Tanzu Application Platform v1.9

VMware Tanzu Application Platform (commonly known as TAP) is an application development platform with a rich set of developer tools. It offers developers a paved path to production to build and deploy software quickly and securely on any compliant public cloud or on-premises Kubernetes cluster.

Important

Tanzu Application Platform v1.9 is a short-term support release. It is no longer supported under the standard VMware Tanzu Support Life Cycle Policy.

To stay up to date with the latest software and security updates, upgrade to a supported version. For supported upgrade paths, see the topic *Upgrade Tanzu Application Platform* in the version you want to upgrade to.

Tanzu Application Platform overview

Tanzu Application Platform:

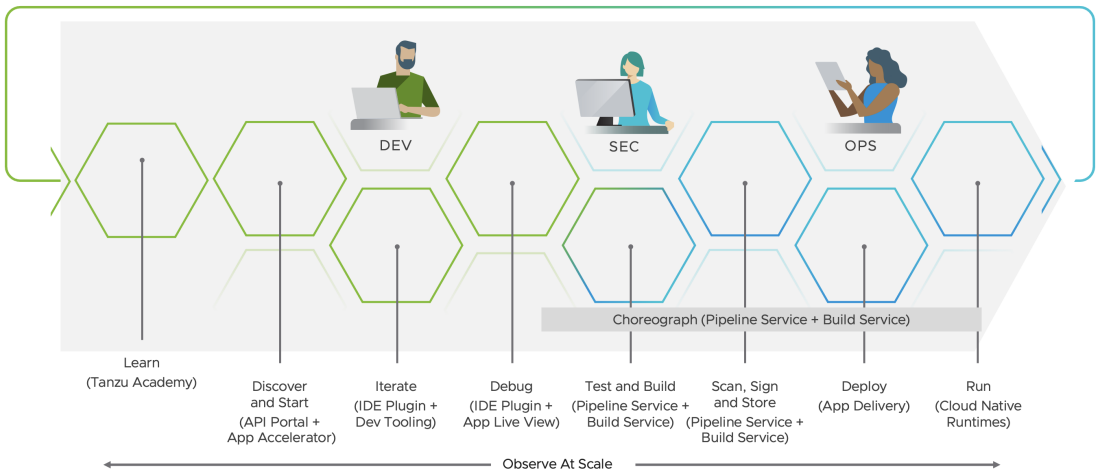
- Delivers a superior developer experience for enterprises building and deploying cloud-native applications on Kubernetes.
- Allows developers to quickly build and test applications regardless of their familiarity with Kubernetes.
- Helps application teams get to production faster by automating source-to-production pipelines.
- Clearly defines the roles of developers and operators so they can work collaboratively and integrate their efforts.

Operations teams can create application scaffolding templates with built-in security and compliance guardrails, making those considerations mostly invisible to developers. Starting with the templates, developers turn source code into a container and get a URL to test their app in minutes.

After the container is built, it updates every time there's a new code commit or dependency patch. An internal API management portal facilitates connecting to other applications and data, regardless of how they're built or the infrastructure they run on.

Simplified workflows

When creating supply chains, you can simplify workflows in both the inner and outer loop of Kubernetes-based app development with Tanzu Application Platform.



- **Inner Loop**
  - The inner loop describes a developer's development cycle of iterating on code.
  - Inner loop activities include coding, testing, and debugging before making a commit.
  - On cloud-native or Kubernetes platforms, developers in the inner loop often build container images and connect their apps to all necessary services and APIs to deploy them to a development environment.
- **Outer Loop**
  - The outer loop describes how operators deploy apps to production and maintain them over time.
  - On a cloud-native platform, outer loop activities include:
    - Building container images.
    - Adding container security.
    - Configuring continuous integration and continuous delivery (CI/CD) pipelines.
  - Outer loop activities are challenging in a Kubernetes-based development environment. App delivery platforms are constructed from various third-party and open source components with numerous configuration options.
- **Supply Chains and choreography**
  - Tanzu Application Platform uses the choreography pattern inherited from the context of microservices^1 and applies it to CI/CD to create a path to production.^2

Supply chains provide a way of codifying all of the steps of your path to production, or what is more commonly known as CI/CD. A supply chain differs from CI/CD in that with a supply chain, you can add every step necessary for an application to reach production or a lower environment.

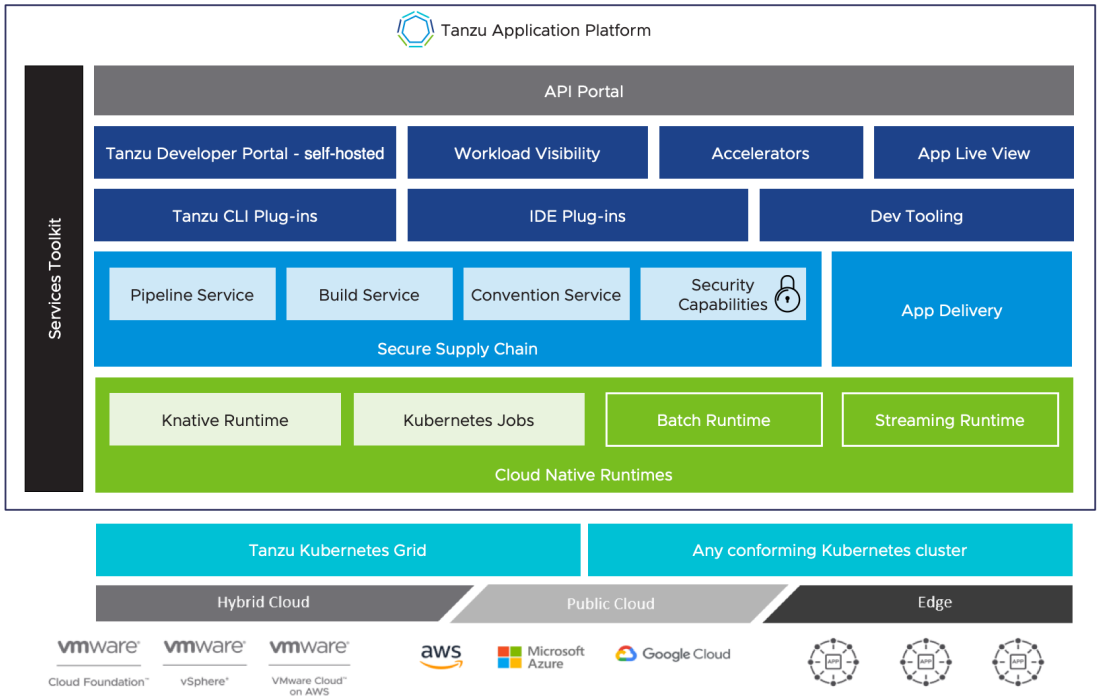
To address the developer experience gap, the path to production allows users to create a unified access point for all of the tools required for their applications to reach a customer-facing environment.

Instead of having separate tools that are loosely coupled to each other for testing and building, security, deploying, and running apps, a path to production defines all four tools in a single, unified layer of abstraction. Where tools typically can't integrate with one another and additional scripting

or webhooks are necessary, a unified automation tool codifies all interactions between each of the tools.

Tanzu Application Platform provides a default set of components that automates pushing an app to staging and production on Kubernetes. This removes the pain points for both inner and outer loops. It also allows operators to customize the platform by replacing Tanzu Application Platform components with other products.

The following diagram shows the layered API and capabilities of Tanzu Application Platform.



For more information about Tanzu Application Platform components, see Components and installation profiles.

Notice of telemetry collection for Tanzu Application Platform

Tanzu Application Platform participates in the VMware Customer Experience Improvement Program (CEIP). As part of CEIP, VMware collects technical information about your organization's use of VMware products and services in association with your organization's VMware license keys. For information about CEIP, see the Trust & Assurance Center. You may join or leave CEIP at any time. The CEIP Standard Participation Level provides VMware with information to improve its products and services, identify and fix problems, and advise you on how to best deploy and use VMware products. For example, this information can enable a proactive product deployment discussion with your VMware account team or VMware support team to help resolve your issues. This information cannot directly identify any individual.

You must acknowledge that you have read the VMware CEIP policy before you can proceed with the installation. For more information, see Install your Tanzu Application Platform profile. To opt out of telemetry participation after installation, see Opting out of telemetry collection.

Tanzu Application Platform release notes

This topic contains release notes for Tanzu Application Platform v1.9.

Important

Tanzu Application Platform v1.9 is a short-term support release. It is no longer supported under the standard VMware Tanzu Support Life Cycle Policy.

To stay up to date with the latest software and security updates, upgrade to a supported version. For supported upgrade paths, see the topic *Upgrade Tanzu Application Platform* in the version you want to upgrade to.

v1.9.1

Release Date: 09 May 2024

v1.9.1 Security fixes

This release has the following security fixes, listed by component and area.

Package Name	Vulnerabilities Resolved

v1.9.1 Resolved issues

The following issues, listed by component and area, are resolved in this release.

v1.9.1 Resolved issues: Supply Chain

- The **Workload** page in the Supply Chain UI now loads at a normal speed when there are more than 100 workloads to display.
- The **Workload Details** page, accessed by clicking on a workload name, now loads in the Supply Chain UI when there are more than 100 workloads to display.

v1.9.1 Resolved issues: Tanzu Developer Portal

- For the Runtime Resource View plug-in, resources all across the cluster are no longer needlessly queried when a Backstage namespace annotation is specified on the entity.

v1.9.1 Known issues

This release has the following known issues, listed by component and area.

v1.9.1 Known issues: Tanzu Application Platform

- On Azure Kubernetes Service (AKS), the Datadog Cluster Agent cannot reconcile the webhook, which leads to an error. For troubleshooting information, see Datadog agent cannot reconcile webhook on AKS.
- The Tanzu Application Platform integration with Tanzu Service Mesh does not work on vSphere with TKR v1.26. For more information about this integration, see Set up Tanzu Service Mesh. As a workaround, you can apply the label to update pod security on a TKr v1.26 Kubernetes namespace as advised by the release notes for TKr 1.26.5 for vSphere 8.x. However, applying this label provides more than the minimum necessary privilege to the resources in developer namespaces.

v1.9.1 Known issues: API Auto Registration

- Registering conflicting `groupId` and `version` with API portal:

  If you create two `CuratedAPIDescriptor`s with the same `groupId` and `version` combination, both reconcile without throwing an error, and the `/openapi?groupId&version` endpoint returns both specifications. If you are adding both specifications to the API portal, only one of them might show up in the API portal UI with a warning indicating that there is a conflict. If you add the route provider annotation for both of the `CuratedAPIDescriptor`s to use Spring Cloud Gateway, the generated API specspecification includes API routes from both `CuratedAPIDescriptor`s.

You can see the `groupId` and `version` information from all `CuratedAPIDescriptor`s by running:

```
$ kubectl get curatedapidescriptors -A

NAMESPACE           NAME         GROUPID            VERSION   STATUS   CURATED
API SPEC URL
my-apps             petstore     test-api-group     1.2.3     Ready    http://A
AR-CONTROLLER-FQDN/openapi/my-apps/petstore
default             mystery      test-api-group     1.2.3     Ready    http://A
AR-CONTROLLER-FQDN/openapi/default/mystery
```

- When creating an `APIDescriptor` with different `apiSpec.url` and `server.url`, the controller incorrectly uses the API spec URL as the server URL. To avoid this issue, use `server.url` only.

v1.9.1 Known issues: App Last Mile Catalog

- The app-config-web, app-config-server, and app-config-worker components do not allow developers to override the default application ports. This means that applications that use non-standard ports do not work. To work around this, you can configure ports by providing values to the resulting Carvel package. This issue is planned to be fixed in a future release.

v1.9.1 Known issues: Application Live View

- On the Run profile, Application Live View fails to reconcile if you use a non-default cluster issuer while installing through Tanzu Mission Control.

v1.9.1 Known issues: Artifact Metadata Repository Observer and CloudEvent Handler

- Periodic reconciliation or restarting of the AMR Observer causes reattempted posting of ImageVulnerabilityScan results. There is an error on duplicate submission of identical ImageVulnerabilityScans you can ignore if the previous submission was successful.

v1.9.1 Known issues: Bitnami Services

- If you try to configure private registry integration for the Bitnami Services after having already created a claim for one or more of the services using the default configuration, the updated private registry configuration does not appear to take effect. This is due to caching behavior in the system which is not accounted for during configuration updates. For a workaround, see Troubleshoot Bitnami Services.

v1.9.1 Known issues: Cartographer Conventions

- Before Tanzu Application Platform v1.9, the `cartographer.tanzu.vmware.com` package contained two products: Cartographer and Cartographer Conventions. In Tanzu Application Platform v1.9.0 the Cartographer Conventions product is removed from the `cartographer.tanzu.vmware.com` package and is distributed in its own package named `cartographer.conventions.apps.tanzu.vmware.com`.

  When you upgrade to Tanzu Application Platform v1.9, an issue might occur when installing the new package for Cartographer Conventions. The upgrade might fail to reconcile and show error messages similar to the following:

  ```
  Resource 'clusterrole/cartographer-conventions-manager-role (rbac.authorizatio
  n.k8s.io/v1) cluster' is already associated with a different app 'cartographer.
  ```

```
app'
```

This message might appear more than once, and it can refer to several resources.

These errors appear when kapp-controller on the cluster tries to install the new Cartographer Conventions package before the Cartographer package has reconciled. The new package for Cartographer Conventions tries to install resources that the existing Cartographer package still owns.

Although it looks like the upgrade fails, if you wait a few minutes, kapp-controller finishes the installation and the packages will reconcile successfully. The system works normally after the reconciliation is complete.

This error does not occur on a new installation of Tanzu Application Platform v1.9.

- While processing workloads with large SBOMs, the Cartographer Convention controller manager pod can fail with the status `CrashLoopBackOff` or `OOMKilled`. For information about how to increase the memory limit for both the convention server and webhook servers, including app-live-view-conventions, spring-boot-webhook, and developer-conventions/webhook, see Troubleshoot Cartographer Conventions.

v1.9.1 Known issues: Crossplane

- The Crossplane `validatingwebhookconfiguration` is not removed when you uninstall the Crossplane package. To workaround, delete the `validatingwebhookconfiguration` manually by running `kubectl delete validatingwebhookconfiguration crossplane`.

v1.9.1 Known issues: Services Toolkit

- An error occurs if `additionalProperties` is `true` in a CompositeResourceDefinition. For more information and a workaround, see Troubleshoot Services Toolkit.

v1.9.1 Known issues: Supply Chain

- Components cannot have more than one resumption defined. When there are multiple resumptions, `WorkloadRuns` are not correctly created after resumptions trigger changes. The current workaround is to assess all triggers in a single resumption.
- Tanzu Supply Chain currently does not include support for Red Hat OpenShift. This means you cannot individually install components for Tanzu Supply Chain and Managed Resource Controller. You also cannot install the Authoring profile that includes those components as standard. Support for Red Hat OpenShift is planned for a later release.
- Tanzu Supply Chain currently does not include support for CA certificates in the Out of the Box components. However, you can edit the components to support CA certificates and use them to construct a new Supply Chain. Support for CA certificates as standard is planned for future versions of Tanzu Supply Chain.
- When you select the **Supply Chains** tab in Tanzu Developer Portal, you might encounter an error related to `data.packaging.carvel.dev`. The error message is related to permission issues and JSON parsing errors. The error message indicates that the user `system:serviceaccount:tap-gui:tap-gui-viewer` cannot list resource `packages` in the API group `data.packaging.carvel.dev` at the cluster scope. Additionally, an unexpected non-whitespace character is reported after JSON at position 4.

  As a temporary workaround, apply an RBAC configuration that includes the get, watch, and list permissions for the resources in the `data.packaging.carvel.dev` API group. This workaround must not be mandated for supply chains that do not generate Carvel packages.

To eliminate the error message, configure RBAC to allow access to the Carvel package resource as follows:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
- apiGroups: [data.packaging.carvel.dev]
 resources: [packages]
 verbs: ['get', 'watch', 'list']
```

- In the **Workload Details** page in the Supply Chain UI, the config writer step takes longer than 20 seconds to load when more than 149 workloads are displayed in the Supply Chain UI.

v1.9.1 Known issues: Supply Chain Choreographer

- The template for the `external-deliverable-template` does not respect the `gitops_credentials_secret` parameter. The value is not present on the deliverable if it is provided in the workload parameter `gitops_credentials_secret` or the supply chain tap-value `ootb_supply_chain*.gitops.credentials_secret`. As a workaround, operators must provide the value as a tap-value for the delivery: `ootb_delivery_basic.source.credentials_secret`. The supply chain's GitOps credentials must authenticate to the same repository as the delivery's source credentials. If a deliverable must use a secret different from that specified by the delivery tap-value, the deliverable must be manually altered when being copied to the Run cluster. Add the secret name as a `source_credentials_secret` parameter on the deliverable.
- By default, Server Workload Carvel packages generated by the Carvel package supply chains no longer contain OpenAPIv3 descriptions of their parameters. These descriptions were omitted to keep the size of the Carvel Package definition under 4 KB, which is the size limit for the string output of a Tekton Task. For information about these parameters, see Carvel Package Supply Chains.
- When using the Carvel Package Supply Chains, if the operator updates the parameter `carvel_package.name_suffix`, existing workloads incorrectly output a Carvel package to the GitOps repository that uses the old value of `carvel_package.name_suffix`. You can ignore or delete this package.
- If the size of the resulting OpenAPIv3 specification exceeds a certain size, approximately 3 KB, the Supply Chain does not function. If you use the default Carvel package parameters, this issue does not occur. If you use custom Carvel package parameters, you might encounter this size limit. If you exceed the size limit, you can either deactivate this feature, or use a workaround. The workaround requires enabling a Tekton feature flag. For more information, see the Tekton documentation.

v1.9.1 Known issues: Supply Chain Security Tools - Policy

- Supply Chain Security Tools - Policy defaults to The Update Framework (TUF) enabled due to incorrect logic. This might cause the package to not reconcile correctly if the default TUF mirrors are not reachable. To work around this, explicitly configure policy controller in the `tap-values.yaml` file to enable TUF:

```
policy:
  tuf_enabled: true
```

v1.9.1 Known issues: Supply Chain Security Tools - Scan

- When using Supply Chain Security Tools (SCST) - Scan 2.0 with a ClusterImageTemplate, the value for the scanning image is overwritten with an incorrect default value from `ootb_supply_chain_testing_scanning.image_scanner_cli` in the `tap-values.yaml` file for templates other than Trivy. You can prevent this by setting the value in your `tap-values.yaml` file to the correct image. For example, for the Grype image packaged with Tanzu Application Platform:

  ```
  ootb_supply_chain_testing_scanning:
    image_scanner_template_name: image-vulnerability-scan-grype
    image_scanning_cli:
      image: registry.tanzu.vmware.com/tanzu-application-platform/tap-packages@sh
  a256:feb1cdbd5c918aae7a89bdb2aa39d486bf6ffc81000764b522842e5934578497
  ```

- The Snyk scanner outputs an incorrectly created date, resulting in an invalid date. If the workload is in a failed state due to an invalid date, wait approximately 10 hours and the workload automatically goes into the ready state. For more about this issue information, see the Snyk GitHub repository.
- Recurring scan has a maximum of approximately 5000 container images that can be scanned at a single time due to size limits configMaps.
- If the supply chain container image scanning is configured to use a different scanner or scanner version than the recurring scanning, the vulnerabilities displayed in Tanzu Developer Portal might be inaccurate.
- SCST - Scan 1.0 fails with the error `secrets 'store-ca-cert' not found` during deployment by using Tanzu Mission Control with a non-default issuer. For how to work around this issue, see Deployment failure with non-default issuer.

v1.9.1 Known issues: Supply Chain Security Tools - Store

- SCST - Store returns an expired certificate error message when a CA certificate expires before the app certificate. For more information, see CA Cert expires.
- When outputting CycloneDX v1.5 SBOMs, the report is found to be an invalid SBOM by CycloneDX validators. This issue is planned to be fixed in a future release.
- SCST - Store automatically detects PostgreSQL database index corruptions. If SCST - Store finds a PostgresSQL database index has been corrupted, SCST - Store will automatically attempt to repair, which might cause reconciliation during package updates. When this happens, the included Postgres database might take some time to complete the repair and accept connections. For more information, see Fix Postgres Database Index Corruption.
- If CA Certificate data is included in the shared Tanzu Application Platform values section, do not configure AMR Observer with CA Certificate data.
- When `observer.deploy_through_tmc` is `true`, properties are auto-configured for Tanzu Mission Control (TMC). This causes the `MultiClusterPropertyCollector` resource to overwrite existing Tanzu Application Platform values for Observer.

  When using Let's Encrypt ACME issuers, the resultant Kubernetes secret resource does not contain a `ca.crt` property. Therefore, when the `MultiClusterPropertyCollector` resource creates the Observer package configuration values secret, the required `ca_cert_data` is empty.

  To work around this issue, add the Certificate Authority (CA) Certificate to the `shared.ca_cert_data` key in the Tanzu Application Platform installation values.

v1.9.1 Known issues: Tanzu Build Service

- During upgrades a large number of builds might be created due to buildpack and stack updates. Some of these builds might fail due to transient network issues, causing the workload to be in an unhealthy state. This resolves itself on subsequent builds after a code change and does not affect the running application.

  If you do not want to wait for subsequent builds to run, you can manually trigger a build. For instructions, see Troubleshooting.

v1.9.1 Known issues: Tanzu Developer Portal

- If you do not configure any authentication providers, and do not allow guest access, the following message appears when loading Tanzu Developer Portal in a browser:

  ```
  No configured authentication providers. Please configure at least one.
  ```

  To resolve this issue, see Troubleshooting.
- Ad-blocking browser extensions and standalone ad-blocking software can interfere with telemetry collection within the VMware Customer Experience Improvement Program and restrict access to all or parts of Tanzu Developer Portal. For more information, see Troubleshooting.
- ScmAuth is a Backstage concept that abstracts Source Code Management (SCM) authentication into a package. An oversight in a recent code-base migration led to the accidental exclusion of custom ScmAuth functions. This exclusion affected some client operations, such as using Application Accelerators to create Git repositories on behalf of users.
- The back-end Kubernetes plug-in reports failure in multicluster environments. In a multicluster environment when one request to a Kubernetes cluster fails, `backstage-kubernetes-backend` reports a failure to the front end. This is a known issue with upstream Backstage and it applies to all released versions of Tanzu Developer Portal. For more information, see this Backstage code in GitHub. This behavior arises from the API at the Backstage level. There are currently no known workarounds. There are plans for upstream commits to Backstage to resolve this issue.

v1.9.1 Known issues: Tanzu Developer Tools for IntelliJ

- The error `com.vdurmont.semver4j.SemverException: Invalid version (no major version)` is shown in the error logs when attempting to perform a workload action before installing the Tanzu CLI apps plug-in.
- If you restart your computer while running Live Update without terminating the Tilt process beforehand, there is a lock that incorrectly shows that Live Update is still running and prevents it from starting again. For the fix, see Troubleshooting.
- Workload actions and Live Update do not work when in a project with spaces in its name, such as `my app`, or in its path, such as `C:\Users\My User\my-app`. For more information, see Troubleshooting.
- An **EDT Thread Exception** error is logged or reported as a notification with a message similar to `"com.intellij.diagnostic.PluginException: 2007 ms to call on EDT TanzuApplyAction#update@ProjectViewPopup"`. For more information, see Troubleshooting.

v1.9.1 Known issues: Tanzu Developer Tools for Visual Studio

- Clicking the red square Stop button in the Visual Studio top toolbar can cause a workload to fail. For more information, see Troubleshooting.

v1.9.1 Component versions

The following table lists the Tanzu Application Platform package versions included with this release. For open source component versions in this Tanzu Application Platform release, see Open source component versions.

Component Name	Version
API Auto Registration	0.5.0
API portal	1.5.0
Application Accelerator	1.9.1
Application Configuration Service	2.3.1
Application Live View APIServer	1.9.1
Application Live View back end	1.9.1
Application Live View connector	1.9.1
Application Live View conventions	1.9.1
Application Single Sign-On	5.1.5
Artifact Metadata Repository Observer	0.5.0
AWS Services	0.3.0
Bitnami Services	0.5.0
Carbon Black Scanner for SCST - Scan (beta)	1.4.0
Cartographer Conventions	0.9.0
cert-manager	2.7.4
Cloud Native Runtimes	2.5.3
Contour	2.2.0
Crossplane	0.5.0
Default Roles	1.1.0
Developer Conventions	0.16.1
External Secrets Operator	0.9.4+tanzu.3
Flux CD Source Controller	1.1.2+tanzu.3
Grype Scanner for SCST - Scan	1.9.1
Local Source Proxy	0.2.1
Managed Resource Controller (beta)	0.2.11
Namespace Provisioner	0.6.2
Out of the Box Delivery - Basic	0.16.6
Out of the Box Supply Chain - Basic	0.16.6
Out of the Box Supply Chain - Testing	0.16.6
Out of the Box Supply Chain - Testing and Scanning	0.16.6
Out of the Box Templates	0.16.6
Service Bindings	0.12.0

Component Name	Version
Service Registry	1.3.2
Services Toolkit	0.14.0
Snyk Scanner for SCST - Scan (beta)	1.3.0
Source Controller	0.9.0
Spring Boot conventions	1.9.1
Spring Cloud Gateway	2.1.10
Supply Chain Choreographer	0.9.0
Supply Chain Security Tools - Policy Controller	1.6.4
Supply Chain Security Tools - Scan	1.9.1
Supply Chain Security Tools - Scan 2.0	0.4.0
Supply Chain Security Tools - Store	1.9.0
Tanzu Application Platform Telemetry	0.7.0
Tanzu Build Service	1.13.0
Tanzu CLI	1.3.0
Tanzu Developer Portal	1.9.2
Tanzu Developer Portal Configurator	1.9.2
Tanzu Supply Chain (beta)	0.2.31
Tekton Pipelines	0.50.3+tanzu.4

v1.9.0

Release Date: 9 April 2024

What's new in Tanzu Application Platform v1.9

This release includes the following platform-wide enhancements.

New platform-wide features

- Tanzu Application Platform v1.9 supports N-2 upgrades, which allows you to upgrade from Tanzu Application Platform v1.7.x to v1.9.x or from Tanzu Application Platform v1.8.x to v1.9.x.

v1.9.0 New features by component and area

This release includes the following changes, listed by component and area.

v1.9.0 Features: Application Accelerator

- Accelerator authors can now use IntelliJ as well as VS Code to create accelerators using the local authoring experience without connecting to a Tanzu Application Platform cluster. For more information, see Use a local Application Accelerator engine server.

- Adds the Spring AI Chat sample accelerator, which provides a sample application you can use to quickly start development of a web application for AI chat based on Spring AI. This web application offers an interactive chat experience that uses Retrieval Augmented Generation (RAG) to enable a user to ask questions about their uploaded documents. For more information, see Spring AI Chat Sample Accelerator.

v1.9.0 Features: Application Live View

- By default, Application Live View connector is deployed as a Deployment to discover applications across all namespaces running in a worker node of a Kubernetes cluster. This overrides the previous behavior where the connector was deployed as a DaemonSet, which made the Kubernetes scheduling pattern unpredictable when a node restarts. For more information, see Connector deployment modes in Application Live View.

v1.9.0 Features: Bitnami Services

- Introduces the package value `claim_namespace`, which enables you to create services in the same namespace as the originating claim. You can set this value globally or on a specific service. For more information, see Package values of Bitnami Services.

v1.9.0 Features: Buildpacks and Stacks

- Adds support for the Tanzu Standard Stack for UBI 8 to the .NET Core and Web Servers buildpacks. For more information about the Tanzu Standard Stack for UBI 8, see the Tanzu Buildpacks documentation.

v1.9.0 Features: Services Toolkit

- You can configure resource limits and requests for the Services Toolkit Controller Manager and Services Toolkit Resource Claims API Server deployments through the package values. For more information, see Scalability.

v1.9.0 Features: Tanzu Developer Portal

- Added configuration to route traffic through a specified HTTP/HTTPS proxy. This includes all outgoing requests made by Backstage and Tanzu Developer Portal. For more information, see Configure HTTP Proxy.
- The DORA plug-in now has the following changes:
    - Added the date range drop-down menu filters **Last 7 Days** and **Last 30 Days**
    - The default date range filter is now **Last 7 Days** instead of **Last 90 Days**
    - Earlier filters have more accurate names: **This Week** is now **Week to Date**, **This Month** is now **Month to Date**, and **This Quarter** is now **Quarter to Date**
    - Added percentage values to show improvements or declines in metrics when compared with the previous time period
    - Added graphs to display changes in Lead Time and Deployment Frequency metrics over time
    - Performance improvements

---

v1.9.0 Breaking changes

This release includes the following changes, listed by component and area.

v1.9.0 Breaking changes: FluxCD Source Controller

- FluxCD Source Controller no longer supports the `git_implementation` field in `GitRepository` version `v1`.

v1.9.0 Breaking changes: Services Toolkit

- The `tanzu services claims` CLI plug-in command has been removed. You must now use the `tanzu services resource-claims` command instead.
- The experimental kubectl-scp plug-in has been removed.
- The experimental multicluster APIs `*.multicluster.x-tanzu.vmware.com/v1alpha1` have been removed.
    - `apiexportrolebindings.projection.apiresources.multicluster.x-tanzu.vmware.com/v1alpha1`
    - `apiresourceimports.projection.apiresources.multicluster.x-tanzu.vmware.com/v1alpha1`
    - `clusterapigroupimports.projection.apiresources.multicluster.x-tanzu.vmware.com/v1alpha1`
    - `downstreamclusterlinks.projection.apiresources.multicluster.x-tanzu.vmware.com/v1alpha1`
    - `upstreamclusterlinks.projection.apiresources.multicluster.x-tanzu.vmware.com/v1alpha1`
    - `clusterresourceexportmonitors.replication.apiresources.multicluster.x-tanzu.vmware.com/v1alpha1`
    - `clusterresourceimportmonitors.replication.apiresources.multicluster.x-tanzu.vmware.com/v1alpha1`
    - `resourceexportmonitorbindings.replication.apiresources.multicluster.x-tanzu.vmware.com/v1alpha1`
    - `resourceimportmonitorbindings.replication.apiresources.multicluster.x-tanzu.vmware.com/v1alpha1`
    - `secretexports.replication.apiresources.multicluster.x-tanzu.vmware.com/v1alpha1`
    - `secretimports.replication.apiresources.multicluster.x-tanzu.vmware.com/v1alpha1`

v1.9.0 Breaking changes: Supply Chain Choreographer

- Supply Chain Choreographer no longer supports the `git_implementation` field in `GitRepository` version `v1`. If you use a custom supply chain, when you upgrade to Tanzu Application Platform v1.9 you must ensure that the `GitRepository` resource conforms to the `v1` API.

v1.9.0 Breaking changes: Supply Chain Security Tools - Scan

- When you configure SCST - Scan with the Metadata Store CA Certificate, you can no longer manually create the secret. Configure the secret in the `values.yaml` file. For more information, see Multicluster setup for Supply Chain Security Tools.

---

v1.9.0 Security fixes

This release has the following security fixes, listed by component and area.

v1.9.0 Resolved issues

The following issues, listed by component and area, are resolved in this release.

v1.9.0 Resolved issues: App Last Mile Catalog

- Resolved an issue where the Deployer component output an error message that was larger than 4 KB. This caused a Tekton error. The Deployer component now outputs a smaller error message that is human readable.

v1.9.0 Resolved issues: AWS Services

- Updated the `endpoint` key name in the binding secret for Amazon MQ (RabbitMQ) claims to `addresses` so that it matches the name that the Spring Cloud Bindings library uses. This key name change is not applied to any existing Amazon MQ (RabbitMQ) claims. If new Amazon MQ (RabbitMQ) claims still do not have the updated `addresses` key name, see Troubleshoot AWS Services.

v1.9.0 Resolved issues: Crossplane

- Fixed an issue that you might encounter if you uninstall and reinstall the Crossplane package on the same cluster. You no longer receive a TLS certificate verification error with service claims never transitioning to `READY=True`.

v1.9.0 Resolved issues: Supply Chain Choreographer

- Supply Chains that use SSH auth with the `git-writer` resource no longer fail in the gitops step.

---

v1.9.0 Known issues

This release has the following known issues, listed by component and area.

v1.9.0 Known issues: Tanzu Application Platform

- On Azure Kubernetes Service (AKS), the Datadog Cluster Agent cannot reconcile the webhook, which leads to an error. For troubleshooting information, see Datadog agent cannot reconcile webhook on AKS.
- The Tanzu Application Platform integration with Tanzu Service Mesh does not work on vSphere with TKR v1.26. For more information about this integration, see Set up Tanzu Service Mesh. As a workaround, you can apply the label to update pod security on a TKr v1.26 Kubernetes namespace as advised by the release notes for TKr 1.26.5 for vSphere 8.x. However, applying this label provides more than the minimum necessary privilege to the resources in developer namespaces.

v1.9.0 Known issues: API Auto Registration

- Registering conflicting `groupId` and `version` with API portal:

  If you create two `CuratedAPIDescriptor`s with the same `groupId` and `version` combination, both reconcile without throwing an error, and the `/openapi?groupId&version` endpoint returns both specifications. If you are adding both specifications to the API portal, only one of them might show up in the API portal UI with a warning indicating that there is a conflict. If you add the route provider annotation for both of the `CuratedAPIDescriptor`s to use Spring Cloud Gateway, the generated API specspecification includes API routes from both `CuratedAPIDescriptor`s.

  You can see the `groupId` and `version` information from all `CuratedAPIDescriptor`s by running:

  ```
  $ kubectl get curatedapidescriptors -A

  NAMESPACE           NAME         GROUPID            VERSION   STATUS   CURATED
  API SPEC URL
  my-apps             petstore     test-api-group     1.2.3     Ready    http://A
  AR-CONTROLLER-FQDN/openapi/my-apps/petstore
  default             mystery      test-api-group     1.2.3     Ready    http://A
  AR-CONTROLLER-FQDN/openapi/default/mystery
  ```

- When creating an `APIDescriptor` with different `apiSpec.url` and `server.url`, the controller incorrectly uses the API spec URL as the server URL. To avoid this issue, use `server.url` only.

v1.9.0 Known issues: App Last Mile Catalog

- The app-config-web, app-config-server, and app-config-worker components do not allow developers to override the default application ports. This means that applications that use non-standard ports do not work. To work around this, you can configure ports by providing values to the resulting Carvel package. This issue is planned to be fixed in a future release.

v1.9.0 Known issues: Application Live View

- On the Run profile, Application Live View fails to reconcile if you use a non-default cluster issuer while installing through Tanzu Mission Control.

v1.9.0 Known issues: Artifact Metadata Repository Observer and CloudEvent Handler

- Periodic reconciliation or restarting of the AMR Observer causes reattempted posting of ImageVulnerabilityScan results. There is an error on duplicate submission of identical ImageVulnerabilityScans you can ignore if the previous submission was successful.

v1.9.0 Known issues: Bitnami Services

- If you try to configure private registry integration for the Bitnami Services after having already created a claim for one or more of the services using the default configuration, the updated private registry configuration does not appear to take effect. This is due to caching behavior in the system which is not accounted for during configuration updates. For a workaround, see Troubleshoot Bitnami Services.

v1.9.0 Known issues: Cartographer Conventions

- Before Tanzu Application Platform v1.9, the `cartographer.tanzu.vmware.com` package contained two products: Cartographer and Cartographer Conventions. In Tanzu Application Platform v1.9.0 the Cartographer Conventions product is removed from the `cartographer.tanzu.vmware.com` package and is distributed in its own package named `cartographer.conventions.apps.tanzu.vmware.com`.

  When you upgrade to Tanzu Application Platform v1.9, an issue might occur when installing the new package for Cartographer Conventions. The upgrade might fail to reconcile and show error messages similar to the following:

  ```
  Resource 'clusterrole/cartographer-conventions-manager-role (rbac.authorizatio
  n.k8s.io/v1) cluster' is already associated with a different app 'cartographer.
  app'
  ```

  This message might appear more than once, and it can refer to several resources.

  These errors appear when kapp-controller on the cluster tries to install the new Cartographer Conventions package before the Cartographer package has reconciled. The new package for Cartographer Conventions tries to install resources that the existing Cartographer package still owns.

  Although it looks like the upgrade fails, if you wait a few minutes, kapp-controller finishes the installation and the packages will reconcile successfully. The system works normally after the reconciliation is complete.

  This error does not occur on a new installation of Tanzu Application Platform v1.9.

- While processing workloads with large SBOMs, the Cartographer Convention controller manager pod can fail with the status `CrashLoopBackOff` or `OOMKilled`. For information about how to increase the memory limit for both the convention server and webhook servers, including app-live-view-conventions, spring-boot-webhook, and developer-conventions/webhook, see Troubleshoot Cartographer Conventions.

v1.9.0 Known issues: Crossplane

- The Crossplane `validatingwebhookconfiguration` is not removed when you uninstall the Crossplane package. To workaround, delete the `validatingwebhookconfiguration` manually by running `kubectl delete validatingwebhookconfiguration crossplane`.

v1.9.0 Known issues: Services Toolkit

- An error occurs if `additionalProperties` is `true` in a CompositeResourceDefinition. For more information and a workaround, see Troubleshoot Services Toolkit.

v1.9.0 Known issues: Supply Chain

- Components cannot have more than one resumption defined. When there are multiple resumptions, `WorkloadRuns` are not correctly created after resumptions trigger changes. The current workaround is to assess all triggers in a single resumption.
- Tanzu Supply Chain currently does not include support for Red Hat OpenShift. This means you cannot individually install components for Tanzu Supply Chain and Managed Resource Controller. You also cannot install the Authoring profile that includes those components as standard. Support for Red Hat OpenShift is planned for a later release.
- Tanzu Supply Chain currently does not include support for CA certificates in the Out of the Box components. However, you can edit the components to support CA certificates and use them to construct a new Supply Chain. Support for CA certificates as standard is planned for future versions of Tanzu Supply Chain.
- When you select the **Supply Chains** tab in Tanzu Developer Portal, you might encounter an error related to `data.packaging.carvel.dev`. The error message is related to permission issues and JSON parsing errors. The error message indicates that the user `system:serviceaccount:tap-gui:tap-gui-viewer` cannot list resource `packages` in the API group `data.packaging.carvel.dev` at the cluster scope. Additionally, an unexpected non-whitespace character is reported after JSON at position 4.

  As a temporary workaround, apply an RBAC configuration that includes the get, watch, and list permissions for the resources in the `data.packaging.carvel.dev` API group. This workaround must not be mandated for supply chains that do not generate Carvel packages.

  To eliminate the error message, configure RBAC to allow access to the Carvel package resource as follows:

  ```
  apiVersion: rbac.authorization.k8s.io/v1
  kind: ClusterRole
  - apiGroups: [data.packaging.carvel.dev]
   resources: [packages]
   verbs: ['get', 'watch', 'list']
  ```

- The **Workload** page in the Supply Chain UI takes a long time to load when there are more than 100 workloads to display.
- The **Workload Details** page, accessed by clicking on a workload name, does not load in the Supply Chain UI when there are more than 100 workloads to display.

v1.9.0 Known issues: Supply Chain Choreographer

- The template for the `external-deliverable-template` does not respect the `gitops_credentials_secret` parameter. The value is not present on the deliverable if it is provided in the workload parameter `gitops_credentials_secret` or the supply chain tap-value `ootb_supply_chain*.gitops.credentials_secret`. As a workaround, operators must provide the value as a tap-value for the delivery: `ootb_delivery_basic.source.credentials_secret`. The supply chain's GitOps credentials must authenticate to the same repository as the delivery's source credentials. If a deliverable must use a secret different from that specified by the delivery tap-value, the

deliverable must be manually altered when being copied to the Run cluster. Add the secret name as a `source_credentials_secret` parameter on the deliverable.

- By default, Server Workload Carvel packages generated by the Carvel package supply chains no longer contain OpenAPIv3 descriptions of their parameters. These descriptions were omitted to keep the size of the Carvel Package definition under 4 KB, which is the size limit for the string output of a Tekton Task. For information about these parameters, see Carvel Package Supply Chains.
- When using the Carvel Package Supply Chains, if the operator updates the parameter `carvel_package.name_suffix`, existing workloads incorrectly output a Carvel package to the GitOps repository that uses the old value of `carvel_package.name_suffix`. You can ignore or delete this package.
- If the size of the resulting OpenAPIv3 specification exceeds a certain size, approximately 3 KB, the Supply Chain does not function. If you use the default Carvel package parameters, this issue does not occur. If you use custom Carvel package parameters, you might encounter this size limit. If you exceed the size limit, you can either deactivate this feature, or use a workaround. The workaround requires enabling a Tekton feature flag. For more information, see the Tekton documentation.

v1.9.0 Known issues: Supply Chain Security Tools - Policy

- Supply Chain Security Tools - Policy defaults to The Update Framework (TUF) enabled due to incorrect logic. This might cause the package to not reconcile correctly if the default TUF mirrors are not reachable. To work around this, explicitly configure policy controller in the `tap-values.yaml` file to enable TUF:

```
policy:
  tuf_enabled: true
```

v1.9.0 Known issues: Supply Chain Security Tools - Scan

- When using Supply Chain Security Tools (SCST) - Scan 2.0 with a ClusterImageTemplate, the value for the scanning image is overwritten with an incorrect default value from `ootb_supply_chain_testing_scanning.image_scanner_cli` in the `tap-values.yaml` file for templates other than Trivy. You can prevent this by setting the value in your `tap-values.yaml` file to the correct image. For example, for the Grype image packaged with Tanzu Application Platform:

```
ootb_supply_chain_testing_scanning:
  image_scanner_template_name: image-vulnerability-scan-grype
  image_scanning_cli:
    image: registry.tanzu.vmware.com/tanzu-application-platform/tap-packages@sh
a256:feb1cdbd5c918aae7a89bdb2aa39d486bf6ffc81000764b522842e5934578497
```

- The Snyk scanner outputs an incorrectly created date, resulting in an invalid date. If the workload is in a failed state due to an invalid date, wait approximately 10 hours and the workload automatically goes into the ready state. For more about this issue information, see the Snyk GitHub repository.
- Recurring scan has a maximum of approximately 5000 container images that can be scanned at a single time due to size limits configMaps.
- If the supply chain container image scanning is configured to use a different scanner or scanner version than the recurring scanning, the vulnerabilities displayed in Tanzu Developer Portal might be inaccurate.

- SCST - Scan 1.0 fails with the error `secrets 'store-ca-cert' not found` during deployment by using Tanzu Mission Control with a non-default issuer. For how to work around this issue, see Deployment failure with non-default issuer.

v1.9.0 Known issues: Supply Chain Security Tools - Store

- SCST - Store returns an expired certificate error message when a CA certificate expires before the app certificate. For more information, see CA Cert expires.
- When outputting CycloneDX v1.5 SBOMs, the report is found to be an invalid SBOM by CycloneDX validators. This issue is planned to be fixed in a future release.
- SCST - Store automatically detects PostgreSQL database index corruptions. If SCST - Store finds a PostgresSQL database index has been corrupted, SCST - Store will automatically attempt to repair, which might cause reconciliation during package updates. When this happens, the included Postgres database might take some time to complete the repair and accept connections. For more information, see Fix Postgres Database Index Corruption.
- When `observer.deploy_through_tmc` is `true`, properties are auto-configured for Tanzu Mission Control (TMC). This causes the `MultiClusterPropertyCollector` resource to overwrite existing Tanzu Application Platform values for Observer.

  When using Let's Encrypt ACME issuers, the resultant Kubernetes secret resource does not contain a `ca.crt` property. Therefore, when the `MultiClusterPropertyCollector` resource creates the Observer package configuration values secret, the required `ca_cert_data` is empty.

  To work around this issue, add the Certificate Authority (CA) Certificate to the `shared.ca_cert_data` key in the Tanzu Application Platform installation values.
- If CA Certificate data is included in the shared Tanzu Application Platform values section, do not configure AMR Observer with CA Certificate data.

v1.9.0 Known issues: Tanzu Build Service

- During upgrades a large number of builds might be created due to buildpack and stack updates. Some of these builds might fail due to transient network issues, causing the workload to be in an unhealthy state. This resolves itself on subsequent builds after a code change and does not affect the running application.

  If you do not want to wait for subsequent builds to run, you can manually trigger a build. For instructions, see Troubleshooting.

v1.9.0 Known issues: Tanzu Developer Portal

- Tanzu Developer Portal Configurator jumps from v1.0.x in Tanzu Application Platform v1.7 to v1.8.x in Tanzu Application Platform v1.8. This version jump enables future versions of Tanzu Developer Portal and Tanzu Developer Portal Configurator to sync going forward.
- If you do not configure any authentication providers, and do not allow guest access, the following message appears when loading Tanzu Developer Portal in a browser:

  ```
  No configured authentication providers. Please configure at least one.
  ```

  To resolve this issue, see Troubleshooting.
- Ad-blocking browser extensions and standalone ad-blocking software can interfere with telemetry collection within the VMware Customer Experience Improvement Program and

restrict access to all or parts of Tanzu Developer Portal. For more information, see Troubleshooting.

- ScmAuth is a Backstage concept that abstracts Source Code Management (SCM) authentication into a package. An oversight in a recent code-base migration led to the accidental exclusion of custom ScmAuth functions. This exclusion affected some client operations, such as using Application Accelerators to create Git repositories on behalf of users.
- The back-end Kubernetes plug-in reports failure in multicluster environments. In a multicluster environment when one request to a Kubernetes cluster fails, `backstage-kubernetes-backend` reports a failure to the front end. This is a known issue with upstream Backstage and it applies to all released versions of Tanzu Developer Portal. For more information, see this Backstage code in GitHub. This behavior arises from the API at the Backstage level. There are currently no known workarounds. There are plans for upstream commits to Backstage to resolve this issue.

v1.9.0 Known issues: Tanzu Developer Tools for IntelliJ

- The error `com.vdurmont.semver4j.SemverException: Invalid version (no major version)` is shown in the error logs when attempting to perform a workload action before installing the Tanzu CLI apps plug-in.
- If you restart your computer while running Live Update without terminating the Tilt process beforehand, there is a lock that incorrectly shows that Live Update is still running and prevents it from starting again. For the fix, see Troubleshooting.
- Workload actions and Live Update do not work when in a project with spaces in its name, such as `my app`, or in its path, such as `C:\Users\My User\my-app`. For more information, see Troubleshooting.
- An **EDT Thread Exception** error is logged or reported as a notification with a message similar to `"com.intellij.diagnostic.PluginException: 2007 ms to call on EDT TanzuApplyAction#update@ProjectViewPopup"`. For more information, see Troubleshooting.

v1.9.0 Known issues: Tanzu Developer Tools for Visual Studio

- Clicking the red square Stop button in the Visual Studio top toolbar can cause a workload to fail. For more information, see Troubleshooting.

---

v1.9.0 Component versions

The following table lists the Tanzu Application Platform package versions included with this release. For open source component versions in this Tanzu Application Platform release, see Open source component versions.

Component Name	Version
API Auto Registration	0.5.0
API portal	1.5.0
Application Accelerator	1.9.1
Application Configuration Service	2.3.1
Application Live View APIServer	1.9.1
Application Live View back end	1.9.1

Component Name	Version
Application Live View connector	1.9.1
Application Live View conventions	1.9.1
Application Single Sign-On	5.1.4
Artifact Metadata Repository Observer	0.5.0
AWS Services	0.3.0
Bitnami Services	0.5.0
Carbon Black Scanner for SCST - Scan (beta)	1.4.0
Cartographer Conventions	0.9.0
cert-manager	2.7.2
Cloud Native Runtimes	2.5.3
Contour	2.2.0
Crossplane	0.5.0
Default Roles	1.1.0
Developer Conventions	0.16.1
External Secrets Operator	0.9.4+tanzu.3
Flux CD Source Controller	1.1.2+tanzu.1
Grype Scanner for SCST - Scan	1.9.0
Local Source Proxy	0.2.1
Managed Resource Controller (beta)	0.2.1
Namespace Provisioner	0.6.2
Out of the Box Delivery - Basic	0.16.1
Out of the Box Supply Chain - Basic	0.16.1
Out of the Box Supply Chain - Testing	0.16.1
Out of the Box Supply Chain - Testing and Scanning	0.16.1
Out of the Box Templates	0.16.1
Service Bindings	0.12.0
Service Registry	1.3.2
Services Toolkit	0.14.0
Snyk Scanner for SCST - Scan (beta)	1.3.0
Source Controller	0.9.0
Spring Boot conventions	1.9.1
Spring Cloud Gateway	2.1.9
Supply Chain Choreographer	0.9.0
Supply Chain Security Tools - Policy Controller	1.6.4
Supply Chain Security Tools - Scan	1.9.1

Component Name	Version
Supply Chain Security Tools - Scan 2.0	0.4.0
Supply Chain Security Tools - Store	1.9.0
Tanzu Application Platform Telemetry	0.7.0
Tanzu Build Service	1.13.0
Tanzu CLI	1.2.0
Tanzu Developer Portal	1.9.1
Tanzu Developer Portal Configurator	1.9.1
Tanzu Supply Chain (beta)	0.2.9
Tekton Pipelines	0.50.3+tanzu.4

Deprecations

The following features, listed by component, are deprecated. Deprecated features remain on this list until they are retired from Tanzu Application Platform.

Cloud Native Runtimes deprecations

- `default_tls_secret` **config option**: After changes in this release, this config option is moved to `contour.default_tls_secret`. `default_tls_secret` is marked for removal in Cloud Native Runtimes v2.7. In the meantime, both options are supported, and `contour.default_tls_secret` takes precedence over `default_tls_secret`.
- `ingress.[internal/external].namespace` **config options**: After changes in this release, these config options are moved to `contour.[internal/external].namespace`. `ingress.[internal/external].namespace` is marked for removal in Cloud Native Runtimes v2.7. In the meantime, both options are supported, and `contour.[internal/external].namespace` takes precedence over `ingress.[internal/external].namespace`.

FluxCD Source Controller deprecations

- FluxCD Source Controller updates the `GitRepository` API from `v1beta2` to `v1`. The controller accepts resources with API versions `v1beta1` and `v1beta2`, saving them as `v1`.

Services Toolkit deprecations

- The following APIs are deprecated and are marked for removal in Tanzu Application Platform v1.11:
  - `clusterexampleusages.services.apps.tanzu.vmware.com/v1alpha1`
  - `clusterresources.services.apps.tanzu.vmware.com/v1alpha1`

Source Controller deprecations

- The Source Controller `ImageRepository` API is deprecated and is marked for removal. Use the `OCIRepository` API instead. The Flux Source Controller installation includes the `OCIRepository` API. For more information about the `OCIRepository` API, see the Flux documentation.

Tekton Pipelines deprecations

- Tekton `ClusterTask` is deprecated and marked for removal. Use the `Task` API instead. For more information, see the Tekton documentation.

Linux Kernel CVEs

Kernel level vulnerabilities are regularly identified and patched by Canonical. Tanzu Application Platform releases with available images, which might contain known vulnerabilities. When Canonical makes patched images available, Tanzu Application Platform incorporates these fixed images into future releases.

The kernel runs on your container host VM, not the Tanzu Application Platform container image. Even with a patched Tanzu Application Platform image, the vulnerability is not mitigated until you deploy your containers on a host with a patched OS. An unpatched host OS might be exploitable if the base image is deployed.

Planning and Architecture Reference

This topic tells you how to access the Tanzu Application Platform (commonly known as TAP) planning and architecture reference documentation.

The Tanzu Application Platform Planning and Architecture Reference documentation is available here.

This documentation helps you to understand the main design issues you encounter when planning your Tanzu Application Platform environment.

Important

You should review the Tanzu Application Platform Planning and Architecture Reference documentation before you install Tanzu Application Platform.

Components and installation profiles for Tanzu Application Platform

This topic lists the components you can install with Tanzu Application Platform (commonly known as TAP). You can install components as individual packages or you can install them using a profile containing a predefined group of packages.

Tanzu Application Platform components

- **API Auto Registration**

  When users deploy a workload that exposes an API, they want that API to automatically show in Tanzu Developer Portal without requiring any added manual steps.

  API Auto Registration is an automated workflow that can use a supply chain to create and manage a Kubernetes Custom Resource (CR) of type `APIDescriptor`. A Kubernetes controller reconciles the CR and updates the API entity in Tanzu Developer Portal to achieve automated API registration from workloads. You can also use API Auto Registration without supply chains by directly applying an `APIDescriptor` CR to the cluster.

- **API portal**

  API portal for VMware Tanzu enables API consumers to find APIs they can use in their own applications.

  Consumers can view detailed API documentation and try out an API to see if it meets their needs. API portal assembles its dashboard and detailed API documentation views by ingesting OpenAPI documentation from the source URLs. An API portal operator can add any number of OpenAPI source URLs to appear in a single instance.

- **Application Accelerator**

  The Application Accelerator component helps app developers and app operators create application accelerators.

  Accelerators are templates that codify best practices and ensure that important configurations and structures are in place. Developers can bootstrap their applications and get started with feature development right away.

  Application operators can create custom accelerators that reflect their desired architectures and configurations and enable fleets of developers to use them. This helps ease operator concerns about whether developers are implementing their best practices.

- **Application Configuration Service**

  Application Configuration Service provides a Kubernetes-native experience to enable the runtime configuration of existing Spring applications that were previously leveraged by using Spring Cloud Config Server.

  Application Configuration Service is compatible with the existing Git repository configuration management approach. It filters runtime configuration for any application by using slices that produce secrets.

- **Application Live View**

Application Live View is a lightweight insight and troubleshooting tool that helps application developers and application operators look inside running applications.

It is based on the concept of Spring Boot Actuators. The application provides information from inside the running processes by using endpoints (in our case, HTTP endpoints). Application Live View uses those endpoints to get the data from the application and to interact with it.

- **Application Single Sign-On**

  Application Single Sign-On enables application users to sign in to their identity provider once and be authorized and identified to access any Kubernetes-deployed workload. It is a secure and straightforward approach for developers and operators to manage access across all workloads in the enterprise.

- **Aria Operations for Applications (AOA) dashboard for Tanzu Application Platform (Beta)**

  This dashboard, powered by Aria Operations for Applications (formerly Tanzu Observability), helps platform engineers monitor the health of a given cluster by showing whether the deployed Tanzu Application Platform components are behaving as expected.

- **AWS Services**

  AWS Services provides an integration with Amazon Web Services (AWS) for Tanzu Application Platform.

  Through integration with Crossplane and Services Toolkit, you can offer services from AWS to apps teams to consume with only minimal setup and configuration required from ops teams. This makes it quick and easy to get started working with these services on Tanzu Application Platform.

- **Bitnami Services**

  Bitnami Services provides a set of services for Tanzu Application Platform backed by corresponding Bitnami Helm Charts. Through integration with Crossplane and Services Toolkit, these Bitnami Services are immediately ready for apps teams to consume, with no additional setup or configuration required from ops teams. This makes it incredibly quick and easy to get started working with services on Tanzu Application Platform.

- **Cartographer Conventions**

  Use Cartographer Conventions to ensure infrastructure uniformity across workloads deployed on the cluster. Cartographer Conventions provide a way to control how applications should be deployed on Kubernetes using a convention. Use Cartographer Conventions to apply the runtime best practices, policies, and conventions of your organization to workloads as they are created on the platform.

- **cert-manager**

  cert-manager adds certificates and certificate issuers as resource types to Kubernetes clusters. It also helps you to obtain, renew, and use those certificates. For more information about cert-manager, see the cert-manager documentation.

- **Cloud Native Runtimes**

  Cloud Native Runtimes for Tanzu is a serverless application runtime for Kubernetes that is based on Knative and runs on a single Kubernetes cluster. For information about Knative, see the Knative documentation.

- **Contour**

  Contour is an ingress controller for Kubernetes that supports dynamic configuration updates and multi-team ingress delegation. It provides the control plane for the Envoy edge and

service proxy. For more information about Contour, see the Contour documentation.

- **Default roles for Tanzu Application Platform**

  This package includes five default roles for users, including app-editor, app-viewer, app-operator, and service accounts including workload and deliverable. These roles are available to help operators limit permissions a user or service account requires on a cluster that runs Tanzu Application Platform. They are built by using aggregated cluster roles in Kubernetes role-based access control (RBAC). Default roles only apply to a user interacting with the cluster by using kubectl and Tanzu CLI.

- **Crossplane**

  Crossplane is an open source, Cloud Native Computing Foundation (CNCF) project built on the foundation of Kubernetes. Tanzu Application Platform uses Crossplane to power a number of capabilities, such as dynamic provisioning of services instances with Services Toolkit and the Bitnami Services.

- **Developer Conventions**

  Developer conventions configure workloads to prepare them for inner loop development.

  It's meant to be a "deploy and forget" component for developers. After it is installed on the cluster with the Tanzu Package CLI, developers do not need to directly interact with it. Developers instead interact with the Tanzu Developer Tools for VSCode IDE Extension or Tanzu CLI Apps plug-in, which rely on the Developer Conventions to edit the workload to enable inner loop capabilities.

- **External Secrets Operator**

  The External Secrets Operator is a Kubernetes operator that integrates with external secret management systems, for example, Google Secrets Manager and Hashicorp Vault. It reads information from external APIs and automatically injects the values into a Kubernetes secret. Tanzu Application Platform uses the External Secrets Operator to simplify Kubernetes secret life cycle management.

- **Flux CD Source Controller**

  The main role of this source management component is to provide a common interface for artifact acquisition.

- **Local Source Proxy**

  Local Source Proxy is a secure and convenient means for you to interact with external registries without providing a lot of registry details.

  With Local Source Proxy, developers can interact with external registries without needing to know registry specifics, such as endpoints, credentials, and certificates. This eliminates the burden of platform and app operators having to distribute registry credentials to developer workstations.

  Developers can also seamlessly deploy their applications without managing registry credentials on their local machines or keeping track of where their local source is uploaded.

- **Namespace Provisioner**

  Namespace Provisioner provides an easy, secure, automated way for Platform Operators to provision namespaces with the resources and proper namespace-level privileges needed for developer workloads to function as intended.

- **Service Bindings**

  Service Bindings create a Kubernetes-wide specification for communicating service secrets to workloads in a consistent way.

- **Service Registry**

  Service Registry for VMware Tanzu provides on-demand Eureka servers for your Tanzu Application Platform clusters. With Service Registry, you can create Eureka servers in your namespaces and bind Spring Boot workloads to them.

- **Services Toolkit**

  Services Toolkit is responsible for backing many of the most exciting and powerful capabilities for services in Tanzu Application Platform. From the integration of an extensive list of cloud-based and on-prem services, through to the offering and discovery of those services, and finally to the claiming and binding of service instances to application workloads, Services Toolkit has the tools you need to make working with services on Tanzu Application Platform simple, easy, and effective.

- **Source Controller**

  Tanzu Source Controller provides a standard interface for artifact acquisition and extends the function of Flux CD Source Controller. Tanzu Source Controller supports the following two resource types:

  - ImageRepository (deprecated)
  - MavenArtifact

- **Spring Boot conventions**

  The Spring Boot convention server has a bundle of smaller conventions applied to any Spring Boot application that is submitted to the supply chain in which the convention controller is configured.

- **Spring Cloud Gateway**

  Spring Cloud Gateway for Kubernetes is an API gateway solution based on the open-source Spring Cloud Gateway project. It provides a simple means to route internal or external API requests to application services that expose APIs.

- **Supply Chain Choreographer**

  Supply Chain Choreographer is based on open-source Cartographer. It enables app operators to create preapproved paths to production by integrating Kubernetes resources with the elements of their existing toolchains, such as Jenkins.

  Each pre-approved supply chain creates a paved road to production. It orchestrates supply chain resources, namely test, build, scan, and deploy. Enabling developers to focus on delivering value to their users. Pre-approved supply chains also assure application operators that all code in production has passed through the steps of an approved workflow.

  Note: Tanzu Supply Chain replaces Supply Chain Choreographer, but is still in beta testing.

- **Supply Chain Security Tools - Policy Controller**

  Supply Chain Security Tools (SCST) - Policy is an admission controller that allows a cluster operator to specify policies to verify image container signatures before admitting them to a cluster. It works with cosign signature format and allows for fine-tuned configuration of policies based on image source patterns.

- **Supply Chain Security Tools - Scan**

  With Supply Chain Security Tools (SCST) - Scan, you can build and deploy secure trusted software that complies with their corporate security requirements.

  To enable this, Supply Chain Security Tools - Scan provides scanning and gate keeping capabilities that Application and DevSecOps teams can incorporate earlier in their path to

production. This is an established industry best practice for reducing security risk and ensuring more efficient remediation.

- **Supply Chain Security Tools - Store**

  Supply Chain Security Tools (SCST) - Store saves software bills of materials (SBoMs) to a database and enables you to query for image, source, package, and vulnerability relationships. It integrates with SCST - Scan to automatically store the resulting source and image vulnerability reports.

- **Tanzu Developer Portal**

  Tanzu Developer Portal lets your developers view your organization's running applications and services. It provides a central location for viewing dependencies, relationships, technical documentation, and even service status. Tanzu Developer Portal is built from the Cloud Native Computing Foundation's project Backstage.

- **Tanzu Application Platform Telemetry**

  Tanzu Application Platform Telemetry is a set of objects that collect data about the use of Tanzu Application Platform and send it back to VMware for product improvements. A benefit of remaining enrolled in telemetry and identifying your company during Tanzu Application Platform installation is that VMware can provide your organization with use reports about Tanzu Application Platform. For information about enrolling in telemetry reports, see Tanzu Application Platform usage reports.

  > **Note**
  >
  > You can opt out of telemetry collection by following the instructions in Opting out of telemetry collection.

- **Tanzu Build Service**

  Tanzu Build Service uses the open-source Cloud Native Build packs project to turn application source code into container images.

  Tanzu Build Service executes reproducible builds that align with modern container standards and keeps images up to date. It does so by leveraging Kubernetes infrastructure with kpack, a Cloud Native Build packs Platform, to orchestrate the image life cycle.

  The kpack CLI tool, kp, can aid in managing kpack resources. Build Service helps you develop and automate containerized software workflows securely and at scale.

- **Tanzu Buildpacks**

  Tanzu Buildpacks provide framework and runtime support for applications. Buildpacks typically examine your applications to work out what dependencies to download and how to configure the apps to communicate with bound services.

  Tanzu Buildpacks use open-source Paketo Buildpacks to allow Tanzu Application Platform users to turn their application source code into container images. From Tanzu Application Platform v1.6, builders, stacks, and buildpacks are packaged separately from Tanzu Build Service, but are included in the same Tanzu Application Platform profiles as Tanzu Build Service. All buildpacks follow the package name format `*.buildpacks.tanzu.vmware.com`.

- **Tanzu Supply Chain (beta)**

  Tanzu Supply Chain is a tool that provides a golden path to production for your teams. Tanzu Supply Chain replaces the supply-chain solution Supply Chain Choreographer, which is based on Cartographer.

- **Tanzu Developer Tools for IntelliJ**

  Tanzu Developer Tools for IntelliJ is the official VMware Tanzu IDE extension for IntelliJ IDEA to help you develop code by using Tanzu Application Platform. This extension enables you to rapidly iterate on your workloads on supported Kubernetes clusters that have Tanzu Application Platform installed.

- **Tanzu Developer Tools for Visual Studio**

  Tanzu Developer Tools for Visual Studio is the official VMware Tanzu IDE extension for Visual Studio to help you develop code by using Tanzu Application Platform. The Visual Studio extension enables live updates of your application while it runs on the cluster and lets you debug your application directly on the cluster.

- **Tanzu Developer Tools for Visual Studio Code**

  Tanzu Developer Tools for VS Code is the official VMware Tanzu IDE extension for VS Code to help you develop code by using Tanzu Application Platform. The VS Code extension enables live updates of your application while it runs on the cluster and lets you debug your application directly on the cluster.

- **Tanzu Application Platform GUI Client**

  Tanzu Application Platform GUI Client is a package with RBAC resources required by Tanzu Developer Portal on clusters with Build, Run and Iterate profiles. It also contains Tanzu Mission Control specific resources. You cannot install this package on the same cluster as Tanzu Developer Portal.

  This package is only used while installing Tanzu Application Platform using Tanzu Mission Control.

- **Tekton Pipelines**

  Tekton is a powerful and flexible open-source framework for creating CI/CD systems, enabling developers to build, test, and deploy across cloud providers and on-premise systems.

Installation profiles in Tanzu Application Platform v1.9

You can deploy Tanzu Application Platform through predefined profiles, each containing various packages, or you can install the packages individually. The profiles allow Tanzu Application Platform to scale across an organization's multicluster, multi-cloud, or hybrid cloud infrastructure. These profiles are not meant to cover all use cases, but serve as a starting point to allow for further customization.

The following profiles are available in Tanzu Application Platform:

- **Full** (`full`): Contains nearly all Tanzu Application Platform packages. For the exceptions to the full profile, see the packages with a check mark in the **Not in a profile** column in the table later in this section.
- **Iterate** (`iterate`): Intended for iterative application development.
- **Build** (`build`): Intended for the transformation of source revisions to workload revisions. Specifically, hosting workloads and SupplyChains.
- **Run** (`run`): Intended for the transformation of workload revisions to running pods. Specifically, hosting deliveries and deliverables.
- **View** (`view`): Intended for instances of applications related to centralized developer experiences. Specifically, Tanzu Developer Portal and Metadata Store.

- **Authoring** (`authoring`): Includes everything in the **Iterate** profile and has extra packages for installing Tanzu Supply Chain (beta).

The following tables list the packages contained in each profile. Packages not included in any profile are available to install as individual packages only. See the component documentation for the package for installation instructions. For a diagram showing the packages contained in each profile, see Overview of multicluster Tanzu Application Platform.

Packages: A to C

Package Name	Full	Iterate	Build	Run	View	Authoring	Not in a profile
API Auto Registration	✓	✓		✓		✓	
API portal	✓				✓		
Application Accelerator	✓				✓		
Application Configuration Service							✓
Application Live View APIServer	✓	✓		✓		✓

Note

You can only install one supply chain at any given time. For information about switching supply chains, see Add testing and scanning to your application.

Language and framework support in Tanzu Application Platform

The following table shows the languages and frameworks supported by Tanzu Application Platform components.

Language or Framework	Tanzu Build Service	Runtime Conventions	Tanzu Developer Tooling	Application Live View	Extended Scanning Coverage using Buildpack SBOMs
Java	✓	✓	✓		✓
Spring Boot	✓	✓	✓	✓	✓
.NET Core	✓		✓	✓	✓
Steeltoe	✓		✓	✓	
NodeJS	✓				✓
Python	✓				✓
golang	✓				✓
PHP	✓				✓
Ruby	✓				✓

Tanzu Developer Tooling: refers to the developer conventions that enable debugging and Live Update function in the inner loop.

Extended Scanning Coverage: When building container images with the Tanzu Build Service, the Cloud Native Build Packs used in the build process for the specified languages produce a Software Bill of Materials (SBOM). Some scan engines support the enhanced ability to use this SBOM as a source for the scan. Out of the Box Supply Chain - Testing and Scanning leverages Anchore's Grype for the image scan, which suppports this capability. In addition, users have the ability to leverage Carbon Black Container image scans, which also supports this enhanced scan coverage.

Installing Tanzu Application Platform

For more information about installing Tanzu Application Platform, see Installing Tanzu Application Platform.

Install Tanzu Application Platform

You can install Tanzu Application Platform (commonly known as TAP) by using one of the following methods:

- Install Tanzu Application Platform online. For Tanzu Application Platform on a Kubernetes cluster with internet access.
- Install Tanzu Application Platform in an air-gapped environment. For Tanzu Application Platform on a Kubernetes cluster air-gapped from external traffic.
- Install Tanzu Application Platform with GitOps (beta). For Tanzu Application Platform on a Kubernetes cluster via a GitOps approach.
- Install Tanzu Application Platform in AWS. For installing Tanzu Application platform using AWS Cloud Services.
- Install Tanzu Application Platform in Azure. For installing Tanzu Application platform using Azure Cloud Services.
- Install Tanzu Application Platform on OpenShift. For Tanzu Application Platform on an OpenShift cluster with internet access.
- Install Tanzu Application Platform with Tanzu Mission Control. For installing Tanzu Application platform on a managed cluster using Tanzu Mission Control.

Install Tanzu Application Platform

You can install Tanzu Application Platform (commonly known as TAP) by using one of the following methods:

- Install Tanzu Application Platform online. For Tanzu Application Platform on a Kubernetes cluster with internet access.
- Install Tanzu Application Platform in an air-gapped environment. For Tanzu Application Platform on a Kubernetes cluster air-gapped from external traffic.
- Install Tanzu Application Platform with GitOps (beta). For Tanzu Application Platform on a Kubernetes cluster via a GitOps approach.
- Install Tanzu Application Platform in AWS. For installing Tanzu Application platform using AWS Cloud Services.
- Install Tanzu Application Platform in Azure. For installing Tanzu Application platform using Azure Cloud Services.
- Install Tanzu Application Platform on OpenShift. For Tanzu Application Platform on an OpenShift cluster with internet access.
- Install Tanzu Application Platform with Tanzu Mission Control. For installing Tanzu Application platform on a managed cluster using Tanzu Mission Control.

Prerequisites and planning for installing Tanzu Application Platform

The following are required to install Tanzu Application Platform (commonly known as TAP):

Installation planning

Before you begin a Tanzu Application Platform installation:

1. Review the Tanzu Application Platform planning and architecture documentation. For more information, see Planning and architecture reference.
2. (Optional) To gain an understanding of Tanzu Application Platform, experiment with a Tanzu Application Platform sandbox. For more information, see Access an experimental developer sandbox environment.

Installation prerequisites

Installation requires:

VMware Tanzu Network and container image registry requirements

- Access to VMware Tanzu Network:
  - A Tanzu Network account to download Tanzu Application Platform packages.
  - Network access to https://registry.tanzu.vmware.com.
- Cluster-specific registry:
  - A container image registry, such as Harbor or Docker Hub for application images, base images, and runtime dependencies. When available, VMware recommends using a paid registry account to avoid potential rate-limiting associated with some free registry offerings.
  - Recommended storage space for container image registry:
    - 1 GB of available storage if installing Tanzu Build Service with the `lite` set of dependencies.
    - 10 GB of available storage if installing Tanzu Build Service with the `full` set of dependencies, which are suitable for offline environments.

    Note

    For production environments, `full` dependencies are recommended to optimize security and performance. For more information about Tanzu Build Service dependencies, see About lite and full dependencies.
- Registry credentials with read and write access available to Tanzu Application Platform to store images.
- Network access to your chosen container image registry.

DNS Records

There are some optional but recommended DNS records you must allocate if you decide to use these particular components:

- Cloud Native Runtimes (Knative): Allocate a wildcard subdomain for your developer's applications. This is specified in the `shared.ingress_domain` key of the `tap-values.yaml` configuration file that you input with the installation. This wildcard must be pointed at the

external IP address of the `tanzu-system-ingress`'s `envoy` service. See Access with the shared Ingress method for more information about `tanzu-system-ingress`.

- Tanzu Developer Portal: If you decide to implement the shared ingress and include Tanzu Developer Portal, allocate a fully Qualified Domain Name (FQDN) that can be pointed at the `tanzu-system-ingress` service. The default host name consists of `tap-gui` and the `shared.ingress_domain` value. For example, `tap-gui.example.com`.
- Supply Chain Security Tools - Store: Similar to Tanzu Developer Portal, allocate a fully Qualified Domain Name (FQDN) that can be pointed at the `tanzu-system-ingress` service. The default host name consists of `metadata-store` and the `shared.ingress_domain` value. For example, `metadata-store.example.com`.
- Artifact Metadata Repository: Similar to the Supply Chain Security Tools (SCST) - Store, allocate a fully Qualified Domain Name (FQDN) that can be pointed at the `tanzu-system-ingress` service. The default host name consists of `amr-graphql` and the `shared.ingress_domain` value. For example, `amr-graphql.example.com`.
- Application Live View: If you select the `ingressEnabled` option, allocate a corresponding fully Qualified Domain Name (FQDN) that can be pointed at the `tanzu-system-ingress` service. The default host name consists of `appliveview` and the `shared.ingress_domain` value. For example, `appliveview.example.com`.

Supply Chain Security Tools - Store

Although Tanzu Application Platform includes a default database for Supply Chain Security Tools (SCST) - Store, VMware discourages using it for production deployments. The included database lacks capabilities typically offered by enterprise-grade databases, such as scaling, high availability, and automated backups. VMware recommends using an external database with production level capabilities. For more information about setting up the database for production, see Database configuration.

Tanzu Developer Portal

For Tanzu Developer Portal, you must have:

- Latest version of Chrome, Firefox, or Edge. Tanzu Developer Portal currently does not support Safari browser.
- Git repository for Tanzu Developer Portal's software catalogs, with a token allowing read access. For more information about how to use your Git repository, see Create an application accelerator. Supported Git infrastructure includes:
    - GitHub
    - GitLab
    - Azure DevOps
- Tanzu Developer Portal Blank Catalog from the Tanzu Application section of VMware Tanzu Network. The Blank Catalog serves as a foundation for your customization, allowing you to populate it with your own content. For more information about formatting your own catalog, see Catalog operations.
    - To install, navigate to Tanzu Network. Under the list of available files to download, there is a folder titled `tanzu-developer-portal-catalogs-latest`. Inside that folder is a compressed archive titled `Tanzu Developer Portal Blank Catalog`. You must extract that catalog to the preceding Git repository of choice. This serves as the configuration location for your organization's catalog inside Tanzu Developer Portal.
- The Tanzu Developer Portal catalog allows for two approaches to store catalog information:

    - The default option uses an in-memory database and is suitable for test and development scenarios. This reads the catalog data from Git URLs that you specify in the `tap-values.yaml` file. This data is temporary. Any operations that cause the `server` pod in the `tap-gui` namespace to be re-created also cause this data to be rebuilt from the Git location. This can cause issues when you manually register entities by using the UI, because they only exist in the database and are lost when that in-memory database gets rebuilt.
    - For production use cases, use a PostgreSQL database that exists outside the Tanzu Application Platform packaging. The PostgreSQL database stores all the catalog data persistently both from the Git locations and the UI manual entity registrations. For more information, see Configure the Tanzu Developer Portal database

Kubernetes cluster requirements

Installation requires Kubernetes cluster v1.26, v1.27, v1.28 or v1.29 on one of the following Kubernetes providers:

- Azure Kubernetes Service.
- Amazon Elastic Kubernetes Service.
    - containerd must be used as the Container Runtime Interface (CRI). Some versions of EKS default to Docker as the container runtime and must be changed to containerd.
    - EKS clusters on Kubernetes version 1.23 and above require the Amazon EBS CSI Driver due to CSIMigrationAWS is enabled by default in Kubernetes version 1.23 and above.
        - Users currently on EKS Kubernetes version 1.22 must install the Amazon EBS CSI Driver before upgrading to Kubernetes version 1.23 and above. See AWS documentation for more information.
    - AWS Fargate is not supported.
- Google Kubernetes Engine.
    - GKE Autopilot clusters do not have the required features enabled.
    - GKE clusters that are set up in zonal mode might detect Kubernetes API errors when the GKE control plane is resized after traffic increases. Users can mitigate this by creating a regional cluster with three control-plane nodes right from the start.
- Red Hat OpenShift Container Platform v4.13, v4.14 and v4.15.
    - vSphere
    - Baremetal
- Tanzu Kubernetes Grid (commonly called TKG) with Standalone Management Cluster. For more information, see the Tanzu Kubernetes Grid documentation.
- vSphere with Tanzu v8.0 Update 1c or later, v7.0 Update 3p or later.
- Tanzu Kubernetes Grid Integrated Edition with vSphere (commonly called TKGi) v1.17 and later.
    - For TKGi with NSX, the total number of Kubernetes object labels and other tags created by both TKGi and Tanzu Application Platform can exceed the number allowed by NSX. Create or update your network profile by setting the `cni_configurations` parameter `extensions.ncp.k8s.label_filtering_regex_list`. For more information, see the VMware Tanzu Kubernetes Grid Integrated Edition documentation.

For more information about the supported Kubernetes versions, see Kubernetes version support for Tanzu Application Platform.

Resource requirements

- To deploy Tanzu Application Platform packages full profile, your cluster must have at least:
  - 8 GB of RAM available per node to Tanzu Application Platform.
  - 16 vCPUs available across all nodes to Tanzu Application Platform.
  - 100 GB of disk space available per node.

  Important

  Tanzu Application Platform requires a minimum of 100 GB per node of ephemeral storage. If you do not allocate at least this amount of ephemeral storage for kubelet on all cluster nodes, you receive the error "minDiskPerNode: some cluster nodes don't meet minimum disk space requirement of '100Gi'." For more information about configuring the storage for a TKG cluster on Supervisor, see v1alpha3 Example: TKC with Default Storage and Node Volumes and v1beta1 Example: Custom Cluster Based on the Default ClusterClass.

- To deploy Tanzu Application Platform packages build, run and iterate (shared) profile, your cluster must have at least:
  - 8 GB of RAM available per node to Tanzu Application Platform.
  - 12 vCPUs available across all nodes to Tanzu Application Platform.
  - 100 GB of disk space available per node.
- To deploy Tanzu Application Platform packages view profile, your cluster must have at least:
  - 8 GB of RAM available per node to Tanzu Application Platform.
  - 8 vCPUs available across all nodes to Tanzu Application Platform.
  - 100 GB of disk space available per node.
- For the full profile or use of Security Chain Security Tools - Store, your cluster must have a configured default StorageClass.
- Pod security policies must be configured so that Tanzu Application Platform controller pods can run as root in the following optional configurations:
  - Tanzu Build Service, in which CustomStacks require root privileges. For more information, see Tanzu Build Service documentation.
  - Supply Chain, in which Kaniko usage requires root privileges to build containers.

  For more information about pod security policies, see Kubernetes documentation.

Tools and CLI requirements

Installation requires:

- The Kubernetes CLI (kubectl) v1.26, v1.27, v1.28 or v1.29 installed and authenticated with admin rights for your target cluster. See Install Tools in the Kubernetes documentation.

Next steps

- Accept Tanzu Application Platform EULAs and installing the Tanzu CLI

Prerequisites and planning for installing Tanzu Application Platform

The following are required to install Tanzu Application Platform (commonly known as TAP):

Installation planning

Before you begin a Tanzu Application Platform installation:

1. Review the Tanzu Application Platform planning and architecture documentation. For more information, see Planning and architecture reference.
2. (Optional) To gain an understanding of Tanzu Application Platform, experiment with a Tanzu Application Platform sandbox. For more information, see Access an experimental developer sandbox environment.

Installation prerequisites

Installation requires:

VMware Tanzu Network and container image registry requirements

- Access to VMware Tanzu Network:
  - A Tanzu Network account to download Tanzu Application Platform packages.
  - Network access to https://registry.tanzu.vmware.com.
- Cluster-specific registry:
  - A container image registry, such as Harbor or Docker Hub for application images, base images, and runtime dependencies. When available, VMware recommends using a paid registry account to avoid potential rate-limiting associated with some free registry offerings.
  - Recommended storage space for container image registry:
    - 1 GB of available storage if installing Tanzu Build Service with the `lite` set of dependencies.
    - 10 GB of available storage if installing Tanzu Build Service with the `full` set of dependencies, which are suitable for offline environments.

    Note

    For production environments, `full` dependencies are recommended to optimize security and performance. For more information about Tanzu Build Service dependencies, see About lite and full dependencies.
- Registry credentials with read and write access available to Tanzu Application Platform to store images.
- Network access to your chosen container image registry.

DNS Records

There are some optional but recommended DNS records you must allocate if you decide to use these particular components:

- Cloud Native Runtimes (Knative): Allocate a wildcard subdomain for your developer's applications. This is specified in the `shared.ingress_domain` key of the `tap-values.yaml` configuration file that you input with the installation. This wildcard must be pointed at the external IP address of the `tanzu-system-ingress`'s `envoy` service. See Access with the shared Ingress method for more information about `tanzu-system-ingress`.
- Tanzu Developer Portal: If you decide to implement the shared ingress and include Tanzu Developer Portal, allocate a fully Qualified Domain Name (FQDN) that can be pointed at the `tanzu-system-ingress` service. The default host name consists of `tap-gui` and the `shared.ingress_domain` value. For example, `tap-gui.example.com`.
- Supply Chain Security Tools - Store: Similar to Tanzu Developer Portal, allocate a fully Qualified Domain Name (FQDN) that can be pointed at the `tanzu-system-ingress` service. The default host name consists of `metadata-store` and the `shared.ingress_domain` value. For example, `metadata-store.example.com`.
- Artifact Metadata Repository: Similar to the Supply Chain Security Tools (SCST) - Store, allocate a fully Qualified Domain Name (FQDN) that can be pointed at the `tanzu-system-ingress` service. The default host name consists of `amr-graphql` and the `shared.ingress_domain` value. For example, `amr-graphql.example.com`.
- Application Live View: If you select the `ingressEnabled` option, allocate a corresponding fully Qualified Domain Name (FQDN) that can be pointed at the `tanzu-system-ingress` service. The default host name consists of `appliveview` and the `shared.ingress_domain` value. For example, `appliveview.example.com`.

Supply Chain Security Tools - Store

Although Tanzu Application Platform includes a default database for Supply Chain Security Tools (SCST) - Store, VMware discourages using it for production deployments. The included database lacks capabilities typically offered by enterprise-grade databases, such as scaling, high availability, and automated backups. VMware recommends using an external database with production level capabilities. For more information about setting up the database for production, see Database configuration.

Tanzu Developer Portal

For Tanzu Developer Portal, you must have:

- Latest version of Chrome, Firefox, or Edge. Tanzu Developer Portal currently does not support Safari browser.
- Git repository for Tanzu Developer Portal's software catalogs, with a token allowing read access. For more information about how to use your Git repository, see Create an application accelerator. Supported Git infrastructure includes:
  - GitHub
  - GitLab
  - Azure DevOps
- Tanzu Developer Portal Blank Catalog from the Tanzu Application section of VMware Tanzu Network. The Blank Catalog serves as a foundation for your customization, allowing you to populate it with your own content. For more information about formatting your own catalog, see Catalog operations.

    - To install, navigate to Tanzu Network. Under the list of available files to download, there is a folder titled `tanzu-developer-portal-catalogs-latest`. Inside that folder is a compressed archive titled `Tanzu Developer Portal Blank Catalog`. You must extract that catalog to the preceding Git repository of choice. This serves as the configuration location for your organization's catalog inside Tanzu Developer Portal.
- The Tanzu Developer Portal catalog allows for two approaches to store catalog information:
    - The default option uses an in-memory database and is suitable for test and development scenarios. This reads the catalog data from Git URLs that you specify in the `tap-values.yaml` file. This data is temporary. Any operations that cause the `server` pod in the `tap-gui` namespace to be re-created also cause this data to be rebuilt from the Git location. This can cause issues when you manually register entities by using the UI, because they only exist in the database and are lost when that in-memory database gets rebuilt.
    - For production use cases, use a PostgreSQL database that exists outside the Tanzu Application Platform packaging. The PostgreSQL database stores all the catalog data persistently both from the Git locations and the UI manual entity registrations. For more information, see Configure the Tanzu Developer Portal database

Kubernetes cluster requirements

Installation requires Kubernetes cluster v1.26, v1.27, v1.28 or v1.29 on one of the following Kubernetes providers:

- Azure Kubernetes Service.
- Amazon Elastic Kubernetes Service.
    - containerd must be used as the Container Runtime Interface (CRI). Some versions of EKS default to Docker as the container runtime and must be changed to containerd.
    - EKS clusters on Kubernetes version 1.23 and above require the Amazon EBS CSI Driver due to CSIMigrationAWS is enabled by default in Kubernetes version 1.23 and above.
        - Users currently on EKS Kubernetes version 1.22 must install the Amazon EBS CSI Driver before upgrading to Kubernetes version 1.23 and above. See AWS documentation for more information.
    - AWS Fargate is not supported.
- Google Kubernetes Engine.
    - GKE Autopilot clusters do not have the required features enabled.
    - GKE clusters that are set up in zonal mode might detect Kubernetes API errors when the GKE control plane is resized after traffic increases. Users can mitigate this by creating a regional cluster with three control-plane nodes right from the start.
- Red Hat OpenShift Container Platform v4.13, v4.14 and v4.15.
    - vSphere
    - Baremetal
- Tanzu Kubernetes Grid (commonly called TKG) with Standalone Management Cluster. For more information, see the Tanzu Kubernetes Grid documentation.
- vSphere with Tanzu v8.0 Update 1c or later, v7.0 Update 3p or later.
- Tanzu Kubernetes Grid Integrated Edition with vSphere (commonly called TKGi) v1.17 and later.

    - For TKGi with NSX, the total number of Kubernetes object labels and other tags created by both TKGi and Tanzu Application Platform can exceed the number allowed by NSX. Create or update your network profile by setting the `cni_configurations` parameter `extensions.ncp.k8s.label_filtering_regex_list`. For more information, see the VMware Tanzu Kubernetes Grid Integrated Edition documentation.

For more information about the supported Kubernetes versions, see Kubernetes version support for Tanzu Application Platform.

Resource requirements

- To deploy Tanzu Application Platform packages full profile, your cluster must have at least:
    - 8 GB of RAM available per node to Tanzu Application Platform.
    - 16 vCPUs available across all nodes to Tanzu Application Platform.
    - 100 GB of disk space available per node.

    Important

    Tanzu Application Platform requires a minimum of 100 GB per node of ephemeral storage. If you do not allocate at least this amount of ephemeral storage for kubelet on all cluster nodes, you receive the error "minDiskPerNode: some cluster nodes don't meet minimum disk space requirement of '100Gi'." For more information about configuring the storage for a TKG cluster on Supervisor, see v1alpha3 Example: TKC with Default Storage and Node Volumes and v1beta1 Example: Custom Cluster Based on the Default ClusterClass.

- To deploy Tanzu Application Platform packages build, run and iterate (shared) profile, your cluster must have at least:
    - 8 GB of RAM available per node to Tanzu Application Platform.
    - 12 vCPUs available across all nodes to Tanzu Application Platform.
    - 100 GB of disk space available per node.
- To deploy Tanzu Application Platform packages view profile, your cluster must have at least:
    - 8 GB of RAM available per node to Tanzu Application Platform.
    - 8 vCPUs available across all nodes to Tanzu Application Platform.
    - 100 GB of disk space available per node.
- For the full profile or use of Security Chain Security Tools - Store, your cluster must have a configured default StorageClass.
- Pod security policies must be configured so that Tanzu Application Platform controller pods can run as root in the following optional configurations:
    - Tanzu Build Service, in which CustomStacks require root privileges. For more information, see Tanzu Build Service documentation.
    - Supply Chain, in which Kaniko usage requires root privileges to build containers.

    For more information about pod security policies, see Kubernetes documentation.

Tools and CLI requirements

Installation requires:

- The Kubernetes CLI (kubectl) v1.26, v1.27, v1.28 or v1.29 installed and authenticated with admin rights for your target cluster. See Install Tools in the Kubernetes documentation.

Next steps

- Accept Tanzu Application Platform EULAs and installing the Tanzu CLI

Kubernetes version support for Tanzu Application Platform

The following is a matrix table providing details of the compatible Kubernetes cluster versions for Tanzu Application Platform v1.9.

Kubernetes Cluster	Support Information
Kubernetes	v1.26, v1.27, v1.28, v1.29
VMware Tanzu Kubernetes Grid	v2.5.0, v2.4.0
VMware Tanzu Kubernetes Grid Integrated Edition with vSphere	v1.17 or later
vSphere with Tanzu	v8.0 Update 1c or later, v7.0 Update 3p or later
OpenShift	v4.13, v4.14, v4.15
Azure Kubernetes Service	Supported
Elastic Kubernetes Service	Supported
Google Kubernetes Engine	Supported

Open source component versions

This topic contains the open source component versions for Tanzu Application Platform v1.9 (commonly known as TAP).

OSS Release Name	Release Version
Backstage	1.22.0
Cartographer Convention	0.8.0
cert injection webhook	0.6.0
cert-manager	1.13.3
contour	1.28.0
crossplane	1.15.0-up.1
External Secrets Operator	0.9.4
Flux CD Source Controller	1.1.2
Grype Vulnerability Scanner (Scan v1)	0.54.0
IntelliJ	Build 222 or later
Kafka by Bitnami (unmanaged)	22.0.0
Knative Serving	1.13.1
kpack	0.13.2
MongoDB by Bitnami (unmanaged)	13.13.1

OSS Release Name	Release Version
MySQL by Bitnami (unmanaged)	9.5.0
Paketo Syft Buildpack	1.10.1
Postgres by Bitnami (unmanaged)	12.2.0
RabbitMQ by Bitnami (unmanaged)	11.10.0
Redis by Bitnami (unmanaged)	17.8.0
Service Bindings	0.8.0
Sigstore Policy Controller	0.8.2
Source Controller	0.9.0
Tekton Pipelines	0.50.3
Tilt	0.30.12 or later
Trivy Vulnerability Scanner (Scan v2)	0.48.3
Visual Studio Code	1.64.0 or later

Install Tanzu CLI

This topic tells you how to accept the EULAs, and install the Tanzu CLI and plug-ins on Tanzu Application Platform (commonly known as TAP).

Accept the End User License Agreements

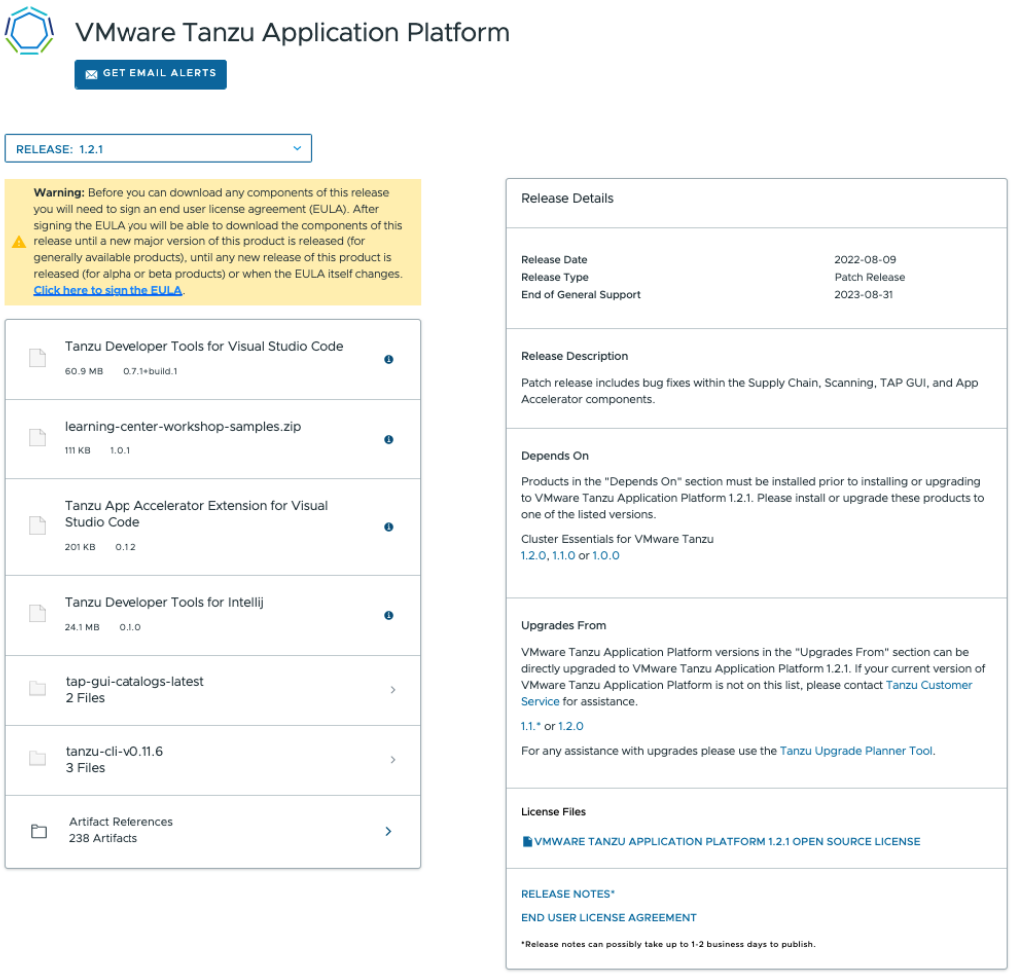
Before downloading and installing Tanzu Application Platform packages, you must accept the End User License Agreements (EULAs) as follows:

1. Sign in to VMware Tanzu Network.
2. Accept or confirm that you have accepted the EULAs for each of the following:
    - Tanzu Application Platform
    - Cluster Essentials for VMware Tanzu

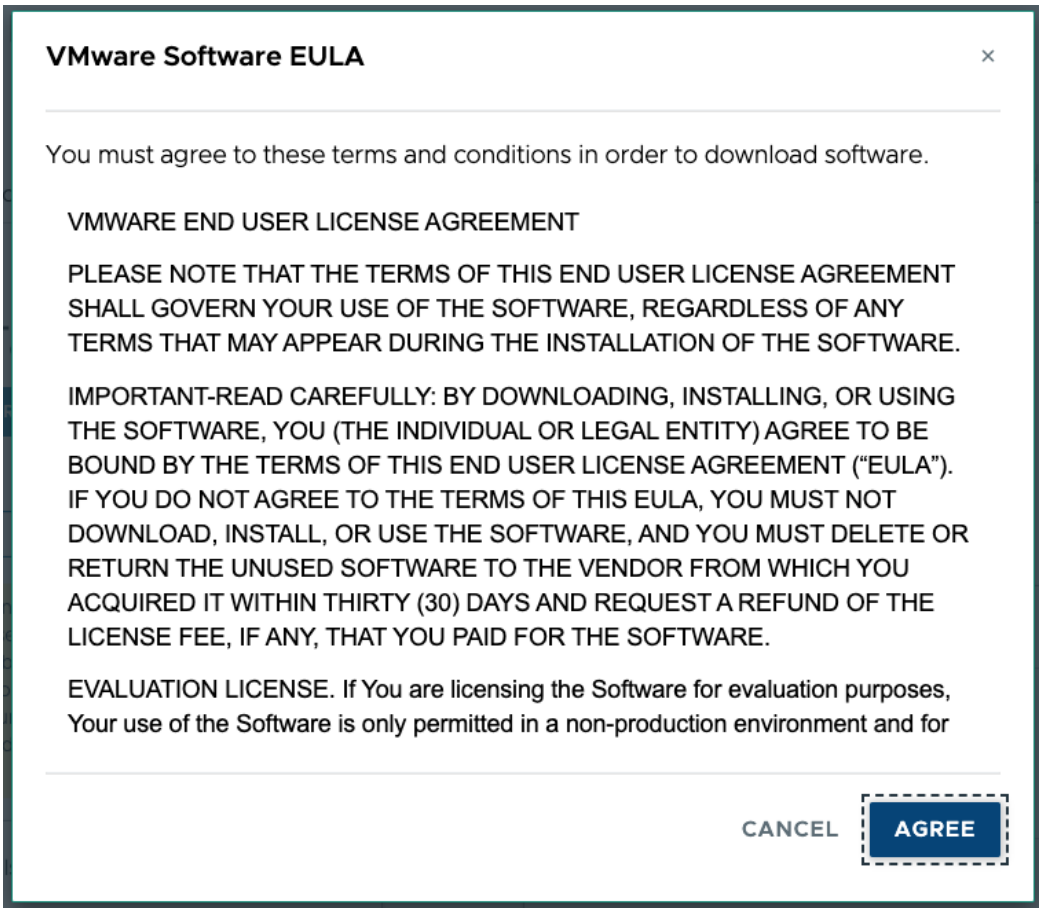
Example of accepting the Tanzu Application Platform EULA

To accept the Tanzu Application Platform EULA:

1. Go to Tanzu Application Platform.
2. Select the ***Click here to sign the EULA*** link in the yellow warning box under the release drop-down menu. If the yellow warning box is not visible, the EULA has already been accepted.



3. Select ***Agree*** in the bottom-right of the dialog box as seen in the following screenshot.



Set the Kubernetes cluster context

For information about the supported Kubernetes cluster providers and versions, see Kubernetes cluster requirements.

To set the Kubernetes cluster context:

1. List the existing contexts by running:

   ```
   kubectl config get-contexts
   ```

   For example:

   ```
   $ kubectl config get-contexts
   CURRENT   NAME                                CLUSTER           AUTHINFO
   NAMESPACE
           aks-repo-trial                      aks-repo-trial    clusterUser_aks-r
   g-01_aks-repo-trial
   *       aks-tap-cluster                     aks-tap-cluster   clusterUser_aks-r
   g-01_aks-tap-cluster
   ```

2. If you are managing multiple cluster contexts, set the context to the cluster that you want to use for the Tanzu Application Platform packages installation by running:

   ```
   kubectl config use-context CONTEXT
   ```

   Where `CONTEXT` is the cluster that you want to use. For example, `aks-tap-cluster`.

   For example:

