that a `WorkloadRun` named `tanzu-java-web-app-run-454m5` was created when you applied the `AppBuildV1` workload and it is in the `Running` state. There are multiple causes for why a new `WorkloadRun` is created for your `Workload`, but few are developer-triggered.

Updates to your `Workload`, such as changing the values in `workload.yaml` and reapplying them to the cluster, create a new `WorkloadRun`. Platform engineering activities such as updating the Buildpack builder images can also cause your `Workload` to rebuild, creating a new `WorkloadRun` with newer base images.

Other activities, such as pushing new commits to the source-code repository referenced by the `Workload`, can also cause a new run of the `Workload` to build the latest source from your Git repository.

9. Use the `tanzu workload run get` command to see more information about which stages your workload is going through. Use the optional `--show-details` flag for more detailed output. Run:

```
tanzu workload run get tanzu-java-web-app-run-454m5 --show-details
```

Example output:

```
  Overview
  name:        tanzu-java-web-app
  kind:        appbuildv1s.supplychains.tanzu.vmware.com/tanzu-java-web-app
  run id:      appbuildv1runs.supplychains.tanzu.vmware.com/tanzu-java-web-app-
run-454m5
  status:      Running
  namespace:   dev
  age:         14m
```

```
  Spec
     1 + |---

```

The output shows you:

- An overview of your workload, such as `name`, `kind`, and `namespace`
- The last 2 successful `WorkloadRuns`
- The last failed `WorkloadRun`
- All running `WorkloadRuns`
- The error section from the last failed `WorkloadRun`

When your `WorkloadRun` has gone through the Supply Chain, the output of the `Workload` and `WorkloadRun` is as follows:

Workload Run Output
tanzu workload run get tanzu-java-web-app-run-454m5 –show-details

```
  Overview
  name:         tanzu-java-web-app
  kind:         appbuildv1s.supplychains.tanzu.vmware.com/tanzu-java-web-app

Workload Get Output
tanzu workload get tanzu-java-web-app

```
  Overview
name:       tanzu-java-web-app
kind:       appbuildv1s.supplychains.tanzu.vmware.com/tanzu-java-web-app
namespace:  dev
age:        74m

  Runs:
ID                           STATUS     DURATION  AGE
tanzu-java-web-app-run-454m5  Succeeded  16m       72m

  To view a run information, use 'tanzu workload run get run-id'
```

Based on the description of the `AppBuildV1` kind from the `tanzu workload kind list` command, the Supply Chain pulls the source code from the Git repository, builds it by using buildpacks, and then packages the output as a Carvel package. That output is then shipped to the GitOps repository that the platform engineer configures.

In your Supply Chain, when the `WorkloadRun` succeeds you can see the URL for the pull request to the GitOps repository in the `tanzu workload run get --show-details` output in the `gitops-pr` stage results.

You have now used Tanzu Supply Chain to deploy your first workload.

Next Steps

See these How-to guides for developers to learn more about Tanzu Supply Chain.

How-to topics for developers

This section contains how-to topics for developers using Tanzu Supply Chain.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

In this section:

- Install the workload CLI plug-in
- Work with workloads

Install the Tanzu Workload CLI plug-in

This topic tells you how to install the Tanzu Workload CLI plug-in. Use this CLI plug-in to work with the workloads provided by platform engineering.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

This plug-in enables you to see workload kinds, deploy workloads, and monitor the workloads. The Tanzu Supply Chain beta release does not include the installation of the Tanzu Workload CLI plug-in as part of the plug-in group.

The Tanzu Workload CLI plug-in provides commands that enable a developer to generate a `Workload` manifest, apply it to a cluster, and delete it from a cluster.

Prepare

Install the latest version of the Tanzu CLI. For more information, see Install Tanzu CLI.

Install Tanzu Workload CLI plug-in

To install the Tanzu Workload CLI plug-in:

1. Install the plug-in by running:

   ```
   tanzu plugin install workload
   ```

2. Verify that you installed the plug-in successfully by running:

   ```
   tanzu workload version
   ```

Note

If you need to uninstall the Tanzu Workload CLI plug-in, run:

```
tanzu plugin delete workload
```

Work with workloads

This topic tells you how to work with workloads when using Tanzu Supply Chain.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

This topic explains how to:

- Find the kinds of workloads you can use
- Create and delete a workload
- Observe runs of your workloads

Find the kinds of workloads you can use

Use the Tanzu Workload CLI plug-in to see available `Workload` kinds by running:

```
tanzu workload kinds list
```

Example:

```
KIND                          VERSION   DESCRIPTION
buildserverapps.vmware.com  v1        Builds a Kubernetes deployment app exposed using
a Service using Buildpacks.
buildwebapps.vmware.com     v1        Pulls the source code from a Git repository and
builds a Knative Service app using Buildpacks.
buildworkerapps.vmware.com  v1        Creates a background worker app deployed as Kube
rnetes deployment using Buildpacks.

  To generate a workload for one of these kinds, use 'tanzu workload generate'
```

Create and delete a workload

In this section you:

- Generate a workload manifest
- Create a workload
- Apply a workload
- Delete a workload

Generate a workload manifest

To generate a workload manifest:

1. Generate a `Workload` manifest with default configuration by running:

   ```
   tanzu workload generate APP-NAME --kind buildwebapps.vmware.com
   ```

   Where `APP-NAME` is the name of the app. For example, `my-web-app`.

   Example:

   ```
   apiVersion: vmware.com/v1
   kind: BuildWebApp
   metadata:
    name: my-web-app
   spec:
    source:
      #! Use this object to retrieve source from a git repository.
      #! The tag, commit, and, branch fields are mutually exclusive, use only one.
      #! Required
      git:
        #! A git branch ref to watch for new source
        branch: ""
        #! A git commit sha to use
        commit: ""
        #! A git tag ref to watch for new source
        tag: ""
        #! The url to the git source repository
        #! Required
        url: ""
      #! path inside the source to build from (build has no access to paths above
   the subPath)
      subPath: ""
   ...
   #! other configuration
   ```

2. Store the `Workload` manifest in a file for use by the `tanzu workload create`, `tanzu workload apply`, and `tanzu workload get` commands, and pipe the output into a `workload.yaml` file, by running:

   ```
   tanzu workload generate APP-NAME --kind buildwebapps.vmware.com > workload.yaml
   ```

   Where `APP-NAME` is the name of the app. For example, `my-web-app`.

Create a workload

To create a workload:

1. Create a `Workload` on the cluster from a manifest by running:

   ```
   tanzu workload create --file workload.yaml --namespace build
   ```

   Example:

   ```
   Creating workload:
        1 + |---
        2 + |apiVersion: vmware.com/v1
        3 + |kind: BuildWebApp
        4 + |metadata:
        5 + |  name: my-web-app
        6 + |  namespace: build
        7 + |spec:
        8 + |  source:
        9 + |    git:
       10 + |      branch: ""
       11 + |      commit: ""
   ```

```
   12 + |      tag: ""
   13 + |      url: ""
   14 + |    subPath: ""
   15 + |  ...
Create workload my-web-app from workload.yaml? [yN]: y
Successfully created workload my-web-app
```

2. Override the `Workload` name provided in the manifest by running:

   ```
   tanzu workload create NAME --file workload.yaml --namespace build
   ```

   Where `NAME` is a name to serve as an argument for the manifest. For example, `my-web-app-2`.

Apply a workload

To apply a workload:

1. The `tanzu workload create` command is only used to create a `Workload` that does not already exist. To update an existing `Workload`, use `tanzu workload apply`. Apply a `Workload` manifest to the cluster by running:

   ```
   tanzu workload apply --file workload.yaml --namespace build
   ```

   Example:

   ```
   Creating workload:
        1 + |---
        2 + |apiVersion: vmware.com/v1
        3 + |kind: BuildWebApp
        4 + |metadata:
        5 + |  name: my-web-app
        6 + |  namespace: build
        7 + |spec:
        8 + |  source:
        9 + |    git:
       10 + |      branch: ""
       11 + |      commit: ""
       12 + |      tag: ""
       13 + |      url: ""
       14 + |    subPath: ""
       15 + |  ...
   Create workload my-web-app from workload.yaml? [yN]: y
   Successfully created workload my-web-app
   ```

2. Override the `Workload` name provided in the manifest by running:

   ```
   tanzu workload apply NAME --file workload.yaml --namespace build
   ```

   Where `NAME` is a name to serve as an argument for the manifest. For example, `my-web-app-2`.

Delete a workload

Delete a `Workload` by name within a namespace by running:

```
tanzu workload delete --file /tmp/workload.yaml --namespace build
```

Example:

```
Really delete the workload my-web-app of kind buildwebapps.vmware.com from the build n
amespace? [yN]: y
Successfully deleted workload my-web-app
```

Note

Deleting a `Workload` prevents new builds while preserving built images in the registry.

Observe the runs of your workload

Use the Tanzu Workload CLI plug-in to observe `Workloads` and their `WorkloadRuns`:

1. List all workloads on the cluster by running:

   ```
   tanzu workload list --namespace build
   ```

   Example:

   ```
   Listing workloads from the build namespace

    NAME        KIND                      VERSION  AGE
    my-web-app  buildwebapps.vmware.com  v1       6m54s
   ```

2. Get the details of the specified `Workload` within a namespace by running:

   ```
   tanzu workload get APP-NAME --namespace build
   ```

   Where `APP-NAME` is the application name. For example, `my-web-app`.

   Example:

   ```
   $ tanzu workload get my-web-app --namespace build
   Overview
    name:       my-web-app
    kind:       buildwebapps.vmware.com/my-web-app
    namespace:  build
    age:        17s

   Runs:
    ID                    STATUS   DURATION  AGE
    my-web-app-run-lxwrm  Running  0s        17s
   ```

3. Get the workload output as YAML for programmatic use by running:

   ```
   tanzu workload get APP-NAME --namespace build -o yaml
   ```

   Where `APP-NAME` is the application name. For example, `my-web-app`.

   Example:

   ```
   $ tanzu workload get my-web-app --namespace build -o yaml
   ---
   apiVersion: vmware.com/v1
   kind: BuildWebApp
   metadata:
    name: my-web-app
    namespace: build
   ```

```
spec:
 ...
```

4. Get the details of the specified workload run within a namespace by running:

```
tanzu workload run get APP-NAME-run-lxwrm -n build --show-details
```

Where `APP-NAME` is the application name. For example, `my-web-app`.

Example:

```
Overview
 name:         my-web-app
 kind:         buildwebapps.vmware.com/my-web-app
 run id:       buildwebappruns.vmware.com/my-web-app-run-lxwrm
 status:       Running
 namespace:    build
 age:          39s

Spec
     1 + |---
     2 + |apiVersion: vmware.com/v1
     3 + |kind: BuildWebApp
     4 + |metadata:
     5 + |  name: my-web-app
     6 + |  namespace: build
     7 + |spec:
     8 + |...

Tanzu Supply Chain Reference

This section provides reference information for Tanzu Supply Chain.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

In this section:

- Component Catalog
- Supply Chain CLI Plug-in Reference
- Workload CLI Plug-in Reference
- Supply Chain API

Catalog of Tanzu Supply Chain Components

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

This section introduces the catalog of components shipped with TAP. You will find all of these components in the “authoring” profile.

app-config-server

Version: 1.0.0

Description:

Generates configuration for a Server application from a Conventions PodIntent. Server applications contain a K8s Deployment and Service and can be configured with Ingress.

Inputs

Name	Type
conventions	conventions

Outputs

Name	Type
oci-yaml-files	oci-yaml-files
oci-ytt-files	oci-ytt-files

Config

```
spec:
  # Configuration for the registry to use
  registry:
    # The name of the registry server, e.g. docker.io
    # +required
    server:
    # The name of the repository
    # +required
    repository:
```

---

app-config-web

Version: 1.0.0

Description:

Generates configuration for a Web application from a Conventions PodIntent. Web applications contain a Knative Service.

Inputs

Name	Type
conventions	conventions

Outputs

Name	Type
oci-yaml-files	oci-yaml-files
oci-ytt-files	oci-ytt-files

Config

```
spec:
  # Configuration for the registry to use
  registry:
    # The name of the repository
    # +required
    repository:
    # The name of the registry server, e.g. docker.io
    # +required
    server:
```

---

app-config-worker

Version: 1.0.0

Description:

Generates configuration for a Worker application from a Conventions PodIntent. Worker applications contain a K8s Deployment.

Inputs

Name	Type
conventions	conventions

Outputs

Name	Type
oci-yaml-files	oci-yaml-files
oci-ytt-files	oci-ytt-files

Config

```
spec:
  # Configuration for the registry to use
  registry:
    # The name of the repository
    # +required
    repository:
    # The name of the registry server, e.g. docker.io
    # +required
    server:
```

---

buildpack-build

Version: 1.0.0

Description:

Builds an app with buildpacks using kpack

Inputs

Name	Type
source	source
git	git

Outputs

Name	Type
image	image

Config

```
spec:
  # Registry to use
  registry:
    # The registry address
    # +required
    server:
    # The repository to use
    # +required
    repository:
  # Kpack build specification
  build:
```

```
    # Service account to use
    serviceAccountName:
    env:
    # Configure workload to use a non-default builder or clusterbuilder
    builder:
      # builder kind
      kind:
      # builder name
      name:
    # cache options
    cache:
      # whether to use a cache image
      enabled:
      # cache image to use
      image:
  source:
    # path inside the source to build from (build has no access to paths above the sub
Path)
    subPath:
```

---

carvel-package

Version: 1.0.0

Description:

Generates a carvel package from OCI images containing raw YAML files and YTT files.

Inputs

Name	Type
oci-yaml-files	oci-yaml-files
oci-ytt-files	oci-ytt-files

Outputs

Name	Type
package	package

Config

```
spec:
  # Configuration for the generated Carvel Package
  carvel:
    # The name of the Carvel Package. Combines with spec.carvel.packageDomain to creat
e the Package refName. If set to "", will use the workload name.
    packageName:
    # Service account that gives kapp-controller privileges to create resources in the
namespace.
    serviceAccountName:
    # Name of the values Secret that provides customized values to the package install
ation's templating steps.
    valuesSecretName:
    # PEM encoded certificate data for the image registry where the files will be push
ed to.
    caCertData:
    # Enable the use of IAAS based authentication for imgpkg.
    iaasAuthEnabled:
```

```
    # The domain of the Carvel Package. Combines with spec.carvel.packageName to creat
e the Package refName. If set to "", will use "default.tap".
    packageDomain:
  gitOps:
    # the branch to commit changes to
    branch:
    # the relative path within the gitops repository to add the package configuration
to.
    subPath:
    # the repository to push the pull request to
    url:
  # Configuration for the registry to use
  registry:
    # The name of the repository
    # +required
    repository:
    # The name of the registry server, e.g. docker.io
    # +required
    server:
```

---

conventions

Version: 1.0.0

Description:

The Conventions component analyzes the `image` input as described in the Cartographer Conventions documentation and produces a `conventions` output image.

Depends on: - Managed Resource Controller. - Tanzu Carvel Package: `managed-resource-controller.apps.tanzu.vmware.com @ >=0.1.2` - Conventions Controller - Tanzu Carvel Package: `cartographer.tanzu.vmware.com @ >= 0.8.10`

Inputs

Name	Type
image	image

Outputs

Name	Type
conventions	conventions

Config

```
spec:
  # May contain an optional array of objects. Each object is a pair of keys: `name` an
d either `value` or `valueFrom`.
  # The Conventions component will translate these values into environment variables i
n the output object.
  env:
```

---

deployer

Version: 1.0.0

Description:

Deploys K8s resources to the cluster.

Inputs

Name	Type
package	package

Outputs

- *none*

Config

```
spec:
  # The path to the yaml to be applied to the cluster.
  subPath:
    # The path to the yaml to be applied to the cluster
    # +required
    path:
```

---

git-writer

Version: 1.0.0

Description:

Writes carvel package config directly to a gitops repository

Inputs

Name	Type
package	package

Outputs

- *none*

Config

```
spec:
  gitOps:
    # the repository to push the pull request to
    # +required
    url:
    # the branch to commit changes to
    branch:
    # the relative path within the gitops repository to add the package configuration
to.
    subPath:
```

---

git-writer-pr

Version: 1.0.0

Description:

Writes carvel package config to a gitops repository and opens a PR

Inputs

Name	Type
package	package

Outputs

Name	Type
git-pr	git-pr

Config

```
spec:
  gitOps:
    # the base branch to create PRs against
    baseBranch:
    # the relative path within the gitops repository to add the package configuration
to.
    subPath:
    # the repository to push the pull request to
    # +required
    url:
```

kaniko-build

Version: 1.0.0

Description

Builds an app with kaniko

Inputs

Name	Type
source	source
git	git

Outputs

Name	Type
image	image

Config

```
spec:
  # Kaniko build specification
  build:
    # path to dockerfile to build
    dockerfile:
    # extra args to pass to kaniko build
```

```
    extra-args:
  # Registry to use
  registry:
    # The repository to use
    # +required
    repository:
    # The registry address
    # +required
    server:
```

---

source-git-provider

Version: 1.0.0

Description:

Source git provider retrieves source code and monitors a git repository.

Inputs

- *none*

Outputs

Name	Type
source	source
git	git

Config

```
spec:
  source:
    # Use this object to retrieve source from a git repository.
    # The tag, commit and branch fields are mutually exclusive, use only one.
    # +required
    git:
      # A git branch ref to watch for new source
      branch:
      # A git commit sha to use
      commit:
      # A git tag ref to watch for new source
      tag:
      # The url to the git source repository
      # +required
      url:
    # The sub path in the bundle to locate source code
    subPath:
```

---

source-package-translator

Version: 1.0.0

Description:

Takes the type source and immediately outputs it as type package.