```
$ kubectl config use-context aks-tap-cluster
Switched to context "aks-tap-cluster".
```

Install or update the Tanzu CLI and plug-ins

The Tanzu CLI and plug-ins enable you to install and use the Tanzu Application Platform functions and features.

Install the Tanzu CLI

The Tanzu CLI core 1.3 distributed with Tanzu Application Platform is forward and backward compatible with all supported Tanzu Application Platform versions. Run a single command to install the plug-in group version that matches the Tanzu Application Platform version on any target environment. For more information, see Install Plugins.

Use a package manager to install Tanzu CLI on Windows, Mac, or Linux OS. Alternatively, download and install manually from Tanzu Network, VMware Customer Connect, or GitHub.

Basic installation instructions are provided below. For more information including how to install the Tanzu CLI and CLI plug-ins in Internet-restricted environments, see the VMware Tanzu CLI documentation.

Note

To retain an existing installation of the Tanzu CLI, move the CLI binary from `/usr/local/bin/tanzu` or `C:\Program Files\tanzu` on Windows to a different location before following the steps below.

Install using a package manager

To install the Tanzu CLI using a package manager:

1. Follow the instructions for your package manager below. This installs the latest version of the CLI available in the package registry.
    - **Homebrew (MacOS):**

      ```
      brew update
      brew install vmware-tanzu/tanzu/tanzu-cli
      ```

    - **Chocolatey (Windows):**

      ```
      choco install tanzu-cli
      ```

      The `tanzu-cli` package is part of the main Chocolatey Community Repository. When a new `tanzu-cli` version is released, it might not be available immediately. If the above command fails, run:

      ```
      choco install tanzu-cli --version TANZU-CLI-VERSION
      ```

      Where `TANZU-CLI-VERSION` is the Tanzu CLI version you want to install.

      For example:

      ```
      choco install tanzu-cli --version 1.3.0
      ```

    - **APT (Debian or Ubuntu):**

```
sudo mkdir -p /etc/apt/keyrings/
sudo apt-get update
sudo apt-get install -y ca-certificates curl gpg
curl -fsSL https://packages.vmware.com/tools/keys/VMWARE-PACKAGING-GPG
-RSA-KEY.pub | sudo gpg --dearmor -o /etc/apt/keyrings/tanzu-archive-k
eyring.gpg
echo "deb [arch=amd64 signed-by=/etc/apt/keyrings/tanzu-archive-keyrin
g.gpg] https://storage.googleapis.com/tanzu-cli-os-packages/apt tanzu-
cli-jessie main" | sudo tee /etc/apt/sources.list.d/tanzu.list
sudo apt-get update
sudo apt-get install -y tanzu-cli
```

- **YUM or DNF (RHEL):**

```
cat << EOF | sudo tee /etc/yum.repos.d/tanzu-cli.repo
[tanzu-cli]
name=Tanzu CLI
baseurl=https://storage.googleapis.com/tanzu-cli-os-packages/rpm/tanzu
-cli
enabled=1
gpgcheck=1
repo_gpgcheck=1
gpgkey=https://packages.vmware.com/tools/keys/VMWARE-PACKAGING-GPG-RSA
-KEY.pub
EOF

sudo yum install -y tanzu-cli # If you are using DNF, run sudo dnf ins
tall -y tanzu-cli.
```

2. Check that the correct version of the CLI is properly installed.

```
tanzu version
version: v1.3.0
...
```

Install from a binary release

Complete the following steps:

1. Download the Tanzu CLI binary from one of the following locations:
   - **VMware Tanzu Network**
     1. Go to VMware Tanzu Network.
     2. Choose the 1.9.1 release from the Release dropdown menu.
     3. Click the tanzu-core-cli-binaries item from the result set.
     4. Download the Tanzu CLI binary for your operating system.
   - **VMware Customer Connect**
     1. Go to VMware Customer Connect.
     2. Download the Tanzu CLI binary for your operating system.
   - **GitHub**
     1. Go to Tanzu CLI release v1.3.0 on GitHub.
     2. Download the Tanzu CLI binary for your operating system, for example, `tanzu-cli-windows-amd64.tar.gz`.
2. Use an extraction tool to unpack the binary file:
   - **macOS:**

```
tar -xvf tanzu-cli-darwin-amd64.tar.gz
```

- **Linux:**

  ```
  tar -xvf tanzu-cli-linux-amd64.tar.gz
  ```

- **Windows:**

  Use the Windows extractor tool to unzip `tanzu-cli-windows-amd64.zip`.

3. Make the CLI available to the system:
   - cd to the directory containing the extracted CLI binary
   - **macOS:**

     Install the binary to `/usr/local/bin`:

     ```
     install tanzu-cli-darwin_amd64 /usr/local/bin/tanzu
     ```

   - **Linux:**

     Install the binary to `/usr/local/bin`:

     ```
     sudo install tanzu-cli-linux_amd64 /usr/local/bin/tanzu
     ```

   - **Windows:**

     1. Create a new `Program Files\tanzu` folder.
     2. Copy the `tanzu-cli-windows_amd64.exe` file into the new `Program Files\tanzu` folder.
     3. Rename `tanzu-cli-windows_amd64.exe` to `tanzu.exe`.
     4. Right-click the `tanzu` folder, select **Properties** > **Security**, and make sure that your user account has the **Full Control** permission.
     5. Use Windows Search to search for `env`.
     6. Select **Edit the system environment variables** and click the **Environment Variables** button.
     7. Select the `Path` row under **System variables**, and click **Edit**.
     8. Click **New** to add a new row and enter the path to the Tanzu CLI. The path value must not include the `.exe` extension. For example, `C:\Program Files\tanzu`.

4. Check that the correct version of the CLI is properly installed:

   ```
   tanzu version
   version: v1.3.0
   ...
   ```

Install Tanzu CLI plug-ins

There is a group of Tanzu CLI plug-ins which extend the Tanzu CLI Core with Tanzu Application Platform specific feature functionality. The plug-ins can be installed as a group with a single command. Versioned releases of the Tanzu Application Platform specific plug-in group align to each supported Tanzu Application Platform version. This makes it easy to switch between different versions of Tanzu Application Platforms environments.

Use the following commands to search for, install, and verify Tanzu CLI plug-in groups.

List the versions of each plug-in group available across Tanzu

```
tanzu plugin group search --show-details
```

List the versions of the Tanzu Application Platform specific plug-in group

```
tanzu plugin group search --name vmware-tap/default --show-details
```

Install the version of the Tanzu Application Platform plug-in group matching your target environment

```
tanzu plugin install --group vmware-tap/default:v1.9
```

Verify the plug-in group list against the plug-ins that were installed

```
tanzu plugin group get vmware-tap/default:v1.9
```

```
tanzu plugin list
```

For air-gapped installation, see the Installing the Tanzu CLI in Internet-Restricted Environments section of the Tanzu CLI documentation.

Next steps

For online installation:

- Deploy Cluster Essentials*
- Install Tanzu Application Platform package and profiles

For air-gapped installation:

- Deploy Cluster Essentials*
- Install Tanzu Application Platform in your air-gapped environment

For installation on AWS Cloud:

- Create AWS Resources for Tanzu Application Platform
- Deploy Cluster Essentials*
- Install Tanzu Application Platform package and profiles on AWS

For installation on Azure Cloud:

- Create Azure Resources for Tanzu Application Platform
- Deploy Cluster Essentials*
- Install Tanzu Application Platform package and profiles on Azure

For installation on OpenShift clusters:

- Deploy Cluster Essentials*
- Install the Tanzu Application Platform package and profiles

For GitOps (beta) installation:

- Deploy Cluster Essentials*
- Install Tanzu Application Platform through GitOps with External Secrets Operator (ESO)

- Install Tanzu Application Platform through Gitops with Secrets OPerationS (SOPS)

* *When you use a VMware Tanzu Kubernetes Grid cluster, you do not need to install Cluster Essentials because the contents of Cluster Essentials are already installed on your cluster.*

Install Tanzu Application Platform (online)

To install Tanzu Application Platform (commonly known as TAP) on your Kubernetes clusters with internet access:

Step	Task	Link
1.	Review the prerequisites to ensure you have met all requirements before installing.	Prerequisites
2.	Accept Tanzu Application Platform EULAs and install the Tanzu CLI.	Accept Tanzu Application Platform EULAs and installing the Tanzu CLI
3.	Install Cluster Essentials for Tanzu*.	Deploy Cluster Essentials
4.	Add the Tanzu Application Platform package repository, prepare your Tanzu Application Platform profile, and install the profile to the cluster.	Install the Tanzu Application Platform package and profiles
5.	(Optional) Install any additional packages that were not in the profile.	Install individual packages
6.	Set up developer namespaces to use your installed packages.	Set up developer namespaces to use your installed packages
7.	Install developer tools into your integrated development environment (IDE).	Install Tanzu Developer Tools for your VS Code

* *When you use a VMware Tanzu Kubernetes Grid cluster, there is no need to install Cluster Essentials because the contents of Cluster Essentials are already installed on your cluster.*

After installing Tanzu Application Platform on to your Kubernetes clusters, proceed with Get started with Tanzu Application Platform.

Install Tanzu Application Platform (online)

To install Tanzu Application Platform (commonly known as TAP) on your Kubernetes clusters with internet access:

Step	Task	Link
1.	Review the prerequisites to ensure you have met all requirements before installing.	Prerequisites
2.	Accept Tanzu Application Platform EULAs and install the Tanzu CLI.	Accept Tanzu Application Platform EULAs and installing the Tanzu CLI
3.	Install Cluster Essentials for Tanzu*.	Deploy Cluster Essentials
4.	Add the Tanzu Application Platform package repository, prepare your Tanzu Application Platform profile, and install the profile to the cluster.	Install the Tanzu Application Platform package and profiles
5.	(Optional) Install any additional packages that were not in the profile.	Install individual packages
6.	Set up developer namespaces to use your installed packages.	Set up developer namespaces to use your installed packages
7.	Install developer tools into your integrated development environment (IDE).	Install Tanzu Developer Tools for your VS Code

* *When you use a VMware Tanzu Kubernetes Grid cluster, there is no need to install Cluster Essentials because the contents of Cluster Essentials are already installed on your cluster.*

After installing Tanzu Application Platform on to your Kubernetes clusters, proceed with Get started with Tanzu Application Platform.

Install Tanzu Application Platform package and profiles

This topic tells you how to install Tanzu Application Platform (commonly known as TAP) packages from your Tanzu Application Platform package repository.

Before installing the packages, ensure you have:

- Completed the Prerequisites.
- Configured and verified the cluster.
- Accepted Tanzu Application Platform EULA and installed Tanzu CLI with any required plug-ins.

Relocate images to a registry

VMware recommends relocating the images from VMware Tanzu Network registry to your own container image registry before attempting installation. If you don't relocate the images, Tanzu Application Platform depends on VMware Tanzu Network for continued operation, and VMware Tanzu Network offers no uptime guarantees. The option to skip relocation is documented for evaluation and proof-of-concept only.

The supported registries are Harbor, Azure Container Registry, Google Container Registry, and Quay.io. See the following documentation for a registry to learn how to set it up:

- Harbor documentation
- Google Container Registry documentation
- Quay.io documentation

To relocate images from the VMware Tanzu Network registry to your registry:

1. Set up environment variables for installation use by running:

```
# Set tanzunet as the source registry to copy the Tanzu Application Platform pa
ckages from.
export IMGPKG_REGISTRY_HOSTNAME_0=registry.tanzu.vmware.com
export IMGPKG_REGISTRY_USERNAME_0=MY-TANZUNET-USERNAME
export IMGPKG_REGISTRY_PASSWORD_0=MY-TANZUNET-PASSWORD

# The user's registry for copying the Tanzu Application Platform package to.
export IMGPKG_REGISTRY_HOSTNAME_1=MY-REGISTRY
export IMGPKG_REGISTRY_USERNAME_1=MY-REGISTRY-USER
export IMGPKG_REGISTRY_PASSWORD_1=MY-REGISTRY-PASSWORD
# These environment variables starting with IMGPKG_* are used by the imgpkg com
mand only.

# The registry from which the Tanzu Application Platform package is retrieved.
export INSTALL_REGISTRY_USERNAME="${IMGPKG_REGISTRY_USERNAME_1}"
export INSTALL_REGISTRY_PASSWORD="${IMGPKG_REGISTRY_PASSWORD_1}"
export INSTALL_REGISTRY_HOSTNAME="${IMGPKG_REGISTRY_HOSTNAME_1}"
export TAP_VERSION=VERSION-NUMBER
export INSTALL_REPO=TARGET-REPOSITORY

# The user's registry used by Tanzu Application Platform to store built images
and the Tanzu Build Service dependencies. These credentials must have write per
mission.
export MY_REGISTRY_USERNAME="${IMGPKG_REGISTRY_USERNAME_1}"
export MY_REGISTRY_PASSWORD="${IMGPKG_REGISTRY_PASSWORD_1}"
export MY_REGISTRY_HOSTNAME="${IMGPKG_REGISTRY_HOSTNAME_1}"
```

Where:

- `MY-REGISTRY-USER` is the user with write access to `MY-REGISTRY`.
- `MY-REGISTRY-PASSWORD` is the password for `MY-REGISTRY-USER`.
- `MY-REGISTRY` is your own container registry.
- `MY-TANZUNET-USERNAME` is the user with access to the images in the VMware Tanzu Network registry `registry.tanzu.vmware.com`.
- `MY-TANZUNET-PASSWORD` is the password for `MY-TANZUNET-USERNAME`.
- `VERSION-NUMBER` is your Tanzu Application Platform version. For example, `1.9.1`.
- `TARGET-REPOSITORY` is your target repository, a folder/repository on `MY-REGISTRY` that serves as the location for the installation files for Tanzu Application Platform.

VMware recommends using a JSON key file to authenticate with Google Container Registry. In this case, the value of `INSTALL_REGISTRY_USERNAME` is `_json_key` and the value of `INSTALL_REGISTRY_PASSWORD` is the content of the JSON key file. For more information about how to generate the JSON key file, see Google Container Registry documentation.

2. Install the Carvel tool imgpkg CLI.

   To query for the available versions of Tanzu Application Platform on VMWare Tanzu Network Registry, run:

   ```
   imgpkg tag list -i registry.tanzu.vmware.com/tanzu-application-platform/tap-pac
   kages | sort -V
   ```

3. Relocate the images with the `imgpkg` CLI by running:

   ```
   imgpkg copy -b registry.tanzu.vmware.com/tanzu-application-platform/tap-package
   s:${TAP_VERSION} --to-repo ${INSTALL_REGISTRY_HOSTNAME}/${INSTALL_REPO}/tap-pac
   kages
   ```

Add the Tanzu Application Platform package repository

Tanzu CLI packages are accessible through repositories. By adding the Tanzu Application Platform package repository, Tanzu Application Platform and its packages become available for installation.

Relocate images to a registry is recommended but not required for installation. If you skip that step, you can run the following commands to set Tanzu Network as the source of the OCI images:

```
# The registry from which the Tanzu Application Platform package is retrieved.
export INSTALL_REGISTRY_USERNAME=TANZUNET_REGISTRY_USERNAME
export INSTALL_REGISTRY_PASSWORD=TANZUNET_REGISTRY_PASSWORD
export INSTALL_REGISTRY_HOSTNAME="registry.tanzu.vmware.com"
export TAP_VERSION=VERSION-NUMBER
export INSTALL_REPO="tanzu-application-platform"

# The user's registry used by Tanzu Application Platform to store built images and the
Tanzu Build Service dependencies. These credentials must have write permission.
export MY_REGISTRY_USERNAME=MY-REGISTRY-USER
export MY_REGISTRY_PASSWORD=MY-REGISTRY-PASSWORD
export MY_REGISTRY_HOSTNAME=MY-REGISTRY
```

Where:

- `TANZUNET_REGISTRY_USERNAME` and `TANZUNET_REGISTRY_PASSWORD` are the credentials to the VMware Tanzu Network registry `registry.tanzu.vmware.com`
- `VERSION-NUMBER` is your Tanzu Application Platform version. For example, `1.9.1`

- `MY_REGISTRY_HOSTNAME` is your own container registry.
- `MY_REGISTRY_USERNAME` is the user with write access to `MY_REGISTRY_HOSTNAME`.
- `MY_REGISTRY_PASSWORD` is the password for `MY_REGISTRY_USERNAME`.

To add the Tanzu Application Platform package repository to your cluster:

1. Create a namespace called `tap-install` for deploying any component packages by running:

   ```
   kubectl create ns tap-install
   ```

   This namespace keeps the objects grouped together logically.

2. Create a registry secret by running:

   ```
   tanzu secret registry add tap-registry \
     --username ${INSTALL_REGISTRY_USERNAME} --password ${INSTALL_REGISTRY_PASSWOR
   D} \
     --server ${INSTALL_REGISTRY_HOSTNAME} \
     --export-to-all-namespaces --yes --namespace tap-install
   ```

3. Create a secret for accessing the user's registry by running:

   ```
   tanzu secret registry add registry-credentials \
       --server   ${MY_REGISTRY_HOSTNAME} \
       --username ${MY_REGISTRY_USERNAME} \
       --password ${MY_REGISTRY_PASSWORD} \
       --namespace tap-install \
       --export-to-all-namespaces \
       --yes
   ```

4. Add the Tanzu Application Platform package repository to the cluster by running:

   ```
   tanzu package repository add tanzu-tap-repository \
     --url ${INSTALL_REGISTRY_HOSTNAME}/${INSTALL_REPO}/tap-packages:$TAP_VERSION
   \
     --namespace tap-install
   ```

5. Get the status of the Tanzu Application Platform package repository, and ensure the status updates to `Reconcile succeeded` by running:

   ```
   tanzu package repository get tanzu-tap-repository --namespace tap-install
   ```

   For example:

   ```
   $ tanzu package repository get tanzu-tap-repository --namespace tap-install
   - Retrieving repository tap...
   NAME:          tanzu-tap-repository
   VERSION:       16253001
   REPOSITORY:    tapmdc.azurecr.io/mdc/1.4.0/tap-packages
   TAG:           1.9.1
   STATUS:        Reconcile succeeded
   REASON:
   ```

   Note

   The `VERSION` and `TAG` numbers differ from the earlier example if you are on Tanzu Application Platform v1.0.2 or earlier.

6. List the available packages by running:

```
tanzu package available list --namespace tap-install
```

For example:

```
$ tanzu package available list --namespace tap-install
/ Retrieving available packages...
  NAME                                                DISPLAY-NAME
SHORT-DESCRIPTION

```

Install your Tanzu Application Platform profile

The `tap.tanzu.vmware.com` package installs predefined sets of packages based on your profile settings. This is done by using the package manager installed by Tanzu Cluster Essentials.

For more information about profiles, see Components and installation profiles.

To prepare to install a profile:

1. List version information for the package by running:

   ```
   tanzu package available list tap.tanzu.vmware.com --namespace tap-install
   ```

2. Create a `tap-values.yaml` file by using the Full Profile sample in the following section as a guide. These samples have the minimum configuration required to deploy Tanzu Application Platform. The sample values file contains the necessary defaults for:

   - The meta-package, or parent Tanzu Application Platform package.
   - Subordinate packages, or individual child packages.

   Keep the values file for future configuration use.

   > **Note**
   >
   > `tap-values.yaml` is set as a Kubernetes secret, which provides secure means to read credentials for Tanzu Application Platform components.

3. View possible configuration settings for your package

Full profile

The following is the YAML file sample for the full-profile. The `profile:` field takes `full` as the default value, but you can also set it to `iterate`, `build`, `run` or `view`. Refer to Install multicluster Tanzu Application Platform profiles for more information.

```
shared:
  ingress_domain: "INGRESS-DOMAIN"
  ingress_issuer: # Optional, can denote a cert-manager.io/v1/ClusterIssuer of your ch
oice. Defaults to "tap-ingress-selfsigned".

  image_registry:
    project_path: "SERVER-NAME/REPO-NAME"
    secret:

  # Takes the value from the shared section by default, but can be overridden by setti
ng a different value.
  kp_default_repository: "KP-DEFAULT-REPO"
  kp_default_repository_secret: # Takes the value from the shared section above by def
ault, but can be overridden by setting a different value.
    name: "KP-DEFAULT-REPO-SECRET"
    namespace: "KP-DEFAULT-REPO-SECRET-NAMESPACE"

local_source_proxy:
  # Takes the value from the project_path under the image_registry section of shared b
y default, but can be overridden by setting a different value.
  repository: "EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE"
  push_secret:
    # When set to true, the secret mentioned in this section is automatically exported
to Local Source Proxy's namespace.
    name: "EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE-SECRET"
    namespace: "EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE-SECRET-NAMESPACE"
    # When set to true, the secret mentioned in this section is automatically exported
to Local Source Proxy's namespace.
    create_export: true

tap_gui:
  metadataStoreAutoconfiguration: true # Creates a service account, the Kubernetes con
trol plane token and the requisite app_config block to enable communications between T
anzu Developer Portal and SCST - Store.
  app_config:
    auth:
      allowGuestAccess: true  # This allows unauthenticated users to log in to your po
rtal. If you want to deactivate it, make sure you configure an alternative auth provid
er.
    catalog:
      locations:
        - type: url
          target: https://GIT-CATALOG-URL/catalog-info.yaml

metadata_store:
  ns_for_export_app_cert: "MY-DEV-NAMESPACE" # Verify this namespace is available with
in your cluster before initiating the Tanzu Application Platform installation.
  app_service_type: ClusterIP # Defaults to LoadBalancer. If shared.ingress_domain is
set earlier, this must be set to ClusterIP.

policy:
  tuf_enabled: false # By default, TUF initialization and keyless verification are dea
ctivated.
tap_telemetry:
  customer_entitlement_account_number: "CUSTOMER-ENTITLEMENT-ACCOUNT-NUMBER" # (Option
al) Identify data for creating the Tanzu Application Platform usage reports.
```

Important

The profile installation no longer includes Grype out of the box. Instead, you can use Namespace Provisioner to install Grype. Namespace Provisioner still uses Grype values to configure the scanner:

```
grype:
  targetImagePullSecret: "TARGET-REGISTRY-CREDENTIALS-SECRET"
```

Where:

- `INGRESS-DOMAIN` is the subdomain for the host name that you point at the `tanzu-shared-ingress` service's External IP address. It is not required to know the External IP address or set up the DNS record while installing. Installing the Tanzu Application Platform package creates the `tanzu-shared-ingress` and its External IP address. You can create the DNS record after completing the installation.
- `KP-DEFAULT-REPO` is a writable repository in your registry. Tanzu Build Service dependencies are written to this location. Examples:
    - Harbor has the form `kp_default_repository: "my-harbor.io/my-project/build-service"`.
    - Docker Hub has the form `kp_default_repository: "my-dockerhub-user/build-service"` or `kp_default_repository: "index.docker.io/my-user/build-service"`.
    - Google Cloud Registry has the form `kp_default_repository: "gcr.io/my-project/build-service"`.
- `KP-DEFAULT-REPO-SECRET` is the secret with user credentials that can write to `KP-DEFAULT-REPO`. You can `docker push` to this location with this credential.
    - You can create a secret configured with a valid registry credential with a name and namespace of your choice. For Google Cloud Registry, use `kp_default_repository_username: _json_key`.
    - You must create the secret before the installation. For example, you can use the `registry-credentials` secret created earlier.
- `KP-DEFAULT-REPO-SECRET-NAMESPACE` is the namespace where `KP-DEFAULT-REPO-SECRET` is created.
    - You must create the namespace before the installation. For example, you can use the `tap-install` namespace created earlier.
- `K8S-DISTRO` (optional) is the type of Kubernetes infrastructure in use. It is only required if the distribution is OpenShift and must be used in coordination with `kubernetes_version`. Supported value: `openshift`.
- `K8S-VERSION` (optional) is the Kubernetes version in use. You can use it independently or in coordination with `kubernetes_distribution`. For example, `1.24.x`, where `x` is the Kubernetes patch version.
- `SERVER-NAME` is the host name of the registry server. Examples:
    - Harbor has the form `server: "my-harbor.io"`.
    - Docker Hub has the form `server: "index.docker.io"`.
    - Google Cloud Registry has the form `server: "gcr.io"`.

- `REPO-NAME` is where workload images are stored in the registry. If this key is passed through the shared section earlier and AWS ECR registry is used, you must ensure that the `SERVER-NAME/REPO-NAME/buildservice` and `SERVER-NAME/REPO-NAME/workloads` exist. AWS ECR expects the paths to be pre-created. Images are written to `SERVER-NAME/REPO-NAME/workload-name`. Examples:
    - Harbor has the form `repository: "my-project/supply-chain"`.
    - Docker Hub has the form `repository: "my-dockerhub-user"`.
    - Google Cloud Registry has the form `repository: "my-project/supply-chain"`.
- `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE` is where the developer's local source is uploaded when using Tanzu CLI to use Local Source Proxy for workload creation.

  If an AWS ECR registry is being used, ensure that the repository already exists. AWS ECR expects the repository path to already exist. This destination is represented as `REGISTRY-SERVER/REPOSITORY-PATH`. For more information, see Install Local Source Proxy.
- `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE-SECRET` is the name of the secret with credentials that allow pushing to the `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE` repository.
- `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE-SECRET-NAMESPACE` is the namespace in which `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE-SECRET` is available.
- `GIT-SOURCE-CREDENTIAL-SECRET-NAME` is the name of the Kubernetes secret in the developer namespace that supplies the Git credentials for the supply chain to fetch source code from. This field is only required if you use a private repository. See Git authentication for more information.
- `GITOPS-CREDENTIAL-SECRET-NAME` is the name of the Kubernetes secret in the developer namespace that supplies the Git credentials for the supply chain to push configuration to. See Git authentication for more information.
- `GIT-CATALOG-URL` is the path to the `catalog-info.yaml` catalog definition file. You can download either a blank or populated catalog file from the Tanzu Application Platform product page. Otherwise, you can use a Backstage-compliant catalog you've already built and posted on the Git infrastructure.
- `MY-DEV-NAMESPACE` is the name of the developer namespace. SCST - Store exports secrets to the namespace, and SCST - Scan deploys the `ScanTemplates` there. This allows the scanning feature to run in this namespace. If there are multiple developer namespaces, use `ns_for_export_app_cert: "*"` to export the SCST - Store CA certificate to all namespaces. To install Grype in multiple namespaces, use a namespace provisioner. For more information, see Namespace Provisioner.
- `TARGET-REGISTRY-CREDENTIALS-SECRET` is the name of the secret that contains the credentials to pull an image from the registry for scanning.
- `CUSTOMER-ENTITLEMENT-ACCOUNT-NUMBER` (optional) refers to the Entitlement Account Number (EAN), which is a unique identifier VMware assigns to its customers. Tanzu Application Platform telemetry uses this number to identify data that belongs to a particular customers and prepare usage reports.

If you use custom CA certificates, you must provide one or more PEM-encoded CA certificates under the `ca_cert_data` key. If you configured `shared.ca_cert_data`, Tanzu Application Platform component packages inherit that value by default.

If you use AWS, the default settings creates a classic LoadBalancer. To use the Network LoadBalancer instead of the classic LoadBalancer for ingress, add the following to your `tap-values.yaml`:

```
contour:
  infrastructure_provider: aws
  envoy:
    service:
      aws:
        LBType: nlb
```

CEIP policy disclosure

Tanzu Application Platform is part of VMware's CEIP program where data is collected to help improve the customer experience. By setting `ceip_policy_disclosed` to `true` (not a string), you acknowledge the program is disclosed to you and you are aware data collection is happening. This field must be set for the installation to be completed.

See Opt out of telemetry collection for more information.

(Optional) Configure your profile with full dependencies

When you install a profile that includes Tanzu Build Service, Tanzu Application Platform is installed with the `lite` set of dependencies. These dependencies consist of buildpacks and stacks required for application builds.

The `lite` set of dependencies do not contain all buildpacks and stacks. To use all buildpacks and stacks, you must install the `full` dependencies. For more information about the differences between `lite` and `full` dependencies, see About lite and full dependencies.

To configure `full` dependencies, add the key-value pair `exclude_dependencies: true` to your `tap-values.yaml` file under the `buildservice` section. For example:

```
buildservice:
  kp_default_repository: "KP-DEFAULT-REPO"
  kp_default_repository_secret: # Takes the value from the shared section by default,
but can be overridden by setting a different value.
    name: "KP-DEFAULT-REPO-SECRET"
    namespace: "KP-DEFAULT-REPO-SECRET-NAMESPACE"
  exclude_dependencies: true
```

After configuring `full` dependencies, you must install the dependencies after you have finished installing your Tanzu Application Platform package. See Install the full dependencies package for more information.

Tanzu Application Platform v1.6.1 and later supports building applications with Ubuntu v22.04 (Jammy).

(Optional) Configure your profile with automatic dependency updates

Tanzu Build Service dependencies might be upgraded between Tanzu Application Platform releases, for example, if a CVE is discovered in the OS (stack update) or language (buildpack update).

Automatic dependency updates enable your cluster to consume the stack and buildpack updates immediately instead of waiting for the next Tanzu Application Platform patch release to pull in the updated dependencies.

- Updates are provided through a separate package repository with available version lines for all supported Tanzu Application Platform minor versions.
- Within a version line, only patch versions are incremented to avoid breaking changes.

- You can customize the packages that you want the automatic dependency updater to update through your `tap-values.yaml` file or your full dependencies values.

Prerequisites: These steps assume a registry secret already exists in the cluster for accessing `registry.tanzu.vmware.com` and your registry.

To enable automatic dependency updates:

1. Add the following to your `tap-values.yaml` file:

   ```
   buildservice:
     dependency_updates:
       allow: true
       scope: SCOPE
       include_packages: [""]
       exclude_packages: [""]
   ```

   Where:

   - `SCOPE` is the list of dependencies you want updated. The options are:
     - `stacks-only` (default): Only stacks and builders are updated. This addresses CVEs in the base image or operating system.
     - `all`: Stacks, builders, and buildpacks are updated. This addresses CVEs in the base image or operating system and CVEs in the language toolchain such as compilers, interpreters, and standard libraries.
     - `custom`: This list is empty by default. Use the `include_packages` key to add packages to be updated.

   

   Note

   You must update the Tanzu Application Platform package install and the Full Dependencies package install after changing the `tap-values.yaml`.

2. Add the Tanzu Build Service Dependency Updates package repository by running:

   ```
   kubectl apply -f - <<EOF
     apiVersion: packaging.carvel.dev/v1alpha1
     kind: PackageRepository
     metadata:
       name: tbs-dependencies-package-repository
       namespace: tap-install
     spec:
       fetch:
         imgpkgBundle:
           image: DEPENDENCY-UPDATER-PACKAGE-REPO
           tagSelection:
             semver:
               constraints: VERSION-CONSTRAINT
   EOF
   ```

   Where:

   - `DEPENDENCY-UPDATER-PACKAGE-REPO` is the location of the package repository. This is `registry.tanzu.vmware.com/build-service-dependency-updater/package-repo` for online installs and the internal container image registry for air-gapped installs.
   - `VERSION-CONSTRAINT` is the Tanzu Application Platform version in the form of `MAJOR.MINOR.x`. For example, `1.8.x`.

After completing this configuration, the repository you set with `DEPENDENCY-UPDATER-PACKAGE-REPO` will be polled for updates and any new releases will automatically be made available to the cluster.

(Optional) Override the default retention behavior for Crossplane CRDs

By default, the `crossplane.tanzu.vmware.com` package is configured to retain all Crossplane CRDs, providers, and managed resources when the package is uninstalled. This is in the interest of caution in relation to accidental deletion of stateful data.

You can configure Tanzu Application Platform to delete Crossplane resources to avoid orphaned resources. To do so, update the `tap-values.yaml` as follows:

```
# tap-values.yaml

crossplane:
  orphan_resources: false
```

Install your Tanzu Application Platform package

Follow these steps to install the Tanzu Application Platform package:

1. Install the package by running:

   ```
   tanzu package install tap -p tap.tanzu.vmware.com -v $TAP_VERSION --values-file
   tap-values.yaml -n tap-install
   ```

2. Verify the package install by running:

   ```
   tanzu package installed get tap -n tap-install
   ```

   This can take 5-10 minutes because it installs several packages on your cluster.

3. Verify that the necessary packages in the profile are installed by running:

   ```
   tanzu package installed list -A
   ```

4. If you configured `full` dependencies in your `tap-values.yaml` file, install the `full` dependencies by following the procedure in Install full dependencies.

Important

After installing the full profile on your cluster, you must set up developer namespaces. Otherwise, creating a workload, a Knative service or other Tanzu Application Platform packages fails. For more information, see Set up developer namespaces to use your installed packages.

You can run the following command after reconfiguring the profile to reinstall the Tanzu Application Platform:

```
tanzu package installed update tap -p tap.tanzu.vmware.com -v $TAP_VERSION  --values-f
ile tap-values.yaml -n tap-install
```

Install the full dependencies package

If you configured `full` dependencies in your `tap-values.yaml` file in Configure your profile with full dependencies earlier, you must install the `full` dependencies package.

1. (Optional) If you have an existing installation of the full dependencies package from a version earlier than Tanzu Application Platform v1.6.1, you must uninstall the full dependencies package and remove the package repository:

   Uninstall the package:

   ```
   tanzu package installed delete full-tbs-deps -n tap-install
   ```

   Remove the package repository:

   ```
   tanzu package repository delete tbs-full-deps-repository -n tap-install
   ```

2. Get the latest version of the Tanzu Application Platform package by running:

   ```
   tanzu package available list tap.tanzu.vmware.com --namespace tap-install
   ```

3. If you have not done so already, you must exclude the default dependencies by adding the key-value pair `exclude_dependencies: true` to your `tap-values.yaml` file under the `buildservice` section. For example:

   ```
   buildservice:
     exclude_dependencies: true
   ```

4. If you have not updated your Tanzu Application Platform package installation after adding the key-value pair `exclude_dependencies: true` to your values file, perform the update by running:

   ```
   tanzu package installed update tap --namespace tap-install --values-file VALUES
   -FILE
   ```

   Where `VALUES-FILE` is the path to the `tap-values.yaml` file you edited earlier.

5. Relocate the Tanzu Build Service `full` dependencies package repository by doing one of the following:

   - Relocate the images directly for online installation:

     ```
     imgpkg copy \
       -b registry.tanzu.vmware.com/tanzu-application-platform/full-deps-packa
     ge-repo:VERSION \
       --to-repo ${INSTALL_REGISTRY_HOSTNAME}/full-deps-package-repo
     ```

     Where `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.

   - Relocate the images to an external storage device and then to the registry in the air-gapped environment:

     ```
     imgpkg copy \
       -b registry.tanzu.vmware.com/tanzu-application-platform/full-deps-packa
     ge-repo:VERSION \
       --to-tar=full-deps-package-repo.tar

     # move full-deps-package-repo.tar to environment with registry access
     imgpkg copy \
       --tar full-deps-package-repo.tar \
       --to-repo=INSTALL-REGISTRY-HOSTNAME/TARGET-REPOSITORY/full-deps-package
     -repo
     ```

Where:

- `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.
- `INSTALL-REGISTRY-HOSTNAME` is your container registry.
- `TARGET-REPOSITORY` is your target repository.

6. Add the Tanzu Build Service `full` dependencies package repository by running:

```
tanzu package repository add full-deps-package-repo \
  --url INSTALL-REGISTRY-HOSTNAME/TARGET-REPOSITORY/full-deps-package-repo:VERS
ION \
  --namespace tap-install
```

Where:

- `INSTALL-REGISTRY-HOSTNAME` is your container registry.
- `TARGET-REPOSITORY` is your target repository.
- `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.

7. Create a new `tbs-full-deps-values.yaml` and copy the `kp_default_repository` key-value pair from your `tap-values.yaml` or `tbs-values.yaml`:

```
---
 kp_default_repository: "REPO-NAME"
 kp_default_repository_secret:
   name: kp-default-repository-creds
   namespace: tap-install
```

Where `REPO-NAME` is copied from the `buildservice.kp_default_repository` field in your `tap-values.yaml` or `tbs-values.yaml`.

1. (Optional) Install the UBI builder.

   The UBI builder uses Red Hat Universal Base Image (UBI) v8 for both build and run images. This builder only supports Java and Node.js. To install the UBI builder, add the key-value pair `enable_ubi_builder: true` to your `tbs-full-deps-values.yaml`.

   ```
   ---
   enable_ubi_builder: true
   ```

2. (Optional) Install the Static builder.

   The Static builder uses Ubuntu Jammy for both build images and a minimal static run image. This builder only supports Golang. To install the Static builder, add the key-value pair `enable_static_builder: true` to your `tbs-full-deps-values.yaml`.

   ```
   ---
   enable_static_builder: true
   ```

8. Install the `full` dependencies package by running:

```
tanzu package install full-deps \
  --package full-deps.buildservice.tanzu.vmware.com \
  --version "> 0.0.0" \
  --namespace tap-install \
  --values-file VALUES-FILE
```

Where `VALUES-FILE` is the path to the `tbs-full-deps-values.yaml` you created earlier.

For more information about the differences between `lite` and `full` dependencies, see About lite and full dependencies.

Access Tanzu Developer Portal

To access Tanzu Developer Portal, you can use the host name that you configured earlier. This host name is pointed at the shared ingress. To configure LoadBalancer for Tanzu Developer Portal, see Access Tanzu Developer Portal.

You're now ready to start using Tanzu Developer Portal. Proceed to the Getting Started topic or the Tanzu Developer Portal - Catalog Operations topic.

Exclude packages from a Tanzu Application Platform profile

To exclude packages from a Tanzu Application Platform profile:

1. Find the full subordinate (child) package name:

   ```
   tanzu package available list --namespace tap-install
   ```

2. Update your `tap-values` file with a section listing the exclusions:

   ```
   profile: PROFILE-VALUE
   excluded_packages:
     - tap-gui.tanzu.vmware.com
     - service-bindings.lab.vmware.com
   ```

Important

If you exclude a package after performing a profile installation including that package, you cannot see the accurate package states immediately after running `tap package installed list -n tap-install`. Also, you can break package dependencies by removing a package. Allow 20 minutes to verify that all packages have reconciled correctly while troubleshooting.

Next steps

- (Optional) Install individual packages
- Set up developer namespaces to use your installed packages
- Replace the default ingress issuer

View possible configuration settings for your package

To view possible configuration settings for a package, run:

```
tanzu package available get tap.tanzu.vmware.com/$TAP_VERSION --values-schema --namesp
ace tap-install
```

Note

The `tap.tanzu.vmware.com` package does not show all configuration settings for packages it plans to install. The package only shows top-level keys. You can view

individual package configuration settings with the same `tanzu package available get` command. For example, to find the keys for Cloud Native Runtimes, you must first identify the version of the package with `tanzu package installed list -n tap-install`, which lists all the installed packages versions. Then run the command `tanzu package available get -n tap-install cnrs.tanzu.vmware.com/CNR-VERSION --values-schema` by using the package version listed for Cloud Native Runtimes.

```
profile: full

# Shared configurations go under the shared key.
shared:
  ingress_domain: tap.example.com

# ...

# For example, Cloud Native Runtimes specific values go under its name.
cnrs:
  provider: local

# For example, App Accelerator specific values go under its name.
accelerator:
  server:
    service_type: "ClusterIP"
```

Shared Keys define values that configure multiple packages. These keys are defined under the `shared` Top-level Key, as summarized in the following table:

Shared Key	Description	Optional
`ca_cert_data`	PEM-encoded certificate data to trust TLS connections with a private CA. This shared key is used by `convention_controller`, `scanning` and the Tanzu `source_controller` (not the Flux CD Source Controller).	Yes
`ingress_domain`	Domain name to be used in service routes and host names for instances of Tanzu Application Platform components.	Yes
`ingress_issuer`	A `cert-manager.io/v1/ClusterIssuer` for issuing TLS certificates to Tanzu Application Platform components. Default value: `tap-ingress-selfsigned`	Yes
`kubernetes_distribution`	Type of Kubernetes infrastructure being used. You can use this shared key in coordination with the `kubernetes_version` key. Supported value: `openshift`.	Yes
`kubernetes_version`	Kubernetes version. You can use this shared key independently or in coordination with the `kubernetes_distribution` key. Supported value: `1.24.x`, where `x` stands for the Kubernetes patch version.	Yes
`image_registry.project_path`	Project path in the container image registry server used for builder and application images.	Yes
`image_registry.username`	User name for the container image registry. Mutually exclusive with `shared.image_registry.secret.name/namespace`	Yes
`image_registry.password`	Password for the container image registry. Mutually exclusive with `shared.image_registry.secret.name/namespace`	Yes
`secret.name`	Secret name for the container image registry credentials of type `kubernetes.io/dockerconfigjson`. Mutually exclusive with `shared.image_registry.username/password`	Yes
`secret.namespace`	Secret namespace for the container image registry credentials. Mutually exclusive with `shared.image_registry.username/password`	Yes

Shared Key	Description	Optional
`activateAppLiveViewSecureAccessControl`	Enable secure access connection between Application Live View components.	Yes

The following table summarizes the top-level keys used for package-specific configuration within your `tap-values.yaml`.

Package	Top-level Key
See table above.	`shared`
API Auto Registration	`api_auto_registration`
API portal	`api_portal`
Application Accelerator	`accelerator`
Application Live View	`appliveview`
Application Live View connector	`appliveview_connector`
Application Live View conventions	`appliveview-conventions`
Cartographer Conventions	`cartographer_conventions`
Cartographer	`cartographer`
Cloud Native Runtimes	`cnrs`
Source Controller	`source_controller`
Supply Chain	`supply_chain`
Supply Chain Basic	`ootb_supply_chain_basic`
Supply Chain Testing	`ootb_supply_chain_testing`
Supply Chain Testing Scanning	`ootb_supply_chain_testing_scanning`
Supply Chain Security Tools - Scan	`scanning`
Supply Chain Security Tools - Scan (Grype Scanner)	`grype`
Supply Chain Security Tools - Store	`metadata_store`
Build Service	`buildservice`
Tanzu Developer Portal	`tap_gui`

For information about package-specific configuration, see Install individual packages.

Install individual packages

You can install Tanzu Application Platform (commonly known as TAP) through predefined profiles or through individual packages. Use this topic to learn how to install each individual package. For more information about installing through profiles, see Components and installation profiles.

Installing individual Tanzu Application Platform packages is useful if you do not want to use a profile to install packages or if you want to install additional packages after installing a profile. Before installing the packages, be sure to complete the prerequisites, configure and verify the cluster, accept the EULA, and install the Tanzu CLI with any required plug-ins. For more information, see Prerequisites.

Install pages for individual Tanzu Application Platform packages

- Install API Auto Registration
- Install API portal
- Install Application Accelerator
- Install Application Configuration Service
- Install Application Live View
- Install Application Single Sign-On
- Install Bitnami Services
- Install cert-manager
- Install Cloud Native Runtimes
- Install Contour
- Install Crossplane
- Install default roles for Tanzu Application Platform
- Install Developer Conventions
- Install Flux CD Source Controller
- Install Out of the Box Templates
- Install Out of the Box Supply Chain with Testing
- Install Out of the Box Supply Chain with Testing and Scanning
- Install Service Bindings
- Install Services Toolkit
- Install Source Controller
- Install Spring Boot conventions
- Install Supply Chain Choreographer
- Install Supply Chain Security Tools - Store
- Install Supply Chain Security Tools - Policy Controller
- Install Supply Chain Security Tools - Scan
- Install Tanzu Developer Portal
- Install Tanzu Build Service
- Install Tekton
- Install Telemetry

Verify the installed packages

Use the following procedure to verify that the packages are installed.

1. List the installed packages by running:

   ```
   tanzu package installed list --namespace tap-install
   ```

   For example:

```
$ tanzu package installed list --namespace tap-install
\ Retrieving installed packages...
NAME                     PACKAGE-NAME                                      PAC
KAGE-VERSION  STATUS
api-portal               api-portal.tanzu.vmware.com                       1.
0.3           Reconcile succeeded
app-accelerator          accelerator.apps.tanzu.vmware.com                 1.
0.0           Reconcile succeeded
app-live-view            appliveview.tanzu.vmware.com                      1.
0.2           Reconcile succeeded
appliveview-conventions  build.appliveview.tanzu.vmware.com                1.
0.2           Reconcile succeeded

Next steps

- Set up developer namespaces to use your installed packages

Set up developer namespaces to use your installed packages

For details about how to automatically set up your developer namespaces, see Provision developer namespaces in Namespace Provisioner.

Additional configuration for testing and scanning

If you plan to install or have already installed Out of the Box Supply Chains with Testing and Scanning, you can use Namespace Provisioner to set up the required resources. For more

information, see Customize installation in the Namespace Provisioner documentation for configuration steps.

Legacy namespace setup

To use the legacy manual process for setting up developer namespaces, see Legacy namespace setup.

Next steps

- Install Tanzu Developer Tools for your VS Code

Provision namespaces manually

This topic tells you how to use Namespace Provisioner to provision namespaces manually in Tanzu Application Platform (commonly known as TAP).

Using Namespace Provisioner is the recommended best practice for setting up developer namespaces on Tanzu Application Platform.

To provision namespaces manually, complete the following steps:

1. Enable single user access.
2. (Optional) Enable additional users with Kubernetes RBAC.

Enable single user access

1. To add read/write registry credentials to the developer namespace, run the following command:

   ```
   tanzu secret registry add registry-credentials --server REGISTRY-SERVER --usern
   ame REGISTRY-USERNAME --password REGISTRY-PASSWORD --namespace YOUR-NAMESPACE
   ```

   Where:

   - `YOUR-NAMESPACE` is the name you give to the developer namespace. For example, use `default` for the default namespace.
   - `REGISTRY-SERVER` is the URL of the registry. You can use the same registry server as in `ootb_supply_chain_basic` - `registry` - `server`. For more information, see Install Tanzu Application Platform package and profiles.
     - For Docker Hub, the value is `https://index.docker.io/v1/`. It must have the leading `https://`, the `v1` path, and the trailing `/`.
     - For Google Container Registry (GCR), the value is `gcr.io`.
   - `REGISTRY-PASSWORD` is the password of the registry.
     - For GCR or Google Artifact Registry, this must be the concatenated version of the JSON key. For example: `"$(cat ~/gcp-key.json)"`

   If you observe the following issue:

   ```
   panic: runtime error: invalid memory address or nil pointer dereference
   [signal SIGSEGV: segmentation violation code=0x1 addr=0x128 pc=0x2bcce00]
   ```

   Use kubectl to create the secret instead:

```
kubectl create secret docker-registry registry-credentials --docker-server=REGI
STRY-SERVER --docker-username=REGISTRY-USERNAME --docker-password=REGISTRY-PASS
WORD -n YOUR-NAMESPACE
```

Note

This step is not required if you install Tanzu Application Platform on AWS with EKS and use IAM Roles for Kubernetes Service Accounts instead of secrets. You can specify the Role Amazon Resource Name (ARN) in the next step.

2. Run the following to add secrets, a service account to execute the supply chain, and RBAC rules to authorize the service account to the developer namespace:

```
cat <<EOF | kubectl -n YOUR-NAMESPACE apply -f -
apiVersion: v1
kind: Secret
metadata:
  name: tap-registry
  annotations:
    secretgen.carvel.dev/image-pull-secret: ""
type: kubernetes.io/dockerconfigjson
data:
  .dockerconfigjson: e30K
---
apiVersion: v1
kind: ServiceAccount
metadata:
  name: default
secrets:
  - name: registry-credentials
imagePullSecrets:
  - name: registry-credentials
  - name: tap-registry
---
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: default-permit-deliverable
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: deliverable
subjects:
  - kind: ServiceAccount
    name: default
---
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: default-permit-workload
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: workload
subjects:
  - kind: ServiceAccount
    name: default
EOF
```

Note

If you install Tanzu Application Platform on AWS with EKS and use IAM Roles for Kubernetes Service Accounts, you must annotate the ARN of the IAM Role and remove the `registry-credentials` secret. Your service account entry then looks like the following:

```
apiVersion: v1
kind: ServiceAccount
metadata:
  name: default
  annotations:
    eks.amazonaws.com/role-arn: <Role ARN>
imagePullSecrets:
  - name: tap-registry
```

Enable additional users with Kubernetes RBAC

Follow these steps to enable additional users in your namespace by using Kubernetes RBAC:

1. (Optional) Before you begin, ensure that you have enabled single user access. If you've set up your developer namespace using Namespace Provisioner, you can skip this step.
2. Choose either of the following options to give developers namespace-level access and view access to the appropriate cluster-level resources:
    - **Option 1:** Use the Tanzu Application Platform RBAC CLI plug-in (beta).

      To use the `tanzu rbac` plug-in to grant `app-viewer` and `app-editor` roles to an identity provider group, run:

      ```
      tanzu rbac binding add -g GROUP-FOR-APP-VIEWER -n YOUR-NAMESPACE -r app-v
      iewer
      tanzu rbac binding add -g GROUP-FOR-APP-EDITOR -n YOUR-NAMESPACE -r app-e
      ditor
      ```

      Where:

        - `YOUR-NAMESPACE` is the name you give to the developer namespace.
        - `GROUP-FOR-APP-VIEWER` is the user group from the upstream identity provider that requires access to `app-viewer` resources on the current namespace and cluster.
        - `GROUP-FOR-APP-EDITOR` is the user group from the upstream identity provider that requires access to `app-editor` resources on the current namespace and cluster.

      For more information about `tanzu rbac`, see Bind a user or group to a default role

      VMware recommends creating a user group in your identity provider's grouping system for each developer namespace and then adding the users accordingly.

      Depending on your identity provider, you might need to take further action to federate user groups appropriately with your cluster. For an example of how to set up Azure Active Directory (Azure AD) with your cluster, see Integrate Azure Active Directory.

    - **Option 2:** Use the native Kubernetes YAML.

      Run the following to apply the RBAC policy:

```
cat <<EOF | kubectl -n YOUR-NAMESPACE apply -f -
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: dev-permit-app-viewer
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: app-viewer
subjects:
  - kind: Group
    name: GROUP-FOR-APP-VIEWER
    apiGroup: rbac.authorization.k8s.io
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: YOUR-NAMESPACE-permit-app-viewer
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: app-viewer-cluster-access
subjects:
  - kind: Group
    name: GROUP-FOR-APP-VIEWER
    apiGroup: rbac.authorization.k8s.io
---
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: dev-permit-app-editor
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: app-editor
subjects:
  - kind: Group
    name: GROUP-FOR-APP-EDITOR
    apiGroup: rbac.authorization.k8s.io
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: YOUR-NAMESPACE-permit-app-editor
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: app-editor-cluster-access
subjects:
  - kind: Group
    name: GROUP-FOR-APP-EDITOR
    apiGroup: rbac.authorization.k8s.io
EOF
```

Where:

- `YOUR-NAMESPACE` is the name you give to the developer namespace.
- `GROUP-FOR-APP-VIEWER` is the user group from the upstream identity provider that requires access to `app-viewer` resources on the current namespace and cluster.
- `GROUP-FOR-APP-EDITOR` is the user group from the upstream identity provider that requires access to `app-editor` resources on the current namespace and cluster.

VMware recommends creating a user group in your identity provider's grouping system for each developer namespace and then adding the users accordingly.

Depending on your identity provider, you might need to take further action to federate user groups appropriately with your cluster.

Rather than granting roles directly to individuals, VMware recommends using your identity provider's user groups system to grant access to a group of developers.

For an example of how to set up Azure Active Directory (AD) with your cluster, see Integrate Azure Active Directory.

3. (Optional) Log in as a non-admin user, such as a developer, to see the effects of RBAC after the role bindings are applied.

Additional configuration for testing and scanning

If you plan to install Out of the Box Supply Chains with Testing and Scanning, see Developer Namespace.

Install Tanzu Developer Tools for your VS Code

This topic tells you how to install VMware Tanzu Developer Tools for Visual Studio Code (VS Code).

Prerequisites

Before installing the extension, you must have:

- VS Code
- kubectl
- Tilt v0.30.12 or later
- Tanzu CLI and plug-ins
- A cluster with the Tanzu Application Platform Full profile or Iterate profile

If you are an app developer, someone else in your organization might have already set up the Tanzu Application Platform environment.

Docker Desktop and local Kubernetes are not prerequisites for using Tanzu Developer Tools for VS Code.

Install

To install VMware Tanzu Developer Tools for VS Code:

1. Open Visual Studio Code.
2. Open the command palette.
3. In the search box enter `Extension`.
4. Click **Extensions: Install Extensions**.
5. The **Extensions** view opens on the left side of your screen. In the search box enter `Tanzu`.
6. Click **Tanzu Developer Tools** and then click **Install**.

Configure

To configure VMware Tanzu Developer Tools for VS Code:

1. Ensure that you are targeting the correct cluster. For more information, see the Kubernetes documentation.
2. Go to **Code** > **Preferences** > **Settings** > **Extensions** > **Tanzu Developer Tools** and set the following:
    - **Confirm Apply Config**: This controls whether the extension asks to confirm user input when applying a workload.
    - **Confirm Debug Port**: This controls whether the extension asks for the debug port when running `Tanzu: Start Java Debug`.
    - **Confirm Local Port**: This controls whether the extension asks for the local port when running `Tanzu: Start Java Debug`.
    - **Confirm Delete**: This controls whether the extension asks for confirmation when deleting a workload.
    - **Enable Live Hover**: This enables Live Hover. For more information, see Integrating Live Hover by using Spring Boot Tools. Restart VS Code for this change to take effect.
    - **Source Image**: The registry location for publishing local source code. For example, `registry.io/yourapp-source`. This must include both a registry and a project name. A source image registry location is optional when Local Source Proxy is configured.
    - **Local Path**: (Optional) The path on the local file system to a directory of source code to build. This is the current directory by default.
    - **Namespace**: (Optional) This is the namespace that workloads are deployed into. The namespace set in kubeconfig is the default.
    - **Tracked Namespaces**: (Optional) Comma-separated list of namespaces. Resources in these namespaces appear in the Tanzu Workloads panel and the Activity panel. If empty, the namespace in the current context is the default.
    - **Wait Timeout**: (Optional) This sets how long to wait for a workload to become ready.
    - **Workload Type**: (Optional) This distinguishes the workload type. Examples include web and server.

Uninstall

To uninstall VMware Tanzu Developer Tools for VS Code:

1. Go to **Code** > **Preferences** > **Settings** > **Extensions**.
2. Right-click the extension and then click **Uninstall**.

Next steps

Proceed to Getting started with Tanzu Developer Tools for Visual Studio Code.

Install Tanzu Application Platform (offline)

To install Tanzu Application Platform (commonly known as TAP) on your Kubernetes clusters in an air-gapped environment:

Step	Task	Link
1.	Review the prerequisites to ensure you have met all requirements before installing.	Prerequisites
2.	Accept Tanzu Application Platform EULAs and install the Tanzu CLI.	Accept Tanzu Application Platform EULAs and installing the Tanzu CLI
3.	Install Cluster Essentials for Tanzu*.	Deploy Cluster Essentials
4.	Add the Tanzu Application Platform package repository, prepare your Tanzu Application Platform profile, and install the profile to the cluster.	Install Tanzu Application Platform in your air-gapped environment
5.	Install Tanzu Build Service full dependencies.	Install the Tanzu Build Service dependencies
6.	Configure custom certificate authorities for Tanzu Developer Portal.	Configure custom certificate authorities for Tanzu Developer Portal
7.	Add the certificate for the private Git repository in the Accelerator system namespace.	Configure Application Accelerator
8.	(Optional) Set up offline vulnerability scanning	Use vulnerability scanning in offline and air-gapped environments
9.	Set up developer namespaces to use your installed packages.	Set up developer namespaces to use your installed packages
10.	Install IDE extensions from Marketplace	Install IDE Extensions in your air-gapped environment

* *When you use a VMware Tanzu Kubernetes Grid cluster, there is no need to install Cluster Essentials because the contents of Cluster Essentials are already installed on your cluster.*

After installing Tanzu Application Platform on to your air-gapped cluster, you can start creating workloads that run in your air-gapped containers.

For more information about the Namespace Provisioner mode, see Work with Git repositories in air-gapped environments with Namespace Provisioner.

For more information about the manual mode, see Deploy an air-gapped workload.

After installing Tanzu Application Platform on to your air-gapped cluster, you can start creating workloads that run in your air-gapped containers.

For more information about the Namespace Provisioner mode, see Work with Git repositories in air-gapped environments with Namespace Provisioner.

For more information about the manual mode, see Deploy an air-gapped workload.

Install Tanzu Application Platform in your air-gapped environment

This topic tells you how to install Tanzu Application Platform (commonly known as TAP) on your Kubernetes cluster and registry that are air-gapped from external traffic.

Before installing the packages, ensure that you have completed the following tasks:

- Review the Prerequisites to ensure that you have set up everything required before beginning the installation.
- Accept Tanzu Application Platform EULA and install Tanzu CLI.
- Deploy Cluster Essentials. This step is optional if you are using VMware Tanzu Kubernetes Grid cluster.