Inputs

Name	Type
source	source

Outputs

Name	Type
package	package

Config

none

---

trivy-image-scan

Version: 1.0.0

Description:

Performs a trivy image scan using the scan 2.0 components

Inputs

Name	Type
image	image
git	git

Outputs

- *none*

Config

```
spec:
  # Configuration for the registry to use
  registry:
    # The name of the repository
    # +required
    repository:
    # The name of the registry server, e.g. docker.io
    # +required
    server:
  source:
    # Fill this object in if you want your source to come from git.
    # The tag, commit and branch fields are mutually exclusive, use only one.
    # +required
    git:
      # A git branch ref to watch for new source
      branch:
      # A git commit sha to use
      commit:
      # A git tag ref to watch for new source
      tag:
      # The url to the git source repository
      # +required
      url:
    # The sub path in the bundle to locate source code
```

```
    subPath:
  # Image Scanning configuration
  scanning:
    service-account-scanner:
    workspace:
      size:
      bindings:
    active-keychains:
    service-account-publisher:
```

Output types for catalog components

This section describes the common types established in Tanzu Supply Chain Components, their purpose and their structure. Use this as a guide to consuming or emitting types from your own custom Components.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

conventions

URL: OCI image containing the `app-config.yaml` file.
Digest: OCI image digest

This output image contains a single file: `app-config.yaml`. The `template` field in this file contains a Kubernetes Pod Template Spec, decorated by the Conventions controller. The Conventions component can also copy the settings in the configurations `spec.env` into the Pod template's `env` field.

git

URL: The source code Git repository URL.
Digest: The source code git commit sha.

git-pr

URL: URL of the pull request.
Digest: SHA digest of the pull request commit.

Output for a Git pull request.

image

URL: OCI image URL for the image built with kpack.
Digest: OCI image digest

An OCI image containing the app built with kpack.

oci-yaml-files

URL: An OCI image containing Kubernetes resource(s) as YAML files.
Digest: OCI image digest.

The resources in this OCI image can be applied to a cluster with no modifications.

The purpose of this OCI image type is to provide the raw Kubernetes resources required to deploy an application onto a cluster.

oci-ytt-files

URL: An OCI image containing files written in the ytt templating language.
Digest: OCI image digest

The files in this OCI image cannot be applied to a cluster, and are intended to be combined with Kubernetes resources from oci-yaml-files.

The purpose of this OCI image type is to provide the ytt Values Schema and Overlays that make a Carvel Package configurable. Separating the ytt files from the raw Kubernetes resources makes the app-config-* components more generally useful. If a Supply Chain author wanted to create a Supply Chain that simply deploys the raw Kubernetes YAML files created by the app-config-* components, instead of putting them into a Carvel Package, they could write a component that takes the input oci-yaml-files, and not the input oci-ytt-files.

package

URL: An OCI image containing a Carvel Package, PackageInstall, and Values YAML file.
Digest: OCI image digest.

The resources in this OCI image can either be deployed to a cluster, or written to a Git repository for use in a GitOps workflow.

The purpose of this OCI image type is to contain a single version of an application as a Carvel Package, as well as the PackageInstall and Values YAML necessary to deploy the Package.

source

URL: OCI image containing the Git repository source code.
Digest: OCI image digest.

An OCI image containing the source code retrieved from a Git repository.

tanzu workload

create, update, view and list Tanzu Workloads.

Options

```
-h, --help              help for workload
    --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)
    --no-color          deactivate color, bold, animations, and emoji output
```

SEE ALSO

- tanzu workload apply - Apply a workload of specific kind on the cluster from the file
- tanzu workload create - Create a workload of specific kind on the cluster from the file
- tanzu workload delete - Delete workload
- tanzu workload generate - Generate a workload manifest with specified configuration
- tanzu workload get - Get details of a workload

- tanzu workload kind - View supported workload types (kinds)
- tanzu workload list - Lists all workloads
- tanzu workload logs - Watch workload related logs
- tanzu workload run - View workload runs

tanzu workload apply

Apply a workload of specific kind on the cluster from the file

```
tanzu workload apply [NAME] [flags]
```

Examples

```
tanzu workload apply --file workload.yaml
  tanzu workload apply my-workload --file workload.yaml --namespace my-namespace
```

Options

```
  -f, --file string      file that contains the workload manifest. Can also be a URL
(default "workload.yaml")
  -h, --help             help for apply
  -n, --namespace name   kubernetes namespace (defaulted from kube config)
  -o, --output string    output of the active workload run along with the status in se
lected format. Supported formats: "json", "yaml", "yml"
  -y, --yes              accept all prompts
```

Options inherited from parent commands

```
      --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)
      --no-color          deactivate color, bold, animations, and emoji output
```

SEE ALSO

- tanzu workload - create, update, view and list Tanzu Workloads.

tanzu workload create

Create a workload of specific kind on the cluster from the file

```
tanzu workload create [NAME] [flags]
```

Examples

```
tanzu workload create --file workload.yaml
  tanzu workload create my-workload --file workload.yaml --namespace my-namespace
```

Options

```
  -f, --file string      file that contains the workload manifest. Can also be a URL
(default "workload.yaml")
```

```
  -h, --help             help for create
  -n, --namespace name   kubernetes namespace (defaulted from kube config)
  -o, --output string    output of the active workload run along with the status in se
lected format. Supported formats: "json", "yaml", "yml"
  -y, --yes              accept all prompts
```

Options inherited from parent commands

```
      --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)
      --no-color          deactivate color, bold, animations, and emoji output
```

SEE ALSO

- tanzu workload - create, update, view and list Tanzu Workloads.

tanzu workload delete

Delete workload

Synopsis

Delete a workload by name within a namespace.

Deleting a workload prevents new builds while preserving built images in the registry.

```
tanzu workload delete [NAME] [flags]
```

Examples

```
tanzu workload delete NAME
  tanzu workload delete NAME --kind kindname
  tanzu workload delete NAME --kind kindname --namespace default
  tanzu workload delete --file workload.yaml
```

Options

```
  -f, --file file path   file path containing the description of a single workload, ot
her flags are layered on top of this resource. Use value "-" to read from stdin
  -h, --help             help for delete
  -k, --kind string      kind of the workload specification
  -n, --namespace name   kubernetes namespace (defaulted from kube config)
  -y, --yes              accept all prompts
```

Options inherited from parent commands

```
      --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)
      --no-color          deactivate color, bold, animations, and emoji output
```

SEE ALSO

- tanzu workload - create, update, view and list Tanzu Workloads.

tanzu workload generate

Generate a workload manifest with specified configuration

Synopsis

Generate a workload manifest with specified configuration.

workload configuration options include: - kind of the workload to generate

```
tanzu workload generate [NAME] [flags]
```

Examples

```
tanzu workload generate NAME
  tanzu workload generate NAME --kind kindname
```

Options

```
  -h, --help          help for generate
  -k, --kind string   kind of the workload specification.
```

Options inherited from parent commands

```
      --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)
      --no-color          deactivate color, bold, animations, and emoji output
```

SEE ALSO

- tanzu workload - create, update, view and list Tanzu Workloads.

tanzu workload generate

Generate a workload manifest with specified configuration

Synopsis

Generate a workload manifest with specified configuration.

workload configuration options include: - kind of the workload to generate

```
tanzu workload generate [NAME] [flags]
```

Examples

```
tanzu workload generate NAME
  tanzu workload generate NAME --kind kindname
```

Options

```
  -h, --help          help for generate
  -k, --kind string   kind of the workload specification.
```

Options inherited from parent commands

```
      --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)
      --no-color          deactivate color, bold, animations, and emoji output
```

SEE ALSO

- tanzu workload - create, update, view and list Tanzu Workloads.

tanzu workload kind

View supported workload types (kinds)

Options

```
  -h, --help   help for kind
```

Options inherited from parent commands

```
      --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)
      --no-color          deactivate color, bold, animations, and emoji output
```

SEE ALSO

- tanzu workload - create, update, view and list Tanzu Workloads.
- tanzu workload kind list - Lists all workload kinds

tanzu workload kind list

Lists all workload kinds

Synopsis

Lists all workload kinds

kind list configuration options include: - Output the kind list formatted

```
tanzu workload kind list [flags]
```

Examples

```
tanzu workload kind list
```

Options

```
  -h, --help   help for list
```

Options inherited from parent commands

```
      --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)
      --no-color          deactivate color, bold, animations, and emoji output
```

SEE ALSO

- tanzu workload kind - View supported workload types (kinds)

tanzu workload list

Lists all workloads

Synopsis

Lists all workloads

list configuration options include: - Output the list for all namespaces - Output the list for a specific namespace - Output the list for a specific kind - Output the list formatted

```
tanzu workload list [flags]
```

Examples

```
tanzu workload list
  tanzu workload list --all-namespaces,
  tanzu workload list --namespace my-namepsace,
  tanzu workload list --kind my-workload-kind,
  tanzu workload list --output yaml
```

Options

```
  -A, --all-namespaces   use all kubernetes namespaces
  -h, --help             help for list
  -k, --kind string      list workloads from the specified workload kind
  -n, --namespace name   kubernetes namespace (defaulted from kube config)
  -o, --output string    output the workloads formatted. Supported formats: "json", "y
aml", "yml"
```

Options inherited from parent commands

```
      --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)
      --no-color          deactivate color, bold, animations, and emoji output
```

SEE ALSO

- tanzu workload - create, update, view and list Tanzu Workloads.

tanzu workload logs

Watch workload-related logs

Synopsis

Stream logs for a workload until canceled. To cancel, press Ctrl+C in the shell or stop the process. As new workload pods start, the logs appear. To see historical logs, use `--since`.

```
tanzu workload logs <NAME> [flags]
```

Examples

```
tanzu workload logs NAME
  tanzu workload logs NAME --since 1h
  tanzu workload logs NAME --since 1h --namespace default
  tanzu workload logs NAME --since 1h --namespace default --run runname
```

Options

```
  -h, --help              help for logs
  -k, --kind string       kind of the workload specification
  -n, --namespace name    kubernetes namespace (defaulted from kube config)
      --run name          workload run name
      --since duration    time duration to start reading logs from (default 1h0m0s)
  -t, --timestamp         print timestamp for each log line
```

Options inherited from parent commands

```
      --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)
      --no-color          deactivate color, bold, animations, and emoji output
```

SEE ALSO

tanzu workload - create, update, view and list Tanzu Workloads.

tanzu workload run

View workload runs

Options

```
  -h, --help   help for run
```

Options inherited from parent commands

```
      --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)
      --no-color          deactivate color, bold, animations, and emoji output
```

SEE ALSO

- tanzu workload - create, update, view and list Tanzu Workloads.
- tanzu workload run get - Get workload run

tanzu workload run get

Get workload run

Synopsis

Get the details of the specified workload run within a namespace.

workload run get configuration options include: - Specify the namespace of the workload run - Output the workload run formatted - Show more details of the workload run

```
tanzu workload run get <NAME> [flags]
```

Examples

```
tanzu workload run get NAME
  tanzu workload run get NAME --namespace namespace
  tanzu workload run get NAME --namespace namespace --show-details
```

Options

```
  -h, --help              help for get
  -n, --namespace name    kubernetes namespace (defaulted from kube config)
  -o, --output string     output the workload run details formatted. Supported formats:
"json", "yaml", "yml"
      --show-details      show more details of the workload run
```

Options inherited from parent commands

```
      --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)
      --no-color          deactivate color, bold, animations, and emoji output
```

SEE ALSO

- tanzu workload run - View workload runs

tanzu supplychain

supplychain management

Options

```
  -h, --help              help for supplychain
      --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)
      --no-color          deactivate color, bold, animations, and emoji output
```

SEE ALSO

- tanzu supplychain component - Interacting with supplychain components
- tanzu supplychain generate - Generate a supplychain scaffold
- tanzu supplychain get - Get supplychain

- tanzu supplychain list - Lists all supplychains

tanzu supplychain component

Interacting with supplychain components

Options

```
  -h, --help   help for component
```

Options inherited from parent commands

```
      --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)
      --no-color          deactivate color, bold, animations, and emoji output
```

SEE ALSO

- tanzu supplychain - supplychain management
- tanzu supplychain component get - Get details of a component
- tanzu supplychain component list - Lists all supplychain components

tanzu supplychain component get

Get details of a component

Synopsis

Get the details of the specified component within a namespace.

component get configuration options include: - Specify the namespace of the component (optional) - Output the component formatted - Show more details of the component

```
tanzu supplychain component get <NAME> [flags]
```

Examples

```
tanzu supplychain component get NAME
  tanzu supplychain component get NAME --namespace default
  tanzu supplychain component get NAME --namespace default --show-details
```

Options

```
  -h, --help             help for get
  -n, --namespace name   kubernetes namespace
  -o, --output string    output the component details formatted. Supported formats: "j
son", "yaml", "yml"
      --show-details     show more details of the component
```

Options inherited from parent commands

```
      --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)
      --no-color          deactivate color, bold, animations, and emoji output
```

SEE ALSO

- tanzu supplychain component - Interacting with supplychain components

tanzu supplychain component list

Lists all supplychain components

Synopsis

Lists all available supplychain components

component list configuration options include: - Output the component list formatted

```
tanzu supplychain component list [flags]
```

Examples

```
tanzu supplychain component list
  tanzu supplychain component list --output yaml
  tanzu supplychain component list --wide
```

Options

```
  -h, --help            help for list
  -o, --output string   output the supplychain component formatted. Supported formats:
"json", "yaml", "yml"
  -w, --wide            output the supplychain component list with additional informat
ion
```

Options inherited from parent commands

```
      --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)
      --no-color          deactivate color, bold, animations, and emoji output
```

SEE ALSO

- tanzu supplychain component - Interacting with supplychain components

tanzu supplychain generate

Generate a supplychain scaffold

Synopsis

Generate a supplychain scaffold

Generate configuration options include: - Kind, component list and the description

```
tanzu supplychain generate [flags]
```

Examples

```
tanzu supplychain generate --kind ServerAppV1 --description DESCRIPTION
```

Options

```
  --allow-defaults       add a section for defaults to the supplychain scaffold
  --allow-overrides      add a section for overrides to the supplychain scaffold
  -c, --component strings    add a component to the supplychain scaffold. This flag ca
n be specified multiple times and the order on the command-line will be reflected on t
he generated scaffold output
  -d, --description string   description of the supplychain
  -h, --help                 help for generate
  -k, --kind string          kind to use as the developer interface
```

Options inherited from parent commands

```
      --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)
      --no-color          deactivate color, bold, animations, and emoji output
```

SEE ALSO

- tanzu supplychain - supplychain management

tanzu supplychain get

Get supplychain

Synopsis

Get the details of the specified supplychain within a namespace.

supplychain get configuration options include: - Specify the namespace of the supplychain - Output the supplychain formatted

```
tanzu supplychain get <NAME> [flags]
```

Examples

```
tanzu supplychain get NAME
```

Options

```
  -h, --help             help for get
  -n, --namespace name   kubernetes namespace (defaulted from kube config)
  -o, --output string    output the supplychains formatted. Supported formats: "json",
"yaml", "yml"
```

Options inherited from parent commands

```
      --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)
      --no-color          deactivate color, bold, animations, and emoji output
```

SEE ALSO

- tanzu supplychain - supplychain management

tanzu supplychain init

Initialize supplychain

Synopsis

Initialize supplychain

Initialize configuration options include: - group name and the description

```
tanzu supplychain init [flags]
```

Examples

```
tanzu supplychain init --group supplychains.tanzu.vmware.com --description DESCRIPTION
```

Options

```
  -d, --description string   description of the group
  -g, --group string         group of the supplychains (default "supplychains.tanzu.vm
ware.com")
  -h, --help                 help for init
```

Options inherited from parent commands

```
      --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)
      --no-color          deactivate color, bold, animations, and emoji output
```

SEE ALSO

- tanzu supplychain - supplychain management

tanzu supplychain list

Lists all supplychains

Synopsis

Lists all supplychains

list configuration options include: - Output the list for all namespaces - Output the list for a specific namespace - Output the list formatted

```
tanzu supplychain list [flags]
```

Examples

```
tanzu supplychain list
  tanzu supplychain list --all-namespaces
```

Options

```
  -A, --all-namespaces   use all kubernetes namespaces
  -g, --group string     list all supplychains from a specific group
  -h, --help             help for list
  -n, --namespace name   kubernetes namespace (defaulted from kube config)
  -o, --output string    output the supplychains formatted. Supported formats: "json",
"yaml", "yml"
  -w, --wide             output the supplychain list with additional information
```

Options inherited from parent commands

```
      --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)
      --no-color          deactivate color, bold, animations, and emoji output
```

Tanzu Supply Chain API

This topic gives you reference information about Tanzu Supply Chain APIs.

> **Caution**
>
> Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

Tanzu Supply Chain introduces two concrete resources and two Duck-typed resources to your Kubernetes cluster.

The concrete resources are:

- `SupplyChain`, which describes a path to production and describes the `Workload` resource you can consume to run this supply chain.
- `Component`, which describes a reusable operation to apply to source, images, configuration, and other artifacts.

The Duck type resources are:

- `Workload`: This resource CRD is created on the cluster when a valid supply chain is applied. This is the API that your `SupplyChain` describes for users to consume.
- `WorkloadRun`: This is a single attempt to deliver the `Workload` through a `SupplyChain`. Every time there is new configuration or external inputs to a workload, a run is generated.

`Workload` and `WorkloadRun` are described as Duck type resources because their final names and CRD are described by the `SupplyChain` and `Component` resources when applied to the cluster. Many fields of each CRD are the same across the system.