Relocate images to a registry

To relocate images from the VMware Tanzu Network registry to your air-gapped registry:

1. Set up environment variables for installation use by running:

   ```
   # Set tanzunet as the source registry to copy the Tanzu Application Platform pa
   ckages from.
   export IMGPKG_REGISTRY_HOSTNAME_0=registry.tanzu.vmware.com
   export IMGPKG_REGISTRY_USERNAME_0=MY-TANZUNET-USERNAME
   export IMGPKG_REGISTRY_PASSWORD_0=MY-TANZUNET-PASSWORD

   # The user's registry for copying the Tanzu Application Platform package to.
   export IMGPKG_REGISTRY_HOSTNAME_1=MY-REGISTRY
   export IMGPKG_REGISTRY_USERNAME_1=MY-REGISTRY-USER
   export IMGPKG_REGISTRY_PASSWORD_1=MY-REGISTRY-PASSWORD
   export TAP_VERSION=VERSION-NUMBER
   export REGISTRY_CA_PATH=PATH-TO-CA
   export TO_REPO=MY-REPO
   ```

   Where:

   - `MY-REGISTRY` is your air-gapped container registry.

- `MY-REGISTRY-USER` is the user with write access to `MY-REGISTRY`.
- `MY-REGISTRY-PASSWORD` is the password for `MY-REGISTRY-USER`.
- `MY-TANZUNET-USERNAME` is the user with access to the images in the VMware Tanzu Network registry `registry.tanzu.vmware.com`
- `MY-TANZUNET-PASSWORD` is the password for `MY-TANZUNET-USERNAME`.
- `VERSION-NUMBER` is your Tanzu Application Platform version. For example, `1.9.1`
- `MY-REPO` is your repository in the air-gapped container image registry. Examples:
  - Harbor has the form `MY-REGISTRY/REPO-NAME/tap-packages`.
  - Docker Hub has the form `MY-REGISTRY/tap-packages`.
  - Google Cloud Registry has the form `MY-REGISTRY/MY-PROJECT/REPO-NAME/tap-packages`.

2. Copy the images into a `.tar` file from the VMware Tanzu Network onto an external storage device with the Carvel tool imgpkg by running:

```
imgpkg copy \
  -b registry.tanzu.vmware.com/tanzu-application-platform/tap-packages:$TAP_VER
SION \
  --to-tar tap-packages-$TAP_VERSION.tar \
  --include-non-distributable-layers
```

3. Relocate the images with the Carvel tool imgpkg by running:

```
imgpkg copy \
  --tar tap-packages-$TAP_VERSION.tar \
  --to-repo $TO_REPO \
  --include-non-distributable-layers \
  --registry-ca-cert-path $REGISTRY_CA_PATH
```

4. Create a namespace called `tap-install` for deploying any component packages by running:

```
kubectl create ns tap-install
```

   This namespace keeps the objects grouped together logically.

5. Create a registry secret by running:

```
tanzu secret registry add tap-registry \
    --server   $IMGPKG_REGISTRY_HOSTNAME_1 \
    --username $IMGPKG_REGISTRY_USERNAME_1 \
    --password $IMGPKG_REGISTRY_PASSWORD_1 \
    --namespace tap-install \
    --export-to-all-namespaces \
    --yes
```

6. Create a secret for accessing the user's registry by running:

```
tanzu secret registry add registry-credentials \
    --server   $IMGPKG_REGISTRY_HOSTNAME_1 \
    --username $IMGPKG_REGISTRY_USERNAME_1 \
    --password $IMGPKG_REGISTRY_PASSWORD_1 \
    --namespace tap-install \
    --export-to-all-namespaces \
    --yes
```

7. Add the Tanzu Application Platform package repository to the cluster by running:

```
tanzu package repository add tanzu-tap-repository \
  --url $IMGPKG_REGISTRY_HOSTNAME_1/tap-packages:$TAP_VERSION \
  --namespace tap-install
```

Where `$TAP_VERSION` is the Tanzu Application Platform version environment variable you defined earlier.

8. Get the status of the Tanzu Application Platform package repository, and ensure the status updates to `Reconcile succeeded` by running:

```
tanzu package repository get tanzu-tap-repository --namespace tap-install
```

Note

The `VERSION` and `TAG` numbers differ from the earlier example if you are on Tanzu Application Platform v1.0.2 or earlier.

9. List the available packages by running:

```
tanzu package available list --namespace tap-install
```

For example:

```
$ tanzu package available list --namespace tap-install
/ Retrieving available packages...
  NAME                                                DISPLAY-NAME

Prepare Sigstore Stack for air-gapped policy controller

Important

This section only applies if the target environment requires support for keyless authorities in `ClusterImagePolicy`. You must set the `policy.tuf_enabled` field to `true` when installing Tanzu Application Platform. By default, keyless authorities support is deactivated.

By default, the public official Sigstore “The Update Framework (TUF) server” is used. You can use an alternative Sigstore Stack by setting `policy.tuf_mirror` and `policy.tuf_root`.

The Sigstore Stack consists of:

- Trillian
- Rekor
- Fulcio
- Certificate Transparency Log (CTLog)
- The Update Framework (TUF)

For an air-gapped environment, an internally accessible Sigstore Stack is required for keyless authorities.

Install your Tanzu Application Platform profile

The `tap.tanzu.vmware.com` package installs predefined sets of packages based on your profile settings. This is done by using the package manager installed by Tanzu Cluster Essentials.

For more information about profiles, see Components and installation profiles.

To prepare to install a profile:

1. List version information for the package by running:

   ```
   tanzu package available list tap.tanzu.vmware.com --namespace tap-install
   ```

2. Create a `tap-values.yaml` file by using the Full Profile sample as a guide. These samples have the minimum configuration required to deploy Tanzu Application Platform. The sample values file contains the necessary defaults for:
   - The meta-package, or parent Tanzu Application Platform package
   - Subordinate packages, or individual child packages

Keep the values file for future configuration use.

Full Profile

To install Tanzu Application Platform with Supply Chain Basic, you must retrieve your cluster's base64 encoded ca certificate from `$HOME/.kube/config`. Retrieve the `certificate-authority-data` from the respective cluster section and input it as `B64_ENCODED_CA` in the `tap-values.yaml`.

The following is the YAML file sample for the full-profile:

```

set earlier, this must be set to ClusterIP.
```

Important

- Tanzu Build Service is installed by default with `lite` depndencies. When installing Tanzu Build Service in an air-gapped environment, the lite dependencies are not available because they require Internet access. You must install the `full` dependencies by setting `exclude_dependencies` to `true`. The existing ClusterStore instances will not be updated if you switch from `lite` dependencies to `full` dependencies after the initial installation completes.
- Installing Grype by using `tap-values.yaml` as follows is deprecated in v1.6 and will be removed in v1.8:

  ```
  grype:
   targetImagePullSecret: "TARGET-REGISTRY-CREDENTIALS-SECRET"
  ```

  You can install Grype by using Namespace Provisioner instead.

Where:

- `INGRESS-DOMAIN` is the subdomain for the host name that you point at the `tanzu-shared-ingress` service's External IP address.
- `KP-DEFAULT-REPO` is a writable repository in your registry. Tanzu Build Service dependencies are written to this location. Examples:
  - Harbor has the form `kp_default_repository: "my-harbor.io/my-project/build-service"`.
  - Docker Hub has the form `kp_default_repository: "my-dockerhub-user/build-service"` or `kp_default_repository: "index.docker.io/my-user/build-service"`.
  - Google Cloud Registry has the form `kp_default_repository: "gcr.io/my-project/build-service"`.
- `KP-DEFAULT-REPO-SECRET` is the secret with user credentials that can write to `KP-DEFAULT-REPO`. You can `docker push` to this location with this credential.
  - For Google Cloud Registry, use `kp_default_repository_username: _json_key`.
  - You must create the secret before the installation. For example, you can use the `registry-credentials` secret created earlier.
- `KP-DEFAULT-REPO-SECRET-NAMESPACE` is the namespace where `KP-DEFAULT-REPO-SECRET` is created.
- `SERVER-NAME` is the host name of the registry server. Examples:
  - Harbor has the form `server: "my-harbor.io"`.
  - Docker Hub has the form `server: "index.docker.io"`.
  - Google Cloud Registry has the form `server: "gcr.io"`.
- `REPO-NAME` is where workload images are stored in the registry. If this key is passed through the shared section earlier and AWS ECR registry is used, you must ensure that the `SERVER-NAME/REPO-NAME/buildservice` and `SERVER-NAME/REPO-NAME/workloads` exist. AWS ECR expects the paths to be pre-created.
- Images are written to `SERVER-NAME/REPO-NAME/workload-name`. Examples:
  - Harbor has the form `repository: "my-project/supply-chain"`.
  - Docker Hub has the form `repository: "my-dockerhub-user"`.

    - Google Cloud Registry has the form `repository: "my-project/supply-chain"`.

- `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE` is where the developer's local source is uploaded when using Tanzu CLI to use Local Source Proxy for workload creation.

  If an AWS ECR registry is being used, ensure that the repository already exists. AWS ECR expects the repository path to already exist. This destination is represented as `REGISTRY-SERVER/REPOSITORY-PATH`. For more information, see Install Local Source Proxy.

- `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE-SECRET` is the name of the secret with credentials that allow pushing to the `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE` repository.
- `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE-SECRET-NAMESPACE` is the namespace in which `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE-SECRET` is available.
- `GIT-SOURCE-CREDENTIAL-SECRET-NAME` is the name of the Kubernetes secret in the developer namespace that supplies the Git credentials for the supply chain to fetch source code from. See Git authentication for more information.
- `GITOPS-CREDENTIAL-SECRET-NAME` is the name of the Kubernetes secret in the developer namespace that supplies the Git credentials for the supply chain to push configuration to. See Git authentication for more information.
- `MAVEN-CREDENTIALS` is the name of the secret with maven creds. This secret must be in the developer namespace. You can create it after the fact.
- `GIT-CATALOG-URL` is the path to the `catalog-info.yaml` catalog definition file. You can download either a blank or populated catalog file from the Tanzu Application Platform product page. Otherwise, you can use a Backstage-compliant catalog you've already built and posted on the Git infrastructure.
- `GITLABURL` is the host name of your GitLab instance.
- `GITLAB-USER` is the user name of your GitLab instance.
- `GITLAB-PASSWORD` is the password for the `GITLAB-USER` of your GitLab instance. This can also be the `GITLAB-TOKEN`.
- `GITLAB-TOKEN` is the API token for your GitLab instance.
- `MY-DEV-NAMESPACE` is the name of the developer namespace. SCST - Store exports secrets to the namespace, and SCST - Scan deploys the `ScanTemplates` there. This allows the scanning feature to run in this namespace. If there are multiple developer namespaces, use `ns_for_export_app_cert: "*"` to export the SCST - Store CA certificate to all namespaces. To install Grype in multiple namespaces, use a namespace provisioner. See Namespace Provisioner.
- `TARGET-REGISTRY-CREDENTIALS-SECRET` is the name of the secret that contains the credentials to pull an image from the registry for scanning.

Note

The `appliveview_connector.backend.sslDisabled` key is deprecated and renamed to `appliveview_connector.backend.sslDeactivated`.

If you use custom CA certificates, you must provide one or more PEM-encoded CA certificates under the `ca_cert_data` key. If you configured `shared.ca_cert_data`, Tanzu Application Platform component packages inherit that value by default.

TLS is enabled by default on Application Live View back end using ClusterIssuer. Set the `ingressEnabled` key to `true` for TLS to be enabled on Application Live View back end using

ClusterIssuer. This key is set to `false` by default.

The `appliveview-cert` certificate is generated by default and its issuerRef points to the `.ingress_issuer` value. The `ingress_issuer` key consumes the value `shared.ingress_issuer` from `tap-values.yaml` by default when you don't specify the `ingress_issuer` in `tap-values.yaml`.

When `ingressEnabled` is `true`, an HTTPProxy object is created in the cluster and `appliveview-cert` certificate is generated by default in the `app_live_view` namespace. The secretName `appliveview-cert` stores this certificate.

To verify the HTTPProxy object with the secret, run:

```
kubectl get httpproxy -A
```

Expected output:

```
NAMESPACE            NAME
FQDN                                                          TLS SECRET
STATUS   STATUS DESCRIPTION
app-live-view        appliveview
appliveview.192.168.42.55.nip.io                              appliveview-cert   va
lid    Valid HTTPProxy
```

The `appliveview_connector.backend.host` key is the back end host in the view cluster. The `appliveview_connector.backend.caCertData` key is the certificate retrieved from the HTTPProxy secret exposed by Application Live View back end in the view cluster. To retrieve this certificate, run the following command in the view cluster:

```
kubectl get secret appliveview-cert -n app-live-view -o yaml |  yq '.data."ca.crt"' |
base64 -d
```

Install your Tanzu Application Platform package

Follow these steps to install the Tanzu Application Platform package:

1. Install the package by running:

   ```
   tanzu package install tap -p tap.tanzu.vmware.com -v $TAP_VERSION --values-file
   tap-values.yaml -n tap-install
   ```

   Where `$TAP_VERSION` is the Tanzu Application Platform version environment variable you defined earlier.

2. Verify the package install by running:

   ```
   tanzu package installed get tap -n tap-install
   ```

   This may take 5-10 minutes because it installs several packages on your cluster.

3. Verify that all the necessary packages in the profile are installed by running:

   ```
   tanzu package installed list -A
   ```

Next steps

- Install the Tanzu Build Service dependencies

Install the Tanzu Build Service dependencies

This topic tells you how to install the Tanzu Build Service (TBS) full dependencies on Tanzu Application Platform (commonly known as TAP).

Install full dependencies

Important

By default, Tanzu Build Service is installed with `lite` dependencies.

When installing Tanzu Build Service in an air-gapped environment, the `lite` dependencies are not available because they require Internet access. You must install the `full` dependencies.

To install `full` dependencies:

1. Get the latest version of the Tanzu Application Platform package by running:

   ```
   tanzu package available list tap.tanzu.vmware.com --namespace tap-install
   ```

2. If you have not done so already, you must exclude the default dependencies by adding the key-value pair `exclude_dependencies: true` to your `tap-values.yaml` file under the `buildservice` section. For example:

   ```
   buildservice:
     exclude_dependencies: true
   ```

3. If you have not updated your Tanzu Application Platform package installation after adding the key-value pair `exclude_dependencies: true` to your values file, perform the update by running:

   ```
   tanzu package installed update tap --namespace tap-install --values-file VALUES
   -FILE
   ```

   Where `VALUES-FILE` is the path to the `tap-values.yaml` file you edited earlier.

4. Relocate the Tanzu Build Service `full` dependencies package repository by doing one of the following:

   - Relocate the images directly for online installation:

     ```
     imgpkg copy \
       -b registry.tanzu.vmware.com/tanzu-application-platform/full-deps-packa
     ge-repo:VERSION \
       --to-repo ${INSTALL_REGISTRY_HOSTNAME}/full-deps-package-repo
     ```

     Where `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.

   - Relocate the images to an external storage device and then to the registry in the air-gapped environment:

     ```
     imgpkg copy \
       -b registry.tanzu.vmware.com/tanzu-application-platform/full-deps-packa
     ge-repo:VERSION \
       --to-tar=full-deps-package-repo.tar

     # move full-deps-package-repo.tar to environment with registry access
     imgpkg copy \
       --tar full-deps-package-repo.tar \
     ```

```
  --to-repo=INSTALL-REGISTRY-HOSTNAME/TARGET-REPOSITORY/full-deps-package
-repo
```

Where:

- `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.
- `INSTALL-REGISTRY-HOSTNAME` is your container registry.
- `TARGET-REPOSITORY` is your target repository.

5. Add the Tanzu Build Service `full` dependencies package repository by running:

```
tanzu package repository add full-deps-package-repo \
  --url INSTALL-REGISTRY-HOSTNAME/TARGET-REPOSITORY/full-deps-package-repo:VERS
ION \
  --namespace tap-install
```

Where:

- `INSTALL-REGISTRY-HOSTNAME` is your container registry.
- `TARGET-REPOSITORY` is your target repository.
- `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.

6. Create a new `tbs-full-deps-values.yaml` and copy the `kp_default_repository` key-value pair from your `tap-values.yaml` or `tbs-values.yaml`:

```
---
 kp_default_repository: "REPO-NAME"
 kp_default_repository_secret:
   name: kp-default-repository-creds
   namespace: tap-install
```

Where `REPO-NAME` is copied from the `buildservice.kp_default_repository` field in your `tap-values.yaml` or `tbs-values.yaml`.

1. (Optional) Install the UBI builder.

   The UBI builder uses Red Hat Universal Base Image (UBI) v8 for both build and run images. This builder only supports Java and Node.js. To install the UBI builder, add the key-value pair `enable_ubi_builder: true` to your `tbs-full-deps-values.yaml`.

   ```
   ---
   enable_ubi_builder: true
   ```

2. (Optional) Install the Static builder.

   The Static builder uses Ubuntu Jammy for both build images and a minimal static run image. This builder only supports Golang. To install the Static builder, add the key-value pair `enable_static_builder: true` to your `tbs-full-deps-values.yaml`.

   ```
   ---
   enable_static_builder: true
   ```

7. Install the `full` dependencies package by running:

```
tanzu package install full-deps \
  --package full-deps.buildservice.tanzu.vmware.com \
  --version "> 0.0.0" \
```

```
  --namespace tap-install \
  --values-file VALUES-FILE
```

Where `VALUES-FILE` is the path to the `tbs-full-deps-values.yaml` you created earlier.

(Optional) Update dependencies out of band of Tanzu Application Platform releases

Tanzu Build Service dependencies might be upgraded between Tanzu Application Platform releases, for example, if a CVE is discovered in the OS (stack update) or language (buildpack update).

Automatic dependency updates enable your cluster to consume the stack and buildpack updates immediately instead of waiting for the next Tanzu Application Platform patch release to pull in the updated dependencies.

- Updates are provided through a separate package repository with available version lines for all supported Tanzu Application Platform minor versions.
- Within a version line, only patch versions are incremented to avoid breaking changes.
- You can customize the packages that you want the automatic dependency updater to update through your `tap-values.yaml` file or your full dependencies values.

Prerequisites: These steps assume a registry secret already exists in the cluster for accessing `registry.tanzu.vmware.com` and your registry.

To enable automatic dependency updates:

1. Relocate the dependency updater package repository to the air-gapped container image registry:
    - If a machine with access to both the air-gapped registry and the internet is available, you can copy the images directly by running:

      ```
      imgpkg copy \
        -b registry.tanzu.vmware.com/build-service-dependency-updater/package-r
      epo:VERSION-CONSTRAINT \
        --to-repo INTERNAL-REPO
      ```

      Where:

        - `VERSION-CONSTRAINT` is the Tanzu Application Platform version in the form of `MAJOR.MINOR.x`. For example, `1.8.x`.
        - `INTERNAL-REPO` is your repository in the air-gapped container image registry. Examples:
            - Harbor has the form `MY-REGISTRY/REPO-NAME/tbs-dep-updater`.
            - Docker Hub has the form `MY-REGISTRY/tbs-dep-updater`.
            - Google Cloud Registry has the form `MY-REGISTRY/MY-PROJECT/REPO-NAME/tbs-dep-updater`.
    - If you can only transfer the data using a physical external storage device:
        1. Copy the images into a `.tar` file from VMware Tanzu Network by running:

           ```
           imgpkg copy \
             -b registry.tanzu.vmware.com/build-service-dependency-updater/pa
           ckage-repo:VERSION-CONSTRAINT \
             --to-tar dependency-updater-VERSION-CONSTRAINT.tar \
             --include-non-distributable-layers
           ```

Where `VERSION-CONSTRAINT` is the Tanzu Application Platform version in the form of `MAJOR.MINOR.x`. For example, `1.8.x`.

2. Import the `.tar` files into the air-gapped container image registry by running:

```
imgpkg copy \
  --tar dependency-updater-VERSION-CONSTRAINT.tar \
  --to-repo INTERNAL-REPO \
  --include-non-distributable-layers \
  --registry-ca-cert-path $REGISTRY_CA_PATH
```

Where:

- `VERSION-CONSTRAINT` is the Tanzu Application Platform version in the form of `MAJOR.MINOR.x`. For example, `1.8.x`.
- `INTERNAL-REPO` is your repository in the air-gapped container image registry. Examples:
  - Harbor has the form `MY-REGISTRY/REPO-NAME/tbs-dep-updater`.
  - Docker Hub has the form `MY-REGISTRY/tbs-dep-updater`.
  - Google Cloud Registry has the form `MY-REGISTRY/MY-PROJECT/REPO-NAME/tbs-dep-updater`.

2. Add the following to your `tap-values.yaml` file:

```
buildservice:
  dependency_updates:
    allow: true
    scope: SCOPE
    include_packages: [""]
    exclude_packages: [""]
```

Where:

- `SCOPE` is the list of dependencies you want updated. The options are:
  - `stacks-only` (default): Only stacks and builders are updated. This addresses CVEs in the base image or operating system.
  - `all`: Stacks, builders, and buildpacks are updated. This addresses CVEs in the base image or operating system and CVEs in the language toolchain such as compilers, interpreters, and standard libraries.
  - `custom`: This list is empty by default. Use the `include_packages` key to add packages to be updated.

Note

You must update the Tanzu Application Platform package install and the Full Dependencies package install after changing the `tap-values.yaml`.

3. Add the Tanzu Build Service Dependency Updates package repository by running:

```
kubectl apply -f - <<EOF
  apiVersion: packaging.carvel.dev/v1alpha1
  kind: PackageRepository
  metadata:
    name: tbs-dependencies-package-repository
```

```
    namespace: tap-install
  spec:
    fetch:
      imgpkgBundle:
        image: DEPENDENCY-UPDATER-PACKAGE-REPO
        tagSelection:
          semver:
            constraints: VERSION-CONSTRAINT
EOF
```

Where:

- `DEPENDENCY-UPDATER-PACKAGE-REPO` is the location of the package repository. This is `registry.tanzu.vmware.com/build-service-dependency-updater/package-repo` for online installs and the internal container image registry for air-gapped installs.
- `VERSION-CONSTRAINT` is the Tanzu Application Platform version in the form of `MAJOR.MINOR.x`. For example, `1.8.x`.

After completing this configuration, the repository you set with `DEPENDENCY-UPDATER-PACKAGE-REPO` will be polled for updates and any new releases will automatically be made available to the cluster.

Next steps

- Configure custom CAs for Tanzu Developer Portal

Configure custom certificate authorities for Tanzu Developer Portal

This topic tells you how to configure your Tanzu Developer Portal to trust unusual certificate authorities (CA) when making outbound connections.

Tanzu Developer Portal might require custom certificates when connecting to persistent databases or custom catalog locations that require SSL. You use overlays with PackageInstalls to make this possible. There are two ways to implement this workaround: you can add a custom CA or you can deactivate all SSL verification.

Add a custom CA

The overlay previously available in this section is no longer necessary. As of Tanzu Application Platform v1.3, the value `ca_cert_data` is supported at the top level of its values file. Any number of newline-delimited CA certificates in PEM format are accepted.

For example:

```
# tap-gui-values.yaml
ca_cert_data: |
  -----BEGIN CERTIFICATE-----
  cert data here
  -----END CERTIFICATE-----

  -----BEGIN CERTIFICATE-----
  other cert data here
  -----END CERTIFICATE-----
app_config:
  # ...
```

Tanzu Developer Portal also inherits `shared.ca_cert_data` from your `tap-values.yaml` file. `shared.ca_cert_data` is newline-concatenated with `ca_certs` given directly to Tanzu Developer Portal.

```
shared:
  ca_cert_data: |
    -----BEGIN CERTIFICATE-----
    cert data here
    -----END CERTIFICATE-----

tap_gui:
  ca_cert_data: |
    -----BEGIN CERTIFICATE-----
    other cert data here
    -----END CERTIFICATE-----
  app_config:
    # ...
```

To verify that Tanzu Developer Portal has processed the custom CA certificates, check that the `ca-certs-data` volume with mount path `/etc/custom-ca-certs-data` is mounted in the Tanzu Developer Portal server pod.

Deactivate all SSL verification

To deactivate SSL verification to allow for self-signed certificates, set the Tanzu Developer Portal pod's environment variable as `NODE_TLS_REJECT_UNAUTHORIZED=0`. When the value equals `0`, certificate validation is deactivated for TLS connections.

To do this, use the `package_overlays` key in the Tanzu Application Platform values file. For instructions, see Customize Package Installation.

The following YAML is an example `Secret` containing an overlay to deactivate TLS:

```
apiVersion: v1
kind: Secret
metadata:
  name: deactivate-tls-overlay
  namespace: tap-install
stringData:
  deactivate-tls-overlay.yml: |
    #@ load("@ytt:overlay", "overlay")
    #@overlay/match by=overlay.subset({"kind":"Deployment", "metadata": {"name": "se
rver", "namespace": "NAMESPACE"}}),expects="1+"
    ---
    spec:
      template:
        spec:
          containers:
            #@overlay/match by=overlay.all,expects="1+"
            #@overlay/match-child-defaults missing_ok=True
            - env:
              - name: NODE_TLS_REJECT_UNAUTHORIZED
                value: "0"
```

Where `NAMESPACE` is the namespace in which your Tanzu Developer Portal instance is deployed. For example, `tap-gui`.

Next steps

- Configure Application Accelerator

Configure Application Accelerator

This topic describes advanced configuration options available for Application Accelerator. This includes configuring Git-Ops style deployments of accelerators and configurations for use with non-

public repositories and in air-gapped environments.

Accelerators are created either using the Tanzu CLI or by applying a YAML manifest using kubectl. Another option is Using a Git-Ops style configuration for deploying a set of managed accelerators.

Application Accelerator pulls content from accelerator source repositories using either the “Flux SourceController” or the “Tanzu Application Platform Source Controller” components. If the repository used is accessible anonymously from a public server, you do not have to configure anything additional. Otherwise, provide authentication as explained in Using non-public repositories. There are also options for making these configurations easier explained in Configuring tap-values.yaml with Git credentials secret

Using a Git-Ops style configuration for deploying a set of managed accelerators

To enable a Git-Ops style of managing resources used for deploying accelerators, there is a new set of properties for the Application Accelerator configuration. The resources are managed using a Carvel kapp-controller App in the `accelerator-system` namespace that watches a Git repository containing the manifests for the accelerators. This means that you can make changes to the manifests, or to the accelerators they point to, and the changes are reconciled and reflected in the deployed resources.

You can specify the following accelerator configuration properties when installing the Application Accelerator. The same properties are provided in the `accelerator` section of the `tap-values.yaml` file:

```
accelerator:
  managed_resources:
    enable: true
    git:
      url: GIT-REPO-URL
      ref: origin/main
      sub_path: null
      secret_ref: git-credentials
```

Where:

- `GIT-REPO-URL` is the URL of a Git repository that contains manifest YAML files for the accelerators that you want to have managed. The URL must start with `https://` or `git@`. You can specify a `sub_path` if necessary and also a `secret_ref` if the repository requires authentication. If not needed, then leave these additional properties out.

  For more information, see Configure tap-values.yaml with Git credentials secret and Creating a manifest with multiple accelerators and fragments in this topic.

Functional and Organizational Considerations

Any accelerator manifest that is defined under the `GIT-REPO-URL` and optional `sub_path` is selected by the kapp-controller app. If there are multiple manifests at the defined `GIT-REPO-URL`, they are all watched for changes and displayed to the user as a merged catalog.

For example: if you have two manifests containing multiple accelerator or fragment definitions, `manifest-1.yaml`, and `manifest-2.yaml`, on the same path in the organizational considerations. The resulting catalog is (`manifest-1.yaml` + `manifest-2.yaml`).

Examples for creating accelerators

A minimal example for creating an accelerator

A minimal example might look like the following manifest:

`spring-cloud-serverless.yaml`

```
apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
kind: Accelerator
metadata:
  name: spring-cloud-serverless
spec:
  git:
    url: https://github.com/vmware-tanzu/application-accelerator-samples
    subPath: spring-cloud-serverless
    ref:
      branch: main
```

This example creates an accelerator named `spring-cloud-serverless`. The `displayName`, `description`, `iconUrl`, and `tags` text boxes are populated based on the content under the `accelerator` key in the `accelerator.yaml` file found in the `main` branch of the Git repository at Application Accelerator Samples under the sub-path `spring-cloud-serverless`. For example:

`accelerator.yaml`

```
accelerator:
  displayName: Spring Cloud Serverless
  description: A simple Spring Cloud Function serverless app
  iconUrl: https://raw.githubusercontent.com/vmware-tanzu/application-accelerator-samp
les/main/icons/icon-cloud.png
  tags:
  - java
  - spring
  - cloud
  - function
  - serverless
  - tanzu
...
```

To create this accelerator with kubectl, run:

```
kubectl apply --namespace --accelerator-system --filename spring-cloud-serverless.yaml
```

Or, you can use the Tanzu CLI and run:

```
tanzu accelerator create spring-cloud-serverless --git-repo https://github.com/vmware-
tanzu/application-accelerator-samples.git --git-branch main --git-sub-path spring-clou
d-serverless
```

An example for creating an accelerator with customized properties

You can specify the `displayName`, `description`, `iconUrl`, and `tags` text boxes and this overrides any values provided in the accelerator's Git repository. The following example explicitly sets those text boxes and the `ignore` text box:

`my-spring-cloud-serverless.yaml`

```
apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
kind: Accelerator
metadata:
  name: my-spring-cloud-serverless
spec:
  displayName: My Spring Cloud Serverless
  description: My own Spring Cloud Function serverless app
  iconUrl: https://raw.githubusercontent.com/vmware-tanzu/application-accelerator-samp
```

```
les/main/icons/icon-cloud.png
  tags:
    - spring
    - cloud
    - function
    - serverless
  git:
    ignore: ".git/, bin/"
    url: https://github.com/vmware-tanzu/application-accelerator-samples
    subPath: spring-cloud-serverless
    ref:
      branch: test
```

To create this accelerator with kubectl, run:

```
kubectl apply --namespace --accelerator-system --filename my-spring-cloud-serverless.y
aml
```

To use the Tanzu CLI, run:

```
tanzu accelerator create my-spring-cloud-serverless --git-repo https://github.com/vmwa
re-tanzu/application-accelerator-samples --git-branch main --git-sub-path spring-cloud
-serverless \
  --description "My own Spring Cloud Function serverless app" \
  --display-name "My Spring Cloud Serverless" \
  --icon-url https://raw.githubusercontent.com/vmware-tanzu/application-accelerator-sa
mples/main/icons/icon-cloud.png \
  --tags "spring,cloud,function,serverless"
```

Note

It is not possible to provide the `git.ignore` option with the Tanzu CLI.

Creating a manifest with multiple accelerators and fragments

You might have a manifest that contains multiple accelerators or fragments. For example:

`accelerator-collection.yaml`

```
---
apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
kind: Accelerator
metadata:
  name: spring-cloud-serverless
spec:
  git:
    url: https://github.com/vmware-tanzu/application-accelerator-samples
    subPath: spring-cloud-serverless
    ref:
      branch: main
---
apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
kind: Accelerator
metadata:
  name: tanzu-java-web-app
spec:
  git:
    url: https://github.com/vmware-tanzu/application-accelerator-samples.git
    subPath: tanzu-java-web-app
    ref:
      branch: main
```

For a larger example of this, see Sample Accelerators Main. Optionally, use this to create an initial catalog of accelerators and fragments during a fresh Application Accelerator install.

Configure `tap-values.yaml` with Git credentials secret

Note

For how to create a new OAuth Token for optional Git repository creation, see Create an Application Accelerator Git repository during project creation.

When deploying accelerators using Git repositories that requires authentication or are installed with custom CA certificates, you must provide some additional authentication values in a secret. The examples in the next section provide more details. This section describes how to configure a Git credentials secret that is used in later Git-based examples.

You can specify the following accelerator configuration properties when installing Application Accelerator. The same properties are provided in the `accelerator` section of the `tap-values.yaml` file:

```
accelerator:
  git_credentials:
    secret_name: git-credentials
    username: GIT-USER-NAME
    password: GIT-CREDENTIALS
    ca_file: CUSTOM-CA-CERT
```

Where:

- `GIT-USER-NAME` is the user name for authenticating with the Git repository.
- `GIT-CREDENTIALS` is the password or access token used for authenticating with the Git repository. VMware recommends using an access token for this.
- `CUSTOM-CA-CERT` is the certificate data needed when accessing the Git repository.

This is an example of this part of a `tap-values.yaml` configuration:

```
accelerator:
  git_credentials:
    secret_name: git-credentials
    username: testuser
    password: s3cret
    ca_file: |
      -----BEGIN CERTIFICATE-----
      .
      .
      .  < certificate data >
      .
      .
      -----END CERTIFICATE-----
```

You can specify the custom CA certificate data using the shared config value `shared.ca_cert_data` and it propagates to all components that can make use of it, including the App Accelerator configuration. The example earlier produces an output such as this using the shared value:

```
shared:
  ca_cert_data: |
    -----BEGIN CERTIFICATE-----
    .
    .
```

```
    .  < certificate data >
    .
    .
    -----END CERTIFICATE-----

accelerator:
  git_credentials:
    secret_name: git-credentials
    username: testuser
    password: s3cret
```

Using non-public repositories

For GitHub repositories that aren't accessible anonymously, you must provide credentials in a Secret.

- For HTTPS repositories the secret must contain user name and password fields. The password field can contain a personal access token instead of an actual password. For more information, see Fluxcd/source-controller basic access authentication.
- For HTTPS with self-signed certificates, you can add a `.data.caFile` value to the secret created for HTTPS authentication. For more information, see fluxcd/source-controller HTTPS Certificate Authority.
- For SSH repositories, the secret must contain identity, identity.pub, and known_hosts text boxes. For more information, see fluxcd/source-controller SSH authentication.
- For Image repositories that aren't publicly available, an image pull secret might be provided. For more information, see Kubernetes documentation on using imagePullSecrets.

Examples for a private Git repository

Example using http credentials

To create an accelerator using a private Git repository, first create a secret with the HTTP credentials.

Note

For better security, use an access token as the password.