SupplyChain API

This topic gives you reference information about the `SupplyChain` resource for Tanzu Supply Chain.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

The supply chain defines the object kind of the `Workload`, the `Components` used, and their order.

Type and Object Metadata

```
apiVersion: supply-chain.apps.tanzu.vmware.com/v1alpha1
kind: SupplyChain
```

`metadata.name`

`metadata.name` is in the form:

`<plural-name>.<group>-<Major>.<minor>.<patch>`

- `plural-name` must match the plural form of `defines.kind`, without the version. For example: `kind: JavaServerAppV3` would have a `plural-name` of `javaserverappv3s`
- `group` must mach `defines.group` (see `spec.defines.group` below)
- `<Major>.<minor>.<patch>` is the version definition.

```
metadata:
  name: hostedapps.widget.com-0.0.1
```

Spec

`spec.config`

The `spec.stages` structure introduces `Components` where the aggregated config sections, form the SupplyChain's configuration and become the Workload's spec.

This configuration can be altered by changing defaults, or overridden and hidden from the `Workload`.

`spec.config.defaults`

Change or add defaults for the config that is presented in the Workload's spec.

`spec.config.defaults` is an array of `path:` and `value:` fields, where:

- `path`: Path to the configuration value, formatted as either:
  - The full path to the field you want to set.
  - The path to any structure where all desired child fields must be set.
- `value`: A string or structure value.

`spec.config.overrides`

Override the value of a config field, so that it no longer appears in the Workload's spec.

`spec.config.overrides` is an array of `path:` and `value:` fields, where:

- `path`: path to the configuration value, formatted as either:
  - The full path to the field you wish to set.
  - The path to any structure where all desired child fields must be set.
- `value`: string or structure value.

Example

```
apiVersion: supply-chain.apps.tanzu.vmware.com/v1alpha1
kind: SupplyChain
spec:
  config:
    defaults:
      - path: spec.source
        value:
          branch: develop
          url: https://our.git.com/our-monorepo
    overrides:
      - path: spec.registry.repository
        value: "YOUR-REGISTRY-REPO"
      - path: spec.registry.server
        value: "YOUR-REGISTRY-SERVER"
```

spec.description

The `spec.description` field is visible to an app developer when they use the CLI to discover available Workload kinds:

```
tanzu workload kind list --wide

KIND                       VERSION     AGE   DESCRIPTION
serverappv2.example.com    v1alpha1    12m   Server application supply chain
```

Recommendation: embed complete documentation in the description.

The description field supports multi-line Plain text or Markdown.

spec.defines

The `spec.defines` object defines the `Workload` custom resource definition (CRD).

spec.defines.group

`spec.defines.group` (**required**) is used to fill in the `group` field in the [CustomResourceDefinitionSpec].

`spec.defines.group` is the classic domain-formatted group of any Kubernetes object. Use your organization's top level domain, or a departmental domain.

spec.defines.kind

`spec.defines.kind` (**required**) is the name of the resource in CamelCase.

spec.defines.plural

`spec.defines.plural` (**required**) is typically the plural down-cased form of the kind. It must be all lowercase.

Recommendation: pluralize the name after the version, e.g: `WebAppV1` becomes `webappv1s`

`spec.defines.singular`

`spec.defines.singular` is optional and defaults to the lowercase of `kind`, for example `ServerAppv1` becomes `serverappv1`.

`spec.defines.shortnames`

`spec.defines.shortnames` is a list and defaults to empty. Use this to specify an array of aliases for your kind. These are great to simplify `kubectl` commands.

Example

```
kind: ServerAppV1
plural: serverappv1s
shortnames:
  - serverapp1
  - sa1
```

`spec.defines.categories`

`spec.defines.categories` is a list and defaults to empty. `spec.defines.categories` specify a collection term for a group of kinds, so that `kubectl get <category>` returns instances of all kinds in the category.

Example

Using `kubectl get apps` would include this kind in the listing

```
kind: ServerAppV1
plural: serverappv1s
categories:
  - apps
```

Complete Example

```
spec:
  defines: # Describes the workload
    kind: HostedApp
    pluralName: hostedapps
    group: example.com
    version: v1alpha1
    categories:
      - apps
    shortnames:
      - hosted1
      - ha1
```

`spec.stages[]`

`spec.stages` break the work to be done by this supply chain into a serial collection of “stages”, each with a component.

This is where you define the operations of this `SupplyChain`.

`spec.stages[].name`

Each stage has a `name`, which is shown to the user in the CLI and UI. `name` can only be composed of hyphens(`-`) and lower case alphanumeric characters (`a-z0-9`).

`spec.stages[].componentRef`

Each stage also has a `componentRef` with a single field `name`. `componentRef.Name` refers to the name of a Tanzu Supply Chain [Component] resource. Currently, [Component] must exist in the same namespace as the `SupplyChain`. For more information, see the Tanzu Supply Chain known issues.

The supply chain returns an error if a component expects an input that has not been output by a previous stage.

`spec.stages[].securityContext`

Each stage can specify a `securityContext` with a single field `runAs`. When this is set to `workload` the stage is executed in the namespace of the Workload rather than the Supply Chain. See Security Model.

Example

```
apiVersion: supply-chain.apps.tanzu.vmware.com/v1alpha1
kind: SupplyChain
spec:
  stages:
    - name: fetch-source
      componentRef:
        name: source-git-provider-1.0.0
      securityContext:
        runAs: workload
    - name: build
      componentRef:
        name: golang-builder-1.0.0
    - name: commit
      componentRef:
        name: commit-writer-1.0.0
```

Status

`status.conditions[]`

Every `status.conditions[]` in Tanzu Supply Chain resources follows a strict set of conventions.

The top-level condition type is `Ready` as SupplyChain is a “living” resource.

The sub-types are:

RBACDefined

Reason	Meaning
Ready	The RoleBindings for the kind declared in `spec.defines` was created on cluster
AlreadyExists	The RoleBinding record already exists. Most common cause of this issue is another Supply Chain with the same `spec.defines` section.
UnknownError	The RoleBinding record failed due to an exceptional error. Look at the reconciler logs and contact Tanzu Support

APIsDefined

Reason	Meaning
Ready	The CRD for the kind declared in `spec.defines` was created on cluster
Conflict	The CRD already exists and is managed by another SupplyChain. Most common cause of this issue is another Supply Chain with the same `spec.defines` section.
Invalid	The CRD is invalid Most common cause of this is an illegal OpenAPIV3Schema in the [Component].
Unknown error	The CRD could not be created due to an exceptional error. Look at the reconciler logs and contact Tanzu Support

StageMapping

Reason	Meaning
Ready	The stages pass all the validation rules.
NoSuchComponent	The referenced component cannot be found.
NoSuchInput	The input to the stage is not emitted by any stage.
InputNotSatisfiedUntilLater	The input to the stage is not emitted by a previous stage.
InputMismatch	The input matches a previous output by name, however the type does not match.
OutputRedefined	The output redefines an existing output. Shadowing of outputs is not supported.

Component API

This topic gives you reference information about the `Component` resource for Tanzu Supply Chain.

> **Caution**
>
> Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

Components define the work to be done in one Stage of the `SupplyChain`.

Type and Object Metadata

```
apiVersion: supply-chain.apps.tanzu.vmware.com/v1alpha1
kind: Component
```

`metadata.name`

`metadata.name:` must have a `-M.m.p` suffix, representing the major, minor and patch of this version of the component. Changes to the config section should coincide with a bump to major or minor versions. Reserve patch increments for changes that do not alter the API, or the behavior significantly.

```
metadata:
  name: source-1.0.0
```

Spec

spec.description

`spec.description` describes the component's purpose. You will see this description in `tanzu workload run list`.

```
spec:
  description: Gets the latest source and stores it in an OCI Image
```

spec.config

`spec.config` defines the configuration in a workload (`spec` of the workload) that is required for the component to operate.

`spec.config` is an array with three fields:

- `path`: describes the path in the workload where this configuration is appended/merged. It must start with `spec.`
- `schema` and `required` define a property. See the (Kubernetes) [https://kubernetes.io/docs/home/] documentation.

Example

```
config:
  - path: spec.source.git
    schema:
      type: object
      description: |
        Fill this object in if you want your source to come from git.
        The tag, commit and branch fields are mutually exclusive,
        use only one.
      properties:
        tag:
          description: A git tag ref to watch for new source
          type: string
        commit:
          description: A git commit sha to use
          type: string
        branch:
          description: A git branch ref to watch for new source
          type: string
        url:
          description: The url to the git source repository
          type: string
      required:
        - url
```

spec.inputs

```
inputs:
  - name: source
    type: source
```

spec.pipelineRun

The `spec.pipelineRun` section defines the work done by this component. `spec.pipelineRun` is used to create a [Tekton PipelineRun] and has many similarities.

`spec.pipelineRun.pipelineRef`

The `spec.pipelineRun.pipelineRef` is required, and it has one field `name` that must refer to the `metadata.name` of a [Tekton Pipeline] that resides in the same namespace as the `Component` and `SupplyChain`.

`spec.pipelineRun.workspaces`

If you need to define workspaces to pass to the Tekton `PipelineRun`, use `spec.pipelineRun.workspaces`. This field is an array of workspace definitions, and is identical to the Tekton Workspaces specification.

`spec.pipelineRun.params`

`spec.pipelineRun.params` are the same as [Tekton PipelineRun Parameters] with one major difference: you can populate them using templates.

The available references for templating are:

reference	source	examples
`$(workload.spec...)`	The workload spec	`$(workload.spec.source.git.url)`
`$(workload.metadata...)`	The workload metadata	`$(workload.metadata.labels)`, `$(workload.metadata.name)`
`$(inputs.<input-name>.[url|digest])`	An input url or digest	`$(inputs.image.url)`, `$(inputs.image.digest)`
`$(resumptions.<resumption-name>.results...)`	A resumption result	`$(resumptions.check-source.results.sha)`

Example

```
spec:
  pipelineRun:
    pipelineRef:
      name: source
    params:
      - name: git-url
        value: $(workload.spec.source.git.url)
      - name: sha
        value: $(resumptions.check-source.results.sha)
    workspaces:
      - name: shared-data
        volumeClaimTemplate:
          spec:
            accessModes:
              - ReadWriteOnce
            resources:
              requests:
                storage: 1Gi
```

spec.outputs

```
  outputs:
    - name: source
      type: source
```

spec.resumptions[]

`spec.resumptions[]` define Tekton `TaskRuns`. They are optional, but useful to describe small, fast tasks that check for dependency changes, such as new source, or new base images.

For a detailed explanation of resumptions, see Core Concepts: Resumptions.

`spec.resumptions[].name`

`spec.resumptions[].name` is visible to end users, so make sure it's suitably meaningful. It's recommended that it's in the form: `check-RESOURCE-TYPE` where `RESOURCE-TYPE` is the kind of resource being polled, such as `source` or `base-image`.

`spec.resumptions[].trigger.runaAfter`

`spec.resumptions[].trigger.runaAfter` describes the rerun period for the task. The task is executed, and after it completes (successfully or otherwise), Tanzu Supply Chain waits the `runaAfter` period and then executes the task again. This continues indefinitely.

`runAfter` can be specified using the `time.ParseDuration()` specification.

`spec.resumptions[].taskRef`

The `spec.resumptions[].taskRef` has one field `name` that must refer to the `metadata.name` of a Tekton `Task` that resides in the same namespace as the `Component` and `SupplyChain`.

This is the task that run's on the resumptions `spec.resumptions[].trigger`

`spec.resumptions[].params`

`spec.resumptions[].params` are the same as Tekton `TaskRun` Parameters with one major difference: you can populate them using templates.

The available references for templating references are:

reference	source	examples
`$(workload.spec...)`	The workload spec	`$(workload.spec.source.git.url)`
`$(workload.metadata...)`	The workload metadata	`$(workload.metadata.labels)`, `$(workload.metadata.name)`
`$(inputs.<input-name>.[url|digest])`	An input url or digest	`$(inputs.image.url)`, `$(inputs.image.digest)`

Example

```
resumptions:
  - name: check-source
    trigger:
      runAfter: 60s
    taskRef:
      name: check-source
    params:
      - name: git-branch
        value: $(workload.spec.source.git.branch)
      - name: git-url
        value: $(workload.spec.source.git.url)
      - name: git-commit
        value: $(workload.spec.source.git.commit)
      - name: git-tag
        value: $(workload.spec.source.git.tag)
```

Status

`status.conditions[]`

Every `status.conditions[]` in Tanzu Supply Chain resources follows a strict set of conventions

`Component` resources are “living”, however they are resistant to changes in their spec, They’re designed to be immutable on production servers, so that accidental spec changes do not break the API delivered to end users.

If a `Component`’s top level condition `Ready` is ever something other than `status: "True"` then the `reason` field should describe the problem with the component.

`status.details`

`status.details` describe some of the observations that Tanzu Supply Chains made about this component. These fields are used to improve the output of `kubernetes get component <name> -owide`, and they summarize the component for platform engineers when they author a `SupplyChain`.

```
status:
  conditions:
  - lastTransitionTime: "2024-02-25T00:40:46Z"
    message: ""
    reason: Ready
    status: "True"
    type: Ready
  details:
    hasResumptions: "False"
    inputs: conventions[conventions[]
    outputs: oci-yaml-files[oci-yaml-files[], oci-ytt-files[oci-ytt-files[]
  observedGeneration: 1
```

`status.docs`

`status.docs` contains a human-readable explanation of the content of the component. It’s useful for CLIs and UIs, and provides a clean summary of the component.

Example

```
docs: |
  # source

  Version: 1.0.0

  ## Description

  Monitors a git repository

  ## Inputs

  * _none_

  ## Outputs

  | Name  | Type |
  | ---   | ---  |
  | source | [source](./output-types.hbs.md#source) |

  ## Config

  ``yaml
```

```
  spec:
    source:
      # Fill this object in if you want your source to come from git.
      # The tag, commit and branch fields are mutually exclusive, use only one.
      git:
        # A git branch ref to watch for new source
        branch:
        # A git commit sha to use
        commit:
        # A git tag ref to watch for new source
        tag:
        # The url to the git source repository
        # +required
        url:
  ``
```

Workload CRD

This topic gives you reference information about the `Workload` resource for Tanzu Supply Chain.

Caution

Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

`Workload` resources are custom resource definitions (CRDs) created by `SupplyChain` resources. They are also one of the two duck type resources in Tanzu Supply Chain.

Static CustomResourceDefinitions API

Every `Workload` resource is defined as a `CustomResourceDefinition`:

```
apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
```

`metadata.labels`

`Workload` resources always have the following labels. The `chain-name` and `chain-namespace` labels reference the location of the SupplyChain resource that created this `Workload`. The `chain-role` identifies this as a Workload. The other possible value is `workload-run`.

```
metadata:
  labels:
    supply-chain.apps.tanzu.vmware.com/chain-name: apps.example.com-1.0.0
    supply-chain.apps.tanzu.vmware.com/chain-namespace: app-sc
    supply-chain.apps.tanzu.vmware.com/chain-role: workload
```

`metadata.name`

The name of the resource is always in the form `<plural>.<group>` from the Supply Chain Defines API.

Example

```
metadata:
  name: appv1s.widget.com
```

`spec.group`, `spec.names` and `spec.versions`

The CRD `group`, `names`, and `versions` are filled with the details found in the Supply Chain Defines API.

Additionally, the `spec.names[].categories[]` array includes a category of `all-workloads`. This ensures that commands such as `kubectl get all-workloads` find all the `SupplyChain`-defined `Workload` resources a user can access.

Example

```
spec:
  conversion:
    strategy: None
  group: example.com
  names:
    categories:
      - all-workloads
    kind: AppV1
    listKind: AppV1List
    plural: appv1s
    singular: appv1
  scope: Namespaced
  versions:
      name: v1alpha1
      schema:
        openAPIV3Schema:
          ...
```

Static Workload API

`metadata.labels`

`Workload` resources always have the following labels. These labels reference the location of the `SupplyChain` resource on cluster.

```
metadata:
  labels:
    supply-chain.apps.tanzu.vmware.com/chain-name: apps.example.com-1.0.0
    supply-chain.apps.tanzu.vmware.com/chain-namespace: app-sc
```

Dynamic Workload API

`spec`

The `spec` of a `Workload` resource is dynamic, however it is immutable after it is applied. The `spec` is derived by combining the Component configurations of all the SupplyChain Stages.

WorkloadRun CRD

This topic gives you reference information about the `WorkloadRun` resource for Tanzu Supply Chain.

Caution

> Tanzu Supply Chain is currently in beta and is not intended for production use. It is intended only for evaluation purposes of the next generation Supply Chain. For the current Supply Chain solution, see the Supply Chain Choreographer documentation.

`WorkloadRun` resources are custom resource definitions (CRDs) created by `SupplyChains`. They are also one of the two duck type resources in Tanzu Supply Chain.

Static CustomResourceDefinitions API

Every `WorkloadRun` resource is defined as a `CustomResourceDefinition`:

```
apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
```

`metadata.labels`

Workload CRDs always have the following labels. The `chain-name` and `chain-namespace` labels reference the location of the SupplyChain resource that created this WorkloadRun. The `chain-role` identifies this as a WorkloadRun. The other possible value is `workload`.

```
metadata:
  labels:
    supply-chain.apps.tanzu.vmware.com/chain-name: apps.example.com-1.0.0
    supply-chain.apps.tanzu.vmware.com/chain-namespace: app-sc
    supply-chain.apps.tanzu.vmware.com/chain-role: workload-run
```

`metadata.name`

The name of the resource is always in the form `<singular>runs.<group>` from the Supply Chain Defines API.

Example

```
metadata:
  name: appv1runs.widget.com
```

`spec.group`, `spec.names` and `spec.versions`

The CRD's `group`, `names` and `versions` is filled in with the details found in the Supply Chain Defines API. However, most names have the word `run` appended.

Additionally, the `spec.names[].categories[]` array includes a category of `all-runs`. This ensures that commands such as `kubectl get all-runs` find all the `SupplyChain` defined `WorkloadRuns` a user can access.

Example

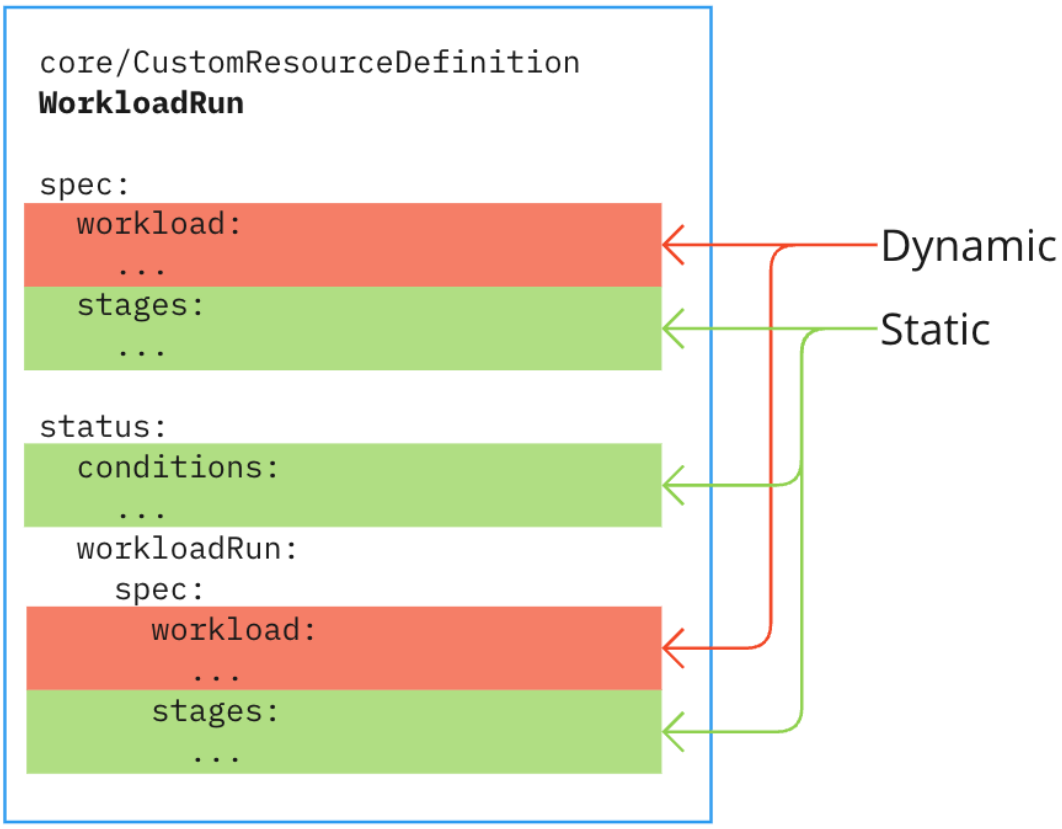
```
spec:
  conversion:
    strategy: None
  group: example.com
  names:
    categories:
      - all-runs
    kind: AppV1Run
    listKind: AppV1RunList
```

```
    plural: appv1runs
    singular: appv1run
  scope: Namespaced
  versions:
    name: v1alpha1
    schema:
      openAPIV3Schema:
        ...
```

Self-Replicating State

`WorkloadRuns` have a complex self-referencing status, that is described in detail in Core Concepts: WorkloadRuns. The majority of the `WorkloadRun` specification appears again in `status.workloadRun`.

This image shows the static and dynamic sections of a WorkloadRun.



Note

The duplication of the `WorkloadRun spec` into `spec.status.workloadRun.spec` is shown here.

The `status` is not duplicated again into the `status.workloadRun` field.

Static WorkloadRun API

`Static` means that the schema of these sections of the `WorkloadRun` is unchanging. This does not mean that these sections do not mutate during the life of the `WorkloadRun`. They do, because they track the progress of the `WorkloadRun`.

`spec.stages[]` and `status.workloadrun.spec.stages[]`

`spec.stages[]` is empty if the run was triggered by a new workload generation, or, if triggered by a Resumption, contains the stages up to but excluding the stage containing the resumption trigger.

`spec.workloadrun.spec.stages[]` initially contains a copy of `spec.stages[]` (if any exist), and as the `WorkloadRun` proceeds, contains the rest of the results for subsequent stages.

`spec.stages[].name` and `status.workloadrun.spec.stages[].name`

`name` is the name of this stage as defined in the SupplyChain.

`spec.stages[].componentRef` and `status.workloadrun.spec.stages[].componentRef`

The sub-fields, `name` and `namespace`, refer to the component that will/has run this stage.

```
name: source-1.0.0
namespace: test-basic
```

`spec.stages[].outputs[]` and `status.workloadrun.spec.stages[].outputs[]`

Each output contains the following fields:

Field	Description
`name:`	The name of the output, defined in the [Component] for this stage.
`type:`	The type of the output, defined in the [Component] for this stage.
`url:`	The url to the artifact where this output is stored. All outputs are stored as supply chain accessible resources (URLs)
`digest:`	A digest representing the state of the output.

`spec.stages[].pipeline` and `status.workloadrun.spec.stages[].pipeline`

Each stage has one `pipeline` object with the following fields:

Field	Description
`passed:`	Empty (`""`) means running, otherwise this is `false` for failed, and `true` for succeeded
`started:`	The Date/Time this pipeline started. Empty (`""`) if not started.
`completed:`	The Date/Time this pipeline finished. Empty (`""`) if still running.
`message:`	Output from the pipeline, which updates until the pipeline is completed.
`results:`	A copy of the [Tekton PipelineRun results].

Example

```
pipeline:
  passed: true
  started: "2024-02-25T19:31:48Z"
  completed: "2024-02-25T19:33:27Z"
  message: 'Tasks Completed: 3 (Failed: 0, Cancelled 0), Skipped: 0'
  results:
```

```
    - name: url
      value: registry.io/my-test/package-store@sha256:bad70a84441cfa49fea2a16a1fb0db31
48f260242cf31bb8fde9547c09ece4bf
    - name: digest
      value: bad70a84441cfa49fea2a16a1fb0db3148f260242cf31bb8fde9547c09ece4bf
```

Dynamic WorkloadRun API

`spec.workload` and `spec.status.workloadRun.spec.workload`

These are the same. Technically, `spec.workload` is the state of the `Workload` when the run is created, and `spec.status.workloadRun.spec.workload` is the state of the `Workload` after the run starts, but they never change, so are in fact identical.

Both contain the `workload.metadata` and `workload.spec` sections of the workload that were used in this run. The `WorkloadRun` "closes over" this state so that it cannot be lost. When viewing a run, you can always tell which `Workload` resource's state was used during the run.

Status

`status.conditions[]`

Every `status.conditions[]` in Tanzu Supply Chain resources follows a strict set of conventions

The top-level condition type is `Succeeded` because `Workload` is a batch resource.

The sub-types are:

PipelinesSucceeded

Reason	Meaning
Succeeded	All [Tekton PipelineRuns] are complete
Running	[Tekton PipelineRuns] are not all complete.
Failed	A [Tekton PipelineRun] failed, and it's likely that the developer can remedy any issues by following the guidance in the message.
PlatformFailed	A [Tekton PipelineRun] failed, and it's unlikely the problem can be remedied with changes to the workload or developer provided input (such as source).

`Message` contains processing information and error messages produced in the pipeline. This information must be specifically appended to the Tekton result named `message` to appear here.

ResumptionsSucceeded

Reason	Meaning
Succeeded	All [Tekton TaskRuns] for all resumptions are complete.
Running	A [Tekton TaskRun] for a resumption is incomplete.
Failed	A [Tekton TaskRun] for a resumption failed, and it's likely that the developer can remedy any issues by following the guidance in the message.
PlatformFailed	A [Tekton TaskRun] for a resumption failed, and it's unlikely the problem can be remedied with changes to the workload or developer provided input (such as source).

`Message` contains processing information and error messages produced in the taskRun. This information must be specifically appended to the Tekton result named `message` to appear here.

Resource Statuses

This topic tells you about the statuses for Tanzu Supply Chain resources.

Every status in Tanzu Supply Chain resources adheres to the same set of rules, starting with those set out by Kubernetes API Conventions.

The `spec.conditions` array is referred to as a Condition Set.

Each Condition Set has a top level condition type selected based on the behavior of the resource, Living and Batch.

Living resource

This resource is never “finished”, instead it modifies it’s managed resources or internal services to match the state of the `spec`. Examples include `services` and `pods`.

A living resource’s top-level condition type is Ready.

However, some Living resources are resistant to changes in their spec. They are “living and immutable”. For example, the Component Resource.

Batch resource

Batch resources complete. They’re expected to terminate after they have achieved the desired outcome. Typically their `spec` is immutable, or if it is mutable, the mutation has no effect.

A batch resource’s top-level condition type is `Succeeded`.

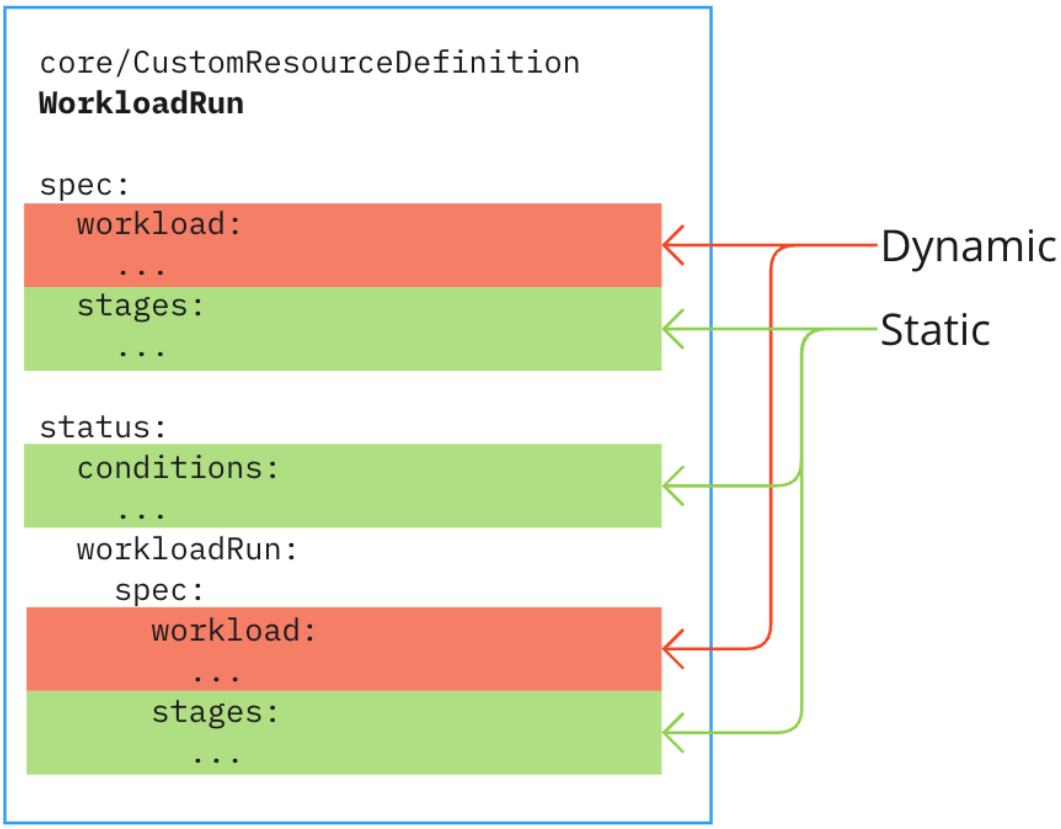
For more information, see the Kubernetes documentation.

Duck type resources

This topic tells you about the duck type resources for Tanzu Supply Chain.

The two duck type resources in Tanzu Supply Chains are Workloads and WorkloadRuns.

In brief, a duck type resource is a resource with significant commonality. A duck type resource is similar to a Class in object-oriented design, but without the inheritance.



Some sections of a duck type API are unchanging (static) and others can and do change (dynamic).

Both Tanzu Supply Chain duck types have dynamic kinds, which means there can be many Kubernetes CRDs that comply with the `WorkloadRun` duck type.

Overview of Tekton

Tekton is a cloud-native, open-source framework for creating CI/CD systems. It allows developers to build, test, and deploy across cloud providers and on-premises systems. For more information about Tekton, see the Tekton documentation.

Overview of Tekton

Tekton is a cloud-native, open-source framework for creating CI/CD systems. It allows developers to build, test, and deploy across cloud providers and on-premises systems. For more information about Tekton, see the Tekton documentation.

Install Tekton

This topic tells you how to install Tekton Pipelines from the Tanzu Application Platform package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install Tekton Pipelines. For more information about profiles, see Components and installation profiles.

Prerequisites

Before installing Tekton Pipelines, complete all prerequisites to install Tanzu Application Platform.

Install Tekton Pipelines

To install Tekton Pipelines:

1. See the Tekton Pipelines package versions available to install by running:

   ```
   tanzu package available list -n tap-install tekton.tanzu.vmware.com
   ```

   For example:

   ```
   $ tanzu package available list -n tap-install tekton.tanzu.vmware.com
   \ Retrieving package versions for tekton.tanzu.vmware.com...
     NAME                     VERSION  RELEASED-AT
     tekton.tanzu.vmware.com  0.30.0   2021-11-18 17:05:37Z
   ```

2. Install Tekton Pipelines by running:

   ```
   tanzu package install tekton-pipelines -n tap-install -p tekton.tanzu.vmware.co
   m -v VERSION
   ```

   Where `VERSION` is the desired version number. For example, `0.30.0`.

   For example:

   ```
   $ tanzu package install tekton-pipelines -n tap-install -p tekton.tanzu.vmware.
   com -v 0.30.0
   - Installing package 'tekton.tanzu.vmware.com'
   \ Getting package metadata for 'tekton.tanzu.vmware.com'
   / Creating service account 'tekton-pipelines-tap-install-sa'
   / Creating cluster admin role 'tekton-pipelines-tap-install-cluster-role'
   / Creating cluster role binding 'tekton-pipelines-tap-install-cluster-rolebindi
   ng'
   / Creating package resource
   - Waiting for 'PackageInstall' reconciliation for 'tekton-pipelines'
   - 'PackageInstall' resource install status: Reconciling

    Added installed package 'tekton-pipelines'
   ```

3. Verify that you installed the package by running:

   ```
   tanzu package installed get tekton-pipelines -n tap-install
   ```

   For example:

   ```
   $ tanzu package installed get tekton-pipelines -n tap-install
   \ Retrieving installation details for tekton...
   NAME:                    tekton-pipelines
   PACKAGE-NAME:            tekton.tanzu.vmware.com
   PACKAGE-VERSION:         0.30.0
   STATUS:                  Reconcile succeeded
   CONDITIONS:              [{ReconcileSucceeded True  }]
   USEFUL-ERROR-MESSAGE:
   ```

   Verify that `STATUS` is `Reconcile succeeded`.

Configure a namespace to use Tekton Pipelines

This section covers configuring a namespace to run Tekton Pipelines. If you rely on a SupplyChain to create Tekton PipelinesRuns in your cluster, skip this step because namespace configuration is covered in Set up developer namespaces to use your installed packages. Otherwise, perform the steps in this section for each namespace where you create Tekton Pipelines.

Service accounts that run Tekton workloads need access to the image pull secrets for the Tanzu package. This includes the `default` service account in a namespace, which is created automatically but is not associated with any image pull secrets. Without these credentials, PipelineRuns fail with a timeout and the pods report that they cannot pull images.

Important

If you are using a registry with a custom CA certificate then you must provide this certificate to Tekton directly by including the CA in the service account used by the supply chain.

The Tanzu Application Platform distribution of Tekton does not support the Tanzu Application Platform field `shared.ca_cert_data`. For more information about setting the CA in the service account, see Use Git authentication with Supply Chain Choreographer.

To configure a namespace to use Tekton Pipelines:

1. Create an image pull secret in the current namespace and fill it from the `tap-registry` secret. For more information, see Relocate images to a registry.
2. Create an empty secret, and annotate it as a target of the secretgen controller, by running:

   ```
   kubectl create secret generic pull-secret --from-literal=.dockerconfigjson={} --type=kubernetes.io/dockerconfigjson
   kubectl annotate secret pull-secret secretgen.carvel.dev/image-pull-secret=""
   ```

3. After you create a `pull-secret` secret in the same namespace as the service account, add the secret to the service account by running:

   ```
   kubectl patch serviceaccount default -p '{"imagePullSecrets": [{"name": "pull-secret"}]}'
   ```

4. Verify that a service account is correctly configured by running:

   ```
   kubectl describe serviceaccount default
   ```

   For example:

   ```
   kubectl describe sa default
   Name:                default
   Namespace:           default
   Labels:              <none>
   Annotations:         <none>
   Image pull secrets:  pull-secret
   Mountable secrets:   default-token-xh6p4
   Tokens:              default-token-xh6p4
   Events:              <none>
   ```

Note

The service account has access to the `pull-secret` image pull secret.

For more details about Tekton Pipelines, see the Tekton documentation and the GitHub repository.

For information about getting started with Tekton, see the Tekton tutorial in GitHub and the getting started guide in the Tekton documentation.

Note

Windows workloads are deactivated and cause an error if any Tasks try to use Windows scripts.