```
kubectl create secret generic https-credentials \
    --namespace accelerator-system \
    --from-literal=username=<user> \
    --from-literal=password=<access-token>
```

Verify that your secret was created by running:

```
kubectl get secret --namespace accelerator-system https-credentials -o yaml
```

The output is similar to:

```
apiVersion: v1
kind: Secret
metadata:
  name: https-credentials
  namespace: accelerator-system
type: Opaque
data:
```

```
  username: <BASE64>
  password: <BASE64>
```

After you created and verified the secret, you can create the accelerator by using the `spec.git.secretRef.name` property:

`private-acc.yaml`

```
apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
kind: Accelerator
metadata:
  name: private-acc
spec:
  displayName: private
  description: Accelerator using a private repository
  git:
    url: REPOSITORY-URL
    ref:
      branch: main
    secretRef:
      name: https-credentials
```

For https credentials, the `REPOSITORY-URL` must use `https://` as the URL scheme.

If you are using the Tanzu CLI, add the `--secret-ref` flag to your `tanzu accelerator create` command and provide the name of the secret for that flag.

Example using http credentials with self-signed certificate

To create an accelerator using a private Git repository with a self-signed certificate, create a secret with the HTTP credentials and the certificate.

Note

For better security, use an access token as the password.

```
kubectl create secret generic https-ca-credentials \
    --namespace accelerator-system \
    --from-literal=username=<user> \
    --from-literal=password=<access-token> \
    --from-file=caFile=<path-to-CA-file>
```

Verify that your secret was created by running:

```
kubectl get secret --namespace accelerator-system https-ca-credentials -o yaml
```

The output is similar to:

```
apiVersion: v1
kind: Secret
metadata:
  name: https-ca-credentials
  namespace: accelerator-system
type: Opaque
data:
  username: <BASE64>
  password: <BASE64>
  caFile: <BASE64>
```

After you have the secret created, you can create the accelerator by using the `spec.git.secretRef.name` property:

`private-acc.yaml`

```
apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
kind: Accelerator
metadata:
  name: private-acc
spec:
  displayName: private
  description: Accelerator using a private repository
  git:
    url: REPOSITORY-URL
    ref:
      branch: main
    secretRef:
      name: https-ca-credentials
```

Important

For https credentials, the `REPOSITORY-URL` must use `https://` as the URL scheme.

If you are using the Tanzu CLI, add the `--secret-ref` flag to your `tanzu accelerator create` command and provide the name of the secret for that flag.

Example using SSH credentials

To create an accelerator using a private Git repository, create a secret with the SSH credentials such as this example:

```
ssh-keygen -q -N "" -f ./identity
ssh-keyscan github.com > ./known_hosts
kubectl create secret generic ssh-credentials \
    --namespace accelerator-system \
    --from-file=./identity \
    --from-file=./identity.pub \
    --from-file=./known_hosts
```

If you have a key file already created, skip the `ssh-keygen` and `ssh-keyscan` steps and replace the values for the `kubectl create secret` command. Such as:

- `--from-file=identity=<path to your identity file>`
- `--from-file=identity.pub=<path to your identity.pub file>`
- `--from-file=known_hosts=<path to your know_hosts file>`

Verify that your secret was created by running:

```
kubectl get secret --namespace accelerator-system ssh-credentials -o yaml
```

The output is similar to :

```
apiVersion: v1
kind: Secret
metadata:
  name: ssh-credentials
  namespace: accelerator-system
type: Opaque
data:
```

```
  identity: <BASE64>
  identity.pub: <BASE64>
  known_hosts: <BASE64>
```

To use this secret when creating an accelerator, provide the secret name in the `spec.git.secretRef.name` property:

`private-acc-ssh.yaml`

```
apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
kind: Accelerator
metadata:
  name: private-acc
spec:
  displayName: private
  description: Accelerator using a private repository
  git:
    url: REPOSITORY-URL
    ref:
      branch: main
    secretRef:
      name: ssh-credentials
```

When using SSH credentials, the `REPOSITORY-URL` must include the user name as part of the URL. For example: `ssh://user@example.com:22/repository.git`. For more information, see Flux documentation.

If you are using the Tanzu CLI, add the `--secret-ref` flag to your `tanzu accelerator create` command and provide the name of the secret for that flag.

Examples for a private source-image repository

If your registry uses a self-signed certificate then you must add the CA certificate data to the configuration for the “Tanzu Application Platform Source Controller” component. Add it under `source_controller.ca_cert_data` in your `tap-values.yaml` file that is used during installation.

`tap-values.yaml`

```
source_controller:
  ca_cert_data: |-
    -----BEGIN CERTIFICATE-----
    .
    .
    .  < certificate data >
    .
    .
    -----END CERTIFICATE-----
```

Example using image-pull credentials

To create an accelerator using a private source-image repository, create a secret with the image-pull credentials:

```
create secret generic registry-credentials \
    --namespace accelerator-system \
    --from-literal=username=<user> \
    --from-literal=password=<password>
```

Verify that your secret was created by running:

```
kubectl get secret --namespace accelerator-system registry-credentials -o yaml
```

The output is similar to:

```
apiVersion: v1
kind: Secret
metadata:
  name: registry-credentials
  namespace: accelerator-system
type: Opaque
data:
  username: <BASE64>
  password: <BASE64>
```

After you have the secret created, you can create the accelerator by using the `spec.git.secretRef.name` property:

`private-acc.yaml`

```
apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
kind: Accelerator
metadata:
  name: private-acc
spec:
  displayName: private
  description: Accelerator using a private repository
  source:
    image: "registry.example.com/test/private-acc-src:latest"
    imagePullSecrets:
    - name: registry-credentials
```

If you are using the Tanzu CLI, add the `--secret-ref` flag to your `tanzu accelerator create` command and provide the name of the secret for that flag.

Configure ingress timeouts when some accelerators take longer to generate

If Tanzu Application Platform is configured to use an ingress for Tanzu Developer Portal and the Accelerator Server, then it might detect a timeout during accelerator generation. This can happen if the accelerator takes a longer time to generate than the default timeout. When this happens, Tanzu Developer Portal appears to continue to run for an indefinite period. In the IDE extension, it shows a `504` error. To mitigate this, you can increase the timeout value for the HTTPProxy resources used for the ingress by applying secrets with overlays to edit the HTTPProxy resources.

Configure an ingress timeout overlay secret for each HTTPProxy

For Tanzu Developer Portal, create the following overlay secret in the `tap-install` namespace:

```
apiVersion: v1
kind: Secret
metadata:
  name: patch-tap-gui-timeout
  namespace: tap-install
stringData:
  patch.yaml: |
    #@ load("@ytt:overlay", "overlay")
    #@overlay/match by=overlay.subset({"kind": "HTTPProxy", "metadata": {"name": "tap-
gui"}})
    ---
    spec:
      routes:
        #@overlay/match by=overlay.subset({"services": [{"name": "server"}]})
        #@overlay/match-child-defaults missing_ok=True
```

```
        - timeoutPolicy:
            idle: 30s
            response: 30s
```

For Accelerator Server (used for IDE extension), create the following overlay secret in the `tap-install` namespace:

```
apiVersion: v1
kind: Secret
metadata:
  name: patch-accelerator-timeout
  namespace: tap-install
stringData:
  patch.yaml: |
    #@ load("@ytt:overlay", "overlay")
    #@overlay/match by=overlay.subset({"kind": "HTTPProxy", "metadata": {"name": "acce
lerator"}})
    ---
    spec:
      routes:
        #@overlay/match by=overlay.subset({"services": [{"name": "acc-server"}]})
        #@overlay/match-child-defaults missing_ok=True
        - timeoutPolicy:
            idle: 30s
            response: 30s
```

Apply the timeout overlay secrets in tap-values.yaml

Add the following `package_overlays` section to `tap-values.yaml` before installing or updating Tanzu Application Platform:

```
package_overlays:
- name: tap-gui
  secrets:
  - name: patch-tap-gui-timeout
- name: accelerator
  secrets:
  - name: patch-accelerator-timeout
```

Configuring skipping TLS verification for access to Source Controller

You can configure the Flux or Tanzu Application Platform Source Controller to use Transport Layer Security (TLS) and use custom certificates. In that case, configure the Accelerator System to skip the TLS verification for calls to access the sources by providing the following property in the `accelerator` section of the `tap-values.yaml` file:

```
sources:
  skip_tls_verify: true
```

Enabling TLS for Accelerator Server

To enable TLS for the Accelerator Server, the following properties must be provided in the `accelerator` section of the `tap-values.yaml` file:

```
server:
  tls:
    enabled: true
```

```
    key: SERVER-PRIVATE-KEY
    crt: SERVER-CERTIFICATE
```

Where:

- `SERVER-PRIVATE-KEY` is the pem encoded server private key.
- `SERVER-CERTIFICATE` is the pem encoded server certificate.

Here is a sample `tap-values.yaml` configuration with TLS enabled for Accelerators Server:

```
server:
  tls:
    enabled: true
    key: |
      -----BEGIN PRIVATE KEY-----
      .
      .  < private key data >
      .
      -----END PRIVATE KEY-----
    crt: |
      -----BEGIN CERTIFICATE-----
      .
      .  < certificate data >
      .
      -----END CERTIFICATE-----
```

Configuring skipping TLS verification of Engine calls for Accelerator Server

If you configure the Accelerator Engine to use TLS and use custom certificates, then you can configure the Accelerator Server to skip the TLS verification for calls to the Engine by providing the following property in the `accelerator` section of the `tap-values.yaml` file:

```
server:
  engine_skip_tls_verify: true
```

Enabling TLS for Accelerator Engine

To enable TLS for the Accelerator Engine, the following properties are provided in the `accelerator` section of the `tap-values.yaml` file:

```
engine:
  tls:
    enabled: true
    key: ENGINE-PRIVATE-KEY
    crt: ENGINE-CERTIFICATE
```

Where:

- `ENGINE-PRIVATE-KEY` is the pem encoded acc-engine private key.
- `ENGINE-CERTIFICATE` is the pem encoded acc-engine certificate.

Here is a sample `tap-values.yaml` configuration with TLS enabled for Accelerators Engine:

```
engine:
  tls:
    enabled: true
    key: |
      -----BEGIN PRIVATE KEY-----
      .
```

```
    .  < private key data >
    .
    -----END PRIVATE KEY-----
  crt: |
    -----BEGIN CERTIFICATE-----
    .
    .  < certificate data >
    .
    -----END CERTIFICATE-----
```

Next steps

- Use vulnerability scanning in offline and air-gapped environments

Use vulnerability scanning in offline and air-gapped environments

Note

For air-gapped (offline) environments, VMware recommends using Aqua Security's Trivy scanner with Scan 2.0. This greatly simplifies the installation and maintenance experiences over Anchore Grype and Scan 1.0. For more information on Scan 1.0 versus Scan 2.0, see Overview of Supply Chain Security Tools - Scan.

Using Trivy with SCST - Scan 2.0

The Aqua Trivy vulnerability scanner uses two databases to perform vulnerability scans:

1. Vulnerability Database: This database contains the vulnerability information used to scan artifacts. This database is built every six hours on GitHub and is distributed using GitHub Container registry (GHCR).
2. Java Index Database: This database enables Trivy to identify the `groupId`, `artifactId`, and `version` of JAR files. It is built once a day on GitHub and distributed using GitHub Container registry (GHCR).

In an online installation of Tanzu Application Platform, these databases are automatically downloaded from GHCR (Github Container Registry) with each scan execution. To enable scanning in an offline environment, these two databases must be relocated to your private container image registry, and Trivy must be configured to use your private location instead of downloading from GHCR.

For more information about the Trivy vulnerability databases, see the Trivy documentation.

Relocate Trivy Images

The databases are stored in an OCI-compliant registry as OCI artifacts. To copy these to your private registry, Trivy recommends using the ORAS CLI.

To make the Trivy databases available in your private registry:

1. Create a repository within your private registry. This example uses aquasecurity to remain consistent with the GHCR repository.
2. Copy the vulnerability database from GHCR to your private registry:

```
oras cp ghcr.io/aquasecurity/trivy-db:2 CONTAINER-REGISTRY/aquasecurity/trivy-d
```

```
b:2
```

> **Note**
>
> The Trivy scanner is hardcoded to use the `2` tag for the vulnerability database.

Where `CONTAINER-REGISTRY` is the URL for your registry. For example, `harbor.example.com`

3. Copy the Java index database from GHCR to your private registry:

```
oras cp ghcr.io/aquasecurity/trivy-java-db:1 harbor.CONTAINER-REGISTRY/aquasecu
rity/trivy-java-db:1
```

Where `CONTAINER-REGISTRY` is the URL for your registry. For example, `harbor.example.com`

> **Note**
>
> The Trivy scanner is hardcoded to use the `1` tag for the Java index database.

The databases are now available locally in your air-gapped environment. The next step is to configure the supply chain to use the air-gapped location for Trivy. For more information about using Trivy in an air-gapped environment, see the Trivy documentation.

Configure Trivy in the Supply Chain

Now that you have relocated the images, you must configure the scanning step of the supply chain to use Trivy with the SCST - Scan 2.0, and provide the location of the database artifacts in the private registry.

1. To enable SCST - Scan 2.0 with Trivy with private registries, update your `tap-values.yaml` file to specify the Trivy `ClusterImageTemplate`. For example:

```
ootb_supply_chain_testing_scanning:
  image_scanner_template_name: image-vulnerability-scan-trivy
  scanning:
    steps:
      env_vars:
      - name: TRIVY_DB_REPOSITORY
        value: CONTAINER-REGISTRY/aquasecurity/trivy-db
      - name: TRIVY_JAVA_DB_REPOSITORY
        value: CONTAINER-REGISTRY/aquasecurity/trivy-java-db
      - name: TRIVY_OFFLINE_SCAN
        value: "true"
```

Where `CONTAINER-REGISTRY` is the URL for your registry. For example, `harbor.example.com`

2. Update your Tanzu Application Platform installation by running:

```
tanzu package installed update tap -p tap.tanzu.vmware.com -v TAP-VERSION  --va
lues-file tap-values.yaml -n tap-install
```

Where `TAP-VERSION` is the version of Tanzu Application Platform installed.

Trivy is now configured to use resources in your air-gapped environment when executed with the supply chain. For more information about using Trivy in an air-gapped environment, see the Trivy documentation.

Using Grype with Scan 1.0

VMware recommends using Aqua Trivy with SCST - Scan 2.0 for offline or air-gapped environments due to the simplified setup and maintenance. However, if you require policy enablement based on vulnerability scanning, use the following steps to enable Grype scanning with SCST - Scan 1.0.

The Grype CLI attempts to perform two over-the-Internet calls:

- One to verify for later versions of the CLI.
- One to update the vulnerability database before scanning.

For the Grype CLI to function in an offline or air-gapped environment, the vulnerability database must be hosted in the environment. You must configure the Grype CLI with the internal URL.

The Grype CLI accepts environment variables to satisfy these needs.

Host the Grype vulnerability database

To host the Grype vulnerability database in an air-gapped environment:

1. Retrieve the Grype listing file from its public endpoint: https://toolbox-data.anchore.io/grype/databases/listing.json.
2. Create your own `listing.json` file.

   Note Different Grype versions require specific database schema versions. To avoid compatibility issues between different versions, include a database schema for each version. For example:

```
    {
      "available": {
        "1": [
          {
            "built": "2023-06-16T01:33:30Z",
            "version": 1,
            "url": "https://toolbox-data.anchore.io/grype/databases/vulnerabili
ty-db_v1_2023-06-16T01:33:30Z_1621f4169ffd15bea9e5.tar.gz",
            "checksum": "sha256:3f2c1b432945cca9a69b2e604f6fb231fec450fdd27f494
6fc5608692b63a9d1"
          }
        ],
        "2": [
          {
            "built": "2023-06-16T01:33:30Z",
            "version": 2,
            "url": "https://toolbox-data.anchore.io/grype/databases/vulnerabili
ty-db_v2_2023-06-16T01:33:30Z_d6eee5e78d9b78285e1a.tar.gz",
            "checksum": "sha256:7b7e3a2a7712c72b8c5cc777733c4d8d140d8cfee65e4f0
4540abbdfe3ef1f65"
          }
        ],
        "3": [
          {
            "built": "2023-06-16T01:33:30Z",
            "version": 3,
            "url": "https://toolbox-data.anchore.io/grype/databases/vulnerabili
ty-db_v3_2023-06-16T01:33:30Z_f96ae38a7b05987c3ece.tar.gz",
            "checksum": "sha256:8ea9fae3fda3bf3bf35bd5e5eb656fc127b59cd3c42db4c
36795556aab8a9cf0"
          }
        ],
        "4": [
          {
```

```
            "built": "2023-06-16T01:33:30Z",
            "version": 4,
            "url": "https://toolbox-data.anchore.io/grype/databases/vulnerabili
ty-db_v4_2023-06-16T01:33:30Z_13bba2fa8ff62b7f8b26.tar.gz",
            "checksum": "sha256:3b53d20241b88e5aa45feb817b325c53d6efbe9fa1fc5a6
7eeddaecafa7687e0"
          }
        ],
        "5": [
          {
            "built": "2023-06-16T01:33:30Z",
            "version": 5,
            "url": "https://toolbox-data.anchore.io/grype/databases/vulnerabili
ty-db_v5_2023-06-16T01:33:30Z_e07da3853f6db6eb1104.tar.gz",
            "checksum": "sha256:93d4d9d2f9e39f86570f832cf85b7149a949ca6f1613581
b10c12393509d884f"
          }
        ]
      }
    }
```

Where `url` points to a tarball containing Grype's `vulnerability.db` and `metadata.json` files.

3. Download and host the tarballs in your internal file server.

> **Note**
>
> Some storage solutions for internal file servers change the name of TAR files automatically because of their limits. Notice these modified names and reflect the changes in the `url`. Ensure that the timestamp in the name is correctly formatted because Grype parses the name of TAR artifact to get the timestamp.

4. Update the download `url` to point at your internal endpoint.

   For information about setting up an offline vulnerability database, see the Anchore Grype README in GitHub.

To enable Grype in offline air-gapped environments

1. Add the following to your `tap-values.yaml` file:

```
grype:
  db:
    dbUpdateUrl: INTERNAL-VULN-DB-URL
```

   Where `INTERNAL-VULN-DB-URL` is the URL that points to the internal file server.

2. Update Tanzu Application Platform:

```
tanzu package installed update tap -f tap-values.yaml -n tap-install
```

Configure Grype environmental variables

1. Create a secret that contains the ytt overlay to add the Grype environment variable to the ScanTemplates.

```
apiVersion: v1
kind: Secret
metadata:
```

```
  name: grype-airgap-environmental-variables
  namespace: tap-install
stringData:
  patch.yaml: |
    #@ load("@ytt:overlay", "overlay")

    #@overlay/match by=overlay.subset({"kind":"ScanTemplate"}),expects="1+"
    ---
    spec:
      template:
        initContainers:
          #@overlay/match by=overlay.subset({"name": "scan-plugin"}), expects
="1+"
          - name: scan-plugin
            #@overlay/match missing_ok=True
            env:
              #@overlay/append
              - name: GRYPE_CHECK_FOR_APP_UPDATE
                value: "false"
```

Where `spec.template.initContainers[]` specifies setting one or more environment variables in the `scan-plugin` `initContainer`.

Note

If you are using the Namespace Provisioner to provision a new developer namespace and want to apply a package overlay for Grype, you must import the overlay `Secret`. See Import overlay secrets.

Troubleshooting

ERROR failed to fetch latest cli version

Symptom

Error message:

```
ERROR failed to fetch latest version: Get "https://toolbox-data.anchore.io/grype/releases/latest/VERSION": dial tcp: lookup toolbox-data.anchore.io on [::1]:53: read udp [::1]:65010->[::1]:53: read: connection refused
```

Cause

The Grype CLI checks for later versions of the CLI by contacting the anchore endpoint over-the-Internet.

Solution

This message is a warning and the Grype scan still runs.

To deactivate this check, set the environment variable `GRYPE_CHECK_FOR_APP_UPDATE` to `false` by using a package overlay:

1. Create a secret that contains the ytt overlay to add the Grype environment variable to the ScanTemplates.

   ```
   apiVersion: v1
   kind: Secret
   ```

```
metadata:
  name: grype-airgap-deactivate-cli-check-overlay
  namespace: tap-install #! namespace where tap is installed
stringData:
  patch.yaml: |
    #@ load("@ytt:overlay", "overlay")

    #@overlay/match by=overlay.subset({"kind":"ScanTemplate"}),expects="1+"
    ---
    spec:
      template:
        initContainers:
          #@overlay/match by=overlay.subset({"name": "scan-plugin"}), expects
="1+"
          - name: scan-plugin
            #@overlay/match missing_ok=True
            env:
              #@overlay/append
              - name: GRYPE_CHECK_FOR_APP_UPDATE
                value: "false"
```

2. Configure `tap-values.yaml` to use `package_overlays`. Add the following to your `tap-values.yaml` file:

```
package_overlays:
  - name: "grype"
    secrets:
        - name: "grype-airgap-deactivate-cli-check-overlay"
```

3. Update Tanzu Application Platform:

```
tanzu package installed update tap -f tap-values.yaml -n tap-install
```

Database is too old

Symptom

Error message:

```
1 error occurred:
  * db could not be loaded: the vulnerability database was built N days/weeks ago (max
allowed age is 5 days)
```

Cause

Grype needs up-to-date vulnerability information to provide accurate matches. By default, it fails to run if the local database was not built in the last 5 days.

Solution

There are two options to resolve this:

1. Stale databases weaken your security posture. VMware recommends updating the database daily.
2. If you cannot update the database daily, configure the data staleness check using the environment variable `GRYPE_DB_MAX_ALLOWED_BUILT_AGE` and apply a package overlay:
    1. Create a secret that contains the ytt overlay to add the Grype environment variable to the ScanTemplates.

```
apiVersion: v1
kind: Secret
metadata:
  name: grype-airgap-override-stale-db-overlay
  namespace: tap-install #! namespace where tap is installed
stringData:
  patch.yaml: |
    #@ load("@ytt:overlay", "overlay")

    #@overlay/match by=overlay.subset({"kind":"ScanTemplate"}),expects="1
+"
    ---
    spec:
      template:
        initContainers:
          #@overlay/match by=overlay.subset({"name": "scan-plugin"}), exp
ects="1+"
          - name: scan-plugin
            #@overlay/match missing_ok=True
            env:
              #@overlay/append
              - name: GRYPE_DB_MAX_ALLOWED_BUILT_AGE #! see note on best
practices
                value: "120h"
```

Note

The default maximum allowed built age of Grype's vulnerability database is 5 days. This means that scanning with a 6 day old database causes the scan to fail. You can use the `GRYPE_DB_MAX_ALLOWED_BUILT_AGE` parameter to override the default in accordance with your security posture.

2. Configure `tap-values.yaml` to use `package_overlays`. Add the following to your `tap-values.yaml` file:

```
package_overlays:
  - name: "grype"
    secrets:
        - name: "grype-airgap-override-stale-db-overlay"
```

3. Update Tanzu Application Platform:

```
tanzu package installed update tap -f tap-values.yaml -n tap-install
```

Vulnerability database is invalid

Symptom

Error message:

```
scan-pod[scan-plugin]  1 error occurred:
scan-pod[scan-plugin]  * failed to load vulnerability db: vulnerability database is in
valid (run db update to correct): database metadata not found: /.cache/grype/db/5
```

Solution

Examine the `listing.json` file you created. This matches the format of the listing file. The listing file is located at Anchore Grype's public endpoint. See the Grype README.md in GitHub.

An example `listing.json`:

```
{
  "available": {
    "5": [
      {
        "built": "2023-03-28T01:29:38Z",
        "version": 5,
        "url": "https://toolbox-data.anchore.io/grype/databases/vulnerability-db_v5_20
23-03-28T01:29:38Z_e49d318c32a6113eed07.tar.gz",
        "checksum": "sha256:408ce2932f04dee929a5df524e92494f2d635c6b19e30ff9f0a50425b1
fc29a1"
      },
      .....
    ]
  }
}
```

Where:

- `5` refers to the Grype vulnerability database schema.
- `built` is the build timestamp in the format `yyyy-MM-ddTHH:mm:ssZ`.
- `url` is the download URL for the tarball containing the database. This points at your internal endpoint. The tarball contains the following files:
    - `vulnerability.db` is an SQLite file that is Grype's vulnerability database. Each time the data shape of the vulnerability database changes, a new schema is created. Different Grype versions require specific database schema versions. For example, Grype `v0.54.0` requires database schema version v5.
    - `metadata.json` file
- `checksum` is the SHA used to verify the database's integrity.

Verify these possible reasons why the vulnerability database is not valid:

1. The database schema is invalid. Confirm that the required database schema for the installed Grype version is used. Confirm that the top level version key matches the nested `version`. For example, the top level version `1` in the following snippet does not match the nested `version: 5`.

    ```
    {
      "available": {
        "1": [{
                "built": "2023-02-08T08_17_20Z",
                "version": 5,
                "url": "https://INTERNAL-ENDPOINT/PATH-TO-TARBALL/vulnerability-db_v
    5_2023-02-08T08_17_20Z_6ef73016d160043c630f.tar.gz",
                "checksum": "sha256:aab8d369933c845878ef1b53bb5c26ee49b91ddc5cd87c9e
    b57ffb203a88a72f"
        }]
      }
    }
    ```

    Where `PATH-TO-TARBALL` is the path to the tarball containing the vulnerability database.

    As stale databases weaken your security posture, VMware recommends using the newest entry of the relevant schema version in the `listing.json` file. See Anchore's grype-db in GitHub.

2. The `built` parameters in the `listing.json` file are incorrectly formatted. The proper format is `yyyy-MM-ddTHH:mm:ssZ`.
3. The `url` that you modified to point at an internal endpoint is not reachable from the cluster. For information about verifying connectivity, see Debug Grype database in a cluster.
4. Verify if there are syntax errors in the listing.json:

   ```
   grype db check
   ```

5. Validate the configured listing.json:

   ```
   grype db list -o raw
   ```

Debug Grype database in a cluster

1. Describe the failed source scan or image scan to verify the name of the ScanTemplate being used.
   - For `sourcescan`, run:

     ```
     kubectl describe sourcescan SCAN-NAME -n DEV-NAMESPACE
     ```

   - For `imagescan`, run:

     ```
     kubectl describe imagescan SCAN-NAME -n DEV-NAMESPACE
     ```

   Where `SCAN-NAME` is the name of the source or image scan that failed.
2. Pause reconciliation of the `grype.scanning.apps.tanzu.vmware.com` package:

   ```
   kctrl package installed pause -i <PACKAGE-INSTALL-NAME> -n tap-install
   ```

   Where `PACKAGE-INSTALL-NAME` is the name of the `grype.scanning.apps.tanzu.vmware.com` package, for example, grype
3. Edit the ScanTemplate's `scan-plugin` container to include a "sleep" entrypoint which allows you to troubleshoot inside the container:

   ```
   - name: scan-plugin
     volumeMounts:
       ...
     image: #@ data.values.scanner.image
     imagePullPolicy: IfNotPresent
     env:
       ...
     command: ["/bin/bash"]
     args:
     - "sleep 1800" # insert 30 min sleep here
   ```

4. Re-run the scan.
5. Get the name of the `scan-plugin` pod.

   ```
   kubectl get pods -n DEV-NAMESPACE
   ```

6. Get a shell to the container.

   ```
   kubectl exec --stdin --tty SCAN-PLUGIN-POD -c step-scan-plugin -- /bin/bash
   ```

Where `SCAN-PLUGIN-POD` is the name of the `scan-plugin` pod. For more information, see the Kubernetes documentation.

7. Inside the container, run Grype CLI commands to report database status and verify connectivity from the cluster to the mirror. See the Grype documentation in GitHub.
    - Report current status of Grype's database, such as location, build date, and checksum:

      ```
      grype db status
      ```

8. Ensure that the built parameters in the `listing.json` have timestamps in this proper format `yyyy-MM-ddTHH:mm:ssZ`.
9. After you complete troubleshooting, to trigger reconciliation, run:

    ```
    kctrl package installed kick -i <PACKAGE-INSTALL-NAME> -n tap-install
    ```

    Where `PACKAGE-INSTALL-NAME` is the name of the `grype.scanning.apps.tanzu.vmware.com` package, such as Grype.

Grype package overlays are not applied to scantemplates created by Namespace Provisioner

If you used the Namespace Provisioner to provision a new developer namespace and want to apply a package overlay for Grype, see Import overlay secrets.

Set up developer namespaces to use your installed packages

For details about how to automatically set up your developer namespaces, see Provision developer namespaces in Namespace Provisioner.

Additional configuration for testing and scanning

If you plan to install or have already installed Out of the Box Supply Chains with Testing and Scanning, you can use Namespace Provisioner to set up the required resources. For more information, see Customize installation in the Namespace Provisioner documentation for configuration steps.

Legacy namespace setup

To use the legacy manual process for setting up developer namespaces, see Legacy namespace setup.

Next steps

For more information about the Namespace Provisioner mode, see Work with Git repositories in air-gapped environments with Namespace Provisioner.

For more information about the manual mode, see Deploy an air-gapped workload.

Install IDE extensions in your air-gapped environment

This topic tells you how to install IDE extensions in your air-gapped environment.

To install VS Code or IntelliJ extensions in an air-gapped environment, you cannot use IDE's built-in UI, because it downloads and install extensions directly from VS Code or IntelliJ Marketplace.

The following are high-level steps to install IDE extensions in your air-gapped environment:

1. Outside the air-gapped environment:
    1. Download the extension as an archive from VS Code or IntelliJ Marketplace.
    2. Copy the extension to a location that is accessible from within the air-gapped environment.
2. In the air-gapped environment:
    1. Install the extension into the IDE by using the archive generated earlier.

Install VS Code in your air-gapped environment

Follow these steps to retrieve the `.vsix` archive and install VS Code in your air-gapped environment:

1. Find the extension you want to install on VS Code Marketplace. For example:
    - Tanzu Developer Tools for Vscode
    - Tanzu App Accelerator for Vscode
2. In a column on the right side of the screen, under **Resources**, click the **Download Extension** link.

    A file called `vmware.tanzu-dev-tools-${version}.vsix` is downloaded.
3. Save the file to a location that is accessible from your air-gapped environment. For example, a USB drive.
4. Repeat these steps for all extensions you want to install, including any dependencies.

    For example, Tanzu Developer Tools for VS Code requires all of the following extensions as dependencies:
    - Red Hat Java
    - Red Hat Yaml
    - Debugger for Java

    The Application Accelerator extension, on the other hand, does not require additional dependencies.
5. In your air-gapped environment, install VS Code extensions as follows:
    1. Open VS Code
    2. Open the command palette by pressing CTRL-SHIFT-P or CMD-SHIFT-P on Mac.
    3. In the search box, type **vsix** and select **Install from VSIX…**.

    You can script this step by using commands such as:

    ```
    code --install-extension ${path_to_vsix_file}
    ```

Install IntelliJ in your air-gapped environment

Follow these steps to retrieve the `.zip` archive and install IntelliJ in your air-gapped environment:

1. Find the extension you want to install on Jetbrains Marketplace. For example, Tanzu Developer Tools for IntelliJ.

2. Click **Get** near the top-right of the screen.
3. Find the version you want to download and click the **Download** link.

   A file called `Tanzu_Developer_Tools-${version}.zip` is downloaded.
4. Save the file to a location that is accessible from your air-gapped environment. For example, a USB drive.
5. Repeat these steps for all extensions you want to install.
6. Follow the instructions in the IntelliJ documentation to install IntelliJ.

Install Tanzu Application Platform (AWS)

You can install Tanzu Application Platform (commonly known as TAP) on Amazon Elastic Kubernetes Services (EKS) by using Amazon Elastic Container Registry (ECR).

To install, take the following steps.

Step	Task	Link
1.	Review the prerequisites to ensure that you have set up everything required before beginning the installation	Prerequisites
2.	Accept Tanzu Application Platform EULAs and install the Tanzu CLI	Accept Tanzu Application Platform EULAs and installing the Tanzu CLI
3.	Create AWS Resources (EKS Cluster, roles, etc)	Create AWS Resources
4.	Install Cluster Essentials for Tanzu	Deploy Cluster Essentials
5.	Add the Tanzu Application Platform package repository, prepare your Tanzu Application Platform profile, and install the profile to the cluster	Install the Tanzu Application Platform package and profiles
6.	(Optional) Install any additional packages that were not in the profile	Install individual packages
7.	Set up developer namespaces to use your installed packages	Set up developer namespaces to use your installed packages
8.	Install developer tools into your integrated development environment (IDE)	Install Tanzu Developer Tools for your VS Code

After installing Tanzu Application Platform on your Kubernetes clusters, get started with Tanzu Application Platform and create your ECR repositories for your workload, such as `tanzu-application-platform/tanzu-java-web-app-default`, `tanzu-application-platform/tanzu-java-web-app-default-bundle`, and `tanzu-application-platform/tanzu-java-web-app-default-source`.

Install Tanzu Application Platform (AWS)

You can install Tanzu Application Platform (commonly known as TAP) on Amazon Elastic Kubernetes Services (EKS) by using Amazon Elastic Container Registry (ECR).

To install, take the following steps.

Step	Task	Link
1.	Review the prerequisites to ensure that you have set up everything required before beginning the installation	Prerequisites
2.	Accept Tanzu Application Platform EULAs and install the Tanzu CLI	Accept Tanzu Application Platform EULAs and installing the Tanzu CLI
3.	Create AWS Resources (EKS Cluster, roles, etc)	Create AWS Resources
4.	Install Cluster Essentials for Tanzu	Deploy Cluster Essentials

Step	Task	Link
5.	Add the Tanzu Application Platform package repository, prepare your Tanzu Application Platform profile, and install the profile to the cluster	Install the Tanzu Application Platform package and profiles
6.	(Optional) Install any additional packages that were not in the profile	Install individual packages
7.	Set up developer namespaces to use your installed packages	Set up developer namespaces to use your installed packages
8.	Install developer tools into your integrated development environment (IDE)	Install Tanzu Developer Tools for your VS Code

After installing Tanzu Application Platform on your Kubernetes clusters, get started with Tanzu Application Platform and create your ECR repositories for your workload, such as `tanzu-application-platform/tanzu-java-web-app-default`, `tanzu-application-platform/tanzu-java-web-app-default-bundle`, and `tanzu-application-platform/tanzu-java-web-app-default-source`.

Create AWS Resources for Tanzu Application Platform

To install Tanzu Application Platform (commonly known as TAP) within the Amazon Web Services (AWS) Ecosystem, you must create several AWS resources. Use this topic to learn how to create:

- An Amazon Elastic Kubernetes Service (EKS) cluster to install Tanzu Application Platform.
- Identity and Access Management (IAM) roles to allow authentication and authorization to read and write from Amazon Elastic Container Registry (ECR).
- ECR Repositories for the Tanzu Application Platform container images. This is because AWS ECR does not support automatically creating container repositories on initial push. For more information, see the AWS repository in GitHub.

Creating these resources enables Tanzu Application Platform to use an IAM role bound to a Kubernetes service account for authentication, rather than the typical username and password stored in a Kubernetes secret strategy. For more information, see this AWS documentation.

This is important when using ECR because authenticating to ECR is a two-step process:

1. Retrieve a token using your AWS credentials.
2. Use the token to authenticate to the registry.

To increase security, the token has a lifetime of 12 hours. This makes storing it as a secret for a service impractical because it has to be refreshed every 12 hours.

Using an IAM role on a service account mitigates the need to retrieve the token at all because it is handled by credential helpers within the services.

Prerequisites

There are numerous methods to manage AWS cloud resources and create EKS clusters. The method presented in the following guide was chosen for simplicity.

Before installing Tanzu Application Platform on AWS, you need:

- An AWS Account. You need to create all of your resources within Amazon Web Services, so you need an Amazon account. For more information, see How do I create and activate a new AWS account?. You need your account ID for this walkthrough.
- AWS CLI. This walkthrough uses the AWS CLI to both query and configure resources in AWS, such as IAM roles. For more information, see this AWS documentation.
- `eksctl` command line. The `eksctl` command line helps you manage the life cycle of EKS clusters. This guide uses it to create clusters. To install `eksctl`, see the eksctl

documentation.

Export environment variables

Variables are used throughout this guide. To simplify the process and minimize the opportunity for errors, export these variables:

```
export AWS_ACCOUNT_ID=012345678901
export AWS_REGION=us-west-2
export EKS_CLUSTER_NAME=tap-on-aws
```

Where:

Variable	Description
AWS_ACCOUNT_ID	Your AWS account ID
AWS_REGION	The AWS region you are going to deploy to
EKS_CLUSTER_NAME	The name of your EKS Cluster

Create an EKS cluster

To create an EKS cluster in the specified region, run:

```
eksctl create cluster --name $EKS_CLUSTER_NAME --managed --region $AWS_REGION --instan
ce-types t3.xlarge --version 1.28 --with-oidc -N 5
```

Creating the control plane and node group can take anywhere from 30-60 minutes.

Note

This step is optional if you already have an existing EKS Cluster v1.23 or later with OpenID Connect (OIDC) authentication enabled. For more information about how to enable the OIDC provider, see AWS documentation.

Install the EBS CSI driver

Tanzu Application Platform requires stateful services. Starting from EKS v1.23, the EBS CSI driver is no longer installed by default. For more information about how to install the EBS CSI driver, see the AWS documentation.

Create the platform container repositories

ECR requires that the container repositories are already created for images to be pushed to them. For Tanzu Application Platform, you must create the following two repositories:

- A repository to store the Tanzu Application Platform service container images
- A repository to store Tanzu Build Service generated Base OS and Builder container images

To create these repositories, run:

```
aws ecr create-repository --repository-name tap-images --region $AWS_REGION
aws ecr create-repository --repository-name tap-build-service --region $AWS_REGION
```

Depending on your installation choices, you might also require the following additional system-related repositories:

- A repository to store Tanzu Build Service full dependencies container images
- A repository to store Tanzu Application Platform's Local Source Proxy container images
- A repository to store Tanzu Cluster Essentials container images

To create these repositories, run:

```
aws ecr create-repository --repository-name full-deps --region $AWS_REGION
aws ecr create-repository --repository-name tap-lsp --region $AWS_REGION
aws ecr create-repository --repository-name tanzu-cluster-essentials --region $AWS_REG
ION
```

Name the repositories any name you want, but remember the names for when you later build the configuration.

Create the workload container repositories

Similar to the platform container repositories, you must create repositories for each workload that Tanzu Application Platform creates before creating any workloads so that a repository is available to upload container images and workload bundles.

When installing Tanzu Application Platform, you must specify a prefix for all workload registries. This topic uses `tanzu-application-platform` as the default value, but you can customize this value in the profile configuration created in Install Tanzu Application Platform package and profiles on AWS.

To use the default value, create two workload repositories for each workload with the following format:

```
tanzu-application-platform/WORKLOADNAME-NAMESPACE
tanzu-application-platform/WORKLOADNAME-NAMESPACE-bundle
```

For example, to create these repositories for the sample workload `tanzu-java-web-app` in the `default` namespace, you can run the following ECR command:

```
aws ecr create-repository --repository-name tanzu-application-platform/tanzu-java-web-
app-default --region $AWS_REGION
aws ecr create-repository --repository-name tanzu-application-platform/tanzu-java-web-
app-default-bundle --region $AWS_REGION
```

Note

The default Supply Chain Choreographer method of storing Kubernetes configuration is RegistryOps, which requires the `bundle` repository. If you enabled the GitOps capability, this repository is not required. For more information about the differences between RegistryOps and GitOps, see Use GitOps or RegistryOps with Supply Chain Choreographer.

Create IAM roles

By default, the EKS cluster is provisioned with an EC2 instance profile that provides read-only access for the entire EKS cluster to the ECR registry within your AWS account. For more information, see this AWS documentation.

However, some of the services within Tanzu Application Platform require write access or batch read access to the container repositories. To provide that access, create IAM roles and add the ARN to the Kubernetes service accounts that those services use. This ensures that only the required services have access to write container images to ECR and the ability for batch read access, rather than a blanket policy that applies to the entire cluster.

Create the following IAM Roles:

- Tanzu Build Service: Gives write access to the repository to allow the service to automatically upload new images. Also provides elevated batch read access to the `tap-images` and `full-deps` repositories. This is limited in scope to the service account for `kpack` and the dependency updater.
- Workload: Gives write access to the entire ECR registry with a prepended path. Also provides elevated batch read access to the `full-deps` repository if you use Tanzu Build Service full dependencies. This prevents you from updating the policy for each new workload created.
- Local Source Proxy: Gives write access to the repository to allow the service to automatically upload new images. This is limited in scope to the service account for Local Source Proxy.

To create the roles, you must establish two policies:

- Trust Policy: Limits the scope to the OIDC endpoint for the Kubernetes cluster and the Kubernetes service account you attach the role to.
- Permission Policy: Limits the scope of actions the role can take on resources.

Note

These policies attempt to achieve a least privilege model. Review them to confirm they adhere to your organization's policies.

To simplify this walkthrough, use a script to create these policy documents and the roles. This script outputs the files and then creates the IAM roles by using the policy documents. If Local Source Proxy is not in your installation plan, you can omit the associated commands.

Run:

```
# Retrieve the OIDC endpoint from the Kubernetes cluster and store it for use in the p
olicy.
export OIDCPROVIDER=$(aws eks describe-cluster --name $EKS_CLUSTER_NAME --region $AWS_
REGION --output json | jq '.cluster.identity.oidc.issuer' | tr -d '"' | sed 's/http
s:\/\///')
cat << EOF > build-service-trust-policy.json

Next steps

- Deploy Cluster Essentials

Important

When you use a VMware Tanzu Kubernetes Grid cluster, you do not need to install Cluster Essentials because the contents of Cluster Essentials are already installed on your cluster.

- Install Tanzu Application Platform package and profiles on AWS

Install Tanzu Application Platform package and profiles on AWS

This topic tells you how to install Tanzu Application Platform (commonly known as TAP) packages from your Tanzu Application Platform package repository on to AWS.

Before installing the packages, ensure you have:

- Completed the Prerequisites.
- Created AWS Resources.
- Accepted Tanzu Application Platform EULA and installed Tanzu CLI with any required plug-ins.
- Installed Cluster Essentials for Tanzu.

Relocate images to a registry

VMware recommends relocating the images from VMware Tanzu Network registry to your own container image registry before attempting installation. If you don't relocate the images, Tanzu Application Platform will depend on VMware Tanzu Network for continued operation, and VMware Tanzu Network offers no uptime guarantees. The option to skip relocation is documented for evaluation and proof-of-concept only.

This section describes how to relocate images to the `tap-images` repository created in Amazon ECR. See Creating AWS Resources for more information.

To relocate images from the VMware Tanzu Network registry to the ECR registry:

1. Set up environment variables for installation use by running:

```
export AWS_ACCOUNT_ID=MY-AWS-ACCOUNT-ID
export AWS_REGION=TARGET-AWS-REGION

# Set tanzunet as the source registry to copy the Tanzu Application Platform pa
ckages from.
export IMGPKG_REGISTRY_HOSTNAME_0=registry.tanzu.vmware.com
export IMGPKG_REGISTRY_USERNAME_0=MY-TANZUNET-USERNAME
export IMGPKG_REGISTRY_PASSWORD_0=MY-TANZUNET-PASSWORD

# The user's registry for copying the Tanzu Application Platform package to.
export IMGPKG_REGISTRY_HOSTNAME_1=$AWS_ACCOUNT_ID.dkr.ecr.$AWS_REGION.amazonaw
s.com
export IMGPKG_REGISTRY_USERNAME_1=AWS
export IMGPKG_REGISTRY_PASSWORD_1=`aws ecr get-login-password --region $AWS_REG
ION`
# These environment variables starting with IMGPKG_* are used by the imgpkg com
mand only.

# The registry from which the Tanzu Application Platform package is retrieved.
export INSTALL_REGISTRY_HOSTNAME=$AWS_ACCOUNT_ID.dkr.ecr.$AWS_REGION.amazonaws.
com
export TAP_VERSION=VERSION-NUMBER
export INSTALL_REPO=tap-images
```

Where:

- `MY-AWS-ACCOUNT-ID` is the account ID you deploy Tanzu Application Platform in. No dashes and must be in the format `012345678901`.
- `MY-TANZUNET-USERNAME` is the user with access to the images in the VMware Tanzu Network registry `registry.tanzu.vmware.com`
- `MY-TANZUNET-PASSWORD` is the password for `MY-TANZUNET-USERNAME`.
- `TARGET-AWS-REGION` is the region you deploy the Tanzu Application Platform to.
- `VERSION-NUMBER` is your Tanzu Application Platform version. For example, `1.9.1`

2. Install the Carvel tool imgpkg CLI.
3. Relocate the images with the `imgpkg` CLI by running:

```
imgpkg copy --concurrency 1 -b registry.tanzu.vmware.com/tanzu-application-plat
form/tap-packages:${TAP_VERSION} --to-repo ${INSTALL_REGISTRY_HOSTNAME}/${INSTA
LL_REPO}
```

Add the Tanzu Application Platform package repository

Tanzu CLI packages are available on repositories. Adding the Tanzu Application Platform package repository makes Tanzu Application Platform and its packages available for installation.

Relocate images to a registry is strongly recommended but not required for installation. If you skip this step, you can use the following values to replace the corresponding variables:

- `INSTALL_REGISTRY_HOSTNAME` is `registry.tanzu.vmware.com`
- `INSTALL_REPO` is `tanzu-application-platform`
- `INSTALL_REGISTRY_USERNAME` and `INSTALL_REGISTRY_PASSWORD` are the credentials to the VMware Tanzu Network registry `registry.tanzu.vmware.com`
- `TAP_VERSION` is your Tanzu Application Platform version. For example, `1.9.1`

To add the Tanzu Application Platform package repository to your cluster:

1. Create a namespace called `tap-install` for deploying any component packages by running:

```
kubectl create ns tap-install
```

This namespace keeps the objects grouped together logically.

2. (Optional) If you haven't relocated the images to ECR, create a secret to your registry by running:

```
tanzu secret registry add tap-registry \
  --username ${INSTALL_REGISTRY_USERNAME} --password ${INSTALL_REGISTRY_PASSWOR
D} \
  --server ${INSTALL_REGISTRY_HOSTNAME} \
  --export-to-all-namespaces --yes --namespace tap-install
```

3. Add the Tanzu Application Platform package repository to the cluster by running:

```
tanzu package repository add tanzu-tap-repository \
  --url ${INSTALL_REGISTRY_HOSTNAME}/${INSTALL_REPO}:${TAP_VERSION} \
  --namespace tap-install
```

4. Get the status of the Tanzu Application Platform package repository, and ensure the status updates to `Reconcile succeeded` by running:

```
tanzu package repository get tanzu-tap-repository --namespace tap-install
```

For example:

```
$ tanzu package repository get tanzu-tap-repository --namespace tap-install
- Retrieving repository tap...
NAME:          tanzu-tap-repository
VERSION:       16253001
REPOSITORY:    123456789012.dkr.ecr.us-west-2.amazonaws.com/tap-images
TAG:           1.9.1
STATUS:        Reconcile succeeded
REASON:
```

5. List the available packages by running:

```
tanzu package available list --namespace tap-install
```

For example:

```
$ tanzu package available list --namespace tap-install
  NAME                                                DISPLAY-NAME

Install your Tanzu Application Platform profile

The `tap.tanzu.vmware.com` package installs predefined sets of packages based on your profile settings. This is done by using the package manager installed by Tanzu Cluster Essentials.

For more information about profiles, see Components and installation profiles.

To prepare to install a profile:

1. List version information for the package by running:

   ```
   tanzu package available list tap.tanzu.vmware.com --namespace tap-install
   ```

2. Create a `tap-values.yaml` file by using the Full Profile (AWS), which contains the minimum configurations required to deploy Tanzu Application Platform on AWS. The sample values file contains the necessary defaults for:

   - The meta-package, or parent Tanzu Application Platform package.
   - Subordinate packages, or individual child packages.

   Keep the values file for future configuration use.

   Note

> `tap-values.yaml` is set as a Kubernetes secret, which provides secure means to read credentials for Tanzu Application Platform components.

3. View possible configuration settings for your package

Full profile (AWS)

The following command generates the YAML file sample for the full-profile on AWS by using the ECR repositories you created earlier. The `profile:` field takes `full` as the default value, but you can also set it to `iterate`, `build`, `run`, or `view`. Refer to Install multicluster Tanzu Application Platform profiles for more information.

```
cat << EOF > tap-values.yaml
shared:
  ingress_domain: "INGRESS-DOMAIN"

ceip_policy_disclosed: true

# The above keys are minimum numbers of entries needed in tap-values.yaml to get a fun
ctioning TAP Full profile installation.

# Below are the keys which may have default values set, but can be overridden.

profile: full # Can take iterate, build, run, view.

supply_chain: basic # Can take testing, testing_scanning.

ootb_supply_chain_basic: # Based on supply_chain set above, can be changed to ootb_sup
ply_chain_testing, ootb_supply_chain_testing_scanning.
  registry:
    server: ${AWS_ACCOUNT_ID}.dkr.ecr.${AWS_REGION}.amazonaws.com
    # The prefix of the ECR repository.  Workloads will need
    # two repositories created:

in your cluster before initiating the Tanzu Application Platform installation.
  app_service_type: ClusterIP # Defaults to LoadBalancer. If shared.ingress_domain is
set earlier, this must be set to ClusterIP.

namespace_provisioner:
  aws_iam_role_arn: "arn:aws:iam::${AWS_ACCOUNT_ID}:role/tap-workload"

tap_telemetry:
  customer_entitlement_account_number: "CUSTOMER-ENTITLEMENT-ACCOUNT-NUMBER" # (Option
al) Identify data for creating Tanzu Application Platform usage reports.
EOF
```

Where:

- `INGRESS-DOMAIN` is the subdomain for the host name that you point at the `tanzu-shared-ingress` service's External IP address.
- `kp_default_repository_aws_iam_role_arn` is the ARN that was created to write to the ECR repository for the build service. This value is generated by the script, but you can modify it manually.
- `namspace_provisioner.aws_iam_role_arn` is the ARN that was created to write to the ECR repository for workloads. This value is generated by the script, but you can modify it manually.
- `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE` is where the developer's local source is uploaded when using Tanzu CLI to use Local Source Proxy for workload creation.

  If an AWS ECR registry is being used, ensure that the repository already exists. AWS ECR expects the repository path to already exist. This destination is represented as `REGISTRY-SERVER/REPOSITORY-PATH`. For more information, see Install Local Source Proxy.
- `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE-SECRET` is the name of the secret with credentials that allow pushing to the `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE` repository.
- `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE-SECRET-NAMESPACE` is the namespace in which `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE-SECRET` is available.
- `GIT-CATALOG-URL` is the path to the `catalog-info.yaml` catalog definition file. You can download either a blank or populated catalog file from the Tanzu Application Platform product page. Otherwise, you can use a Backstage-compliant catalog you've already built and posted on the Git infrastructure.
- `MY-DEV-NAMESPACE` is the name of the developer namespace. SCST - Store exports secrets to the namespace, and SCST - Scan deploys the `ScanTemplates` there. This allows the

scanning feature to run in this namespace. If there are multiple developer namespaces, use `ns_for_export_app_cert: "*"` to export the SCST - Store CA certificate to all namespaces.

- `CUSTOMER-ENTITLEMENT-ACCOUNT-NUMBER` (optional) refers to the Entitlement Account Number (EAN), which is a unique identifier VMware assigns to its customers. Tanzu Application Platform telemetry uses this number to identify data that belongs to a particular customers and prepare usage reports.

For AWS, the default settings creates a classic LoadBalancer. To use the Network LoadBalancer instead of the classic LoadBalancer for ingress, add the following to your `tap-values.yaml`:

```
contour:
  infrastructure_provider: aws
  envoy:
    service:
      aws:
        LBType: nlb
```

(Optional) Additional Build Service configurations

The following tasks are optional during the Tanzu Application Platform installation process:

- (Optional) Configure your profile with full dependencies
- (Optional) Configure your profile with the Jammy stack only

(Optional) Configure your profile with full dependencies

When you install a profile that includes Tanzu Build Service, Tanzu Application Platform is installed with the `lite` set of dependencies. These dependencies consist of buildpacks and stacks required for application builds.

The `lite` set of dependencies do not contain all buildpacks and stacks. To use all buildpacks and stacks, you must install the `full` dependencies. For more information about the differences between `lite` and `full` dependencies, see About lite and full dependencies.

To configure `full` dependencies, add the key-value pair `exclude_dependencies: true` to your `tap-values.yaml` file under the `buildservice` section. For example:

```
buildservice:
  kp_default_repository: ${AWS_ACCOUNT_ID}.dkr.ecr.${AWS_REGION}.amazonaws.com/tap-bui
ld-service
  exclude_dependencies: true
```

After configuring `full` dependencies, you must install the dependencies after you have finished installing your Tanzu Application Platform package. See Install the full dependencies package for more information.

Tanzu Application Platform v1.9.1 supports building applications with Ubuntu v22.04 (Jammy).

Install your Tanzu Application Platform package

Follow these steps to install the Tanzu Application Platform package:

1. Install the package by running:

   ```
   tanzu package install tap -p tap.tanzu.vmware.com -v ${TAP_VERSION} --values-fi
   le tap-values.yaml -n tap-install
   ```

2. Verify the package install by running:

```
tanzu package installed get tap -n tap-install
```

This can take 5-10 minutes because it installs several packages on your cluster.

3. Verify that the necessary packages in the profile are installed by running:

```
tanzu package installed list -A
```

4. If you configured `full` dependencies in your `tbs-values.yaml` file, install the `full` dependencies by following the procedure in Install full dependencies.

After installing the Full profile on your cluster, you can install the Tanzu Developer Tools for VS Code Extension to help you develop against it. For instructions, see Install Tanzu Developer Tools for your VS Code.

Note

You can run the following command after reconfiguring the profile to reinstall the Tanzu Application Platform:

```
tanzu package installed update tap -p tap.tanzu.vmware.com -v ${TAP_VERSION}  --values
-file tap-values.yaml -n tap-install
```

Install the full dependencies package

If you configured `full` dependencies in your `tap-values.yaml` file in Configure your profile with full dependencies earlier, you must install the `full` dependencies package.

1. Create an ECR repository for Tanzu Build Service full dependencies by running:

```
aws ecr create-repository --repository-name full-deps --region ${AWS_REGION}
```

2. (Optional) If you have an existing installation of the full dependencies package from a version earlier than Tanzu Application Platform v1.9.1, you must uninstall the full dependencies package and remove the package repository:

    1. Uninstall the package:

```
tanzu package installed delete full-tbs-deps -n tap-install
```

    2. Remove the package repository:

```
tanzu package repository delete tbs-full-deps-repository -n tap-install
```

Important

The package and repository names might differ depending on your installation configurations.

3. Get the latest version of the Tanzu Application Platform package by running:

```
tanzu package available list tap.tanzu.vmware.com --namespace tap-install
```

4. If you have not done so already, you must exclude the default dependencies by adding the key-value pair `exclude_dependencies: true` to your `tap-values.yaml` file under the

`buildservice` section. For example:

```
buildservice:
  exclude_dependencies: true
```

5. If you have not updated your Tanzu Application Platform package installation after adding the key-value pair `exclude_dependencies: true` to your values file, perform the update by running:

   ```
   tanzu package installed update tap --namespace tap-install --values-file VALUES
   -FILE
   ```

   Where `VALUES-FILE` is the path to the `tap-values.yaml` file you edited earlier.

6. Relocate the Tanzu Build Service `full` dependencies package repository by doing one of the following:

   - Relocate the images directly for online installation:

     ```
     imgpkg copy \
       -b registry.tanzu.vmware.com/tanzu-application-platform/full-deps-packa
     ge-repo:VERSION \
       --to-repo ${INSTALL_REGISTRY_HOSTNAME}/full-deps-package-repo
     ```

     Where `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.

   - Relocate the images to an external storage device and then to the registry in the air-gapped environment:

     ```
     imgpkg copy \
       -b registry.tanzu.vmware.com/tanzu-application-platform/full-deps-packa
     ge-repo:VERSION \
       --to-tar=full-deps-package-repo.tar

     # move full-deps-package-repo.tar to environment with registry access
     imgpkg copy \
       --tar full-deps-package-repo.tar \
       --to-repo=INSTALL-REGISTRY-HOSTNAME/TARGET-REPOSITORY/full-deps-package
     -repo
     ```

     Where:

     - `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.
     - `INSTALL-REGISTRY-HOSTNAME` is your container registry.
     - `TARGET-REPOSITORY` is your target repository.

7. Add the Tanzu Build Service `full` dependencies package repository by running:

   ```
   tanzu package repository add full-deps-package-repo \
     --url INSTALL-REGISTRY-HOSTNAME/TARGET-REPOSITORY/full-deps-package-repo:VERS
   ION \
     --namespace tap-install
   ```

   Where:

   - `INSTALL-REGISTRY-HOSTNAME` is your container registry.
   - `TARGET-REPOSITORY` is your target repository.

- `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.

8. Create a new `tbs-full-deps-values.yaml` and copy the `kp_default_repository` key-value pair from your `tap-values.yaml` or `tbs-values.yaml`:

   ```
   ---
    kp_default_repository: "REPO-NAME"
    kp_default_repository_secret:
      name: kp-default-repository-creds
      namespace: tap-install
   ```

   Where `REPO-NAME` is copied from the `buildservice.kp_default_repository` field in your `tap-values.yaml` or `tbs-values.yaml`.

   1. (Optional) Install the UBI builder.

      The UBI builder uses Red Hat Universal Base Image (UBI) v8 for both build and run images. This builder only supports Java and Node.js. To install the UBI builder, add the key-value pair `enable_ubi_builder: true` to your `tbs-full-deps-values.yaml`.

      ```
      ---
      enable_ubi_builder: true
      ```

   2. (Optional) Install the Static builder.

      The Static builder uses Ubuntu Jammy for both build images and a minimal static run image. This builder only supports Golang. To install the Static builder, add the key-value pair `enable_static_builder: true` to your `tbs-full-deps-values.yaml`.

      ```
      ---
      enable_static_builder: true
      ```

9. Install the `full` dependencies package by running:

   ```
   tanzu package install full-deps \
     --package full-deps.buildservice.tanzu.vmware.com \
     --version "> 0.0.0" \
     --namespace tap-install \
     --values-file VALUES-FILE
   ```

   Where `VALUES-FILE` is the path to the `tbs-full-deps-values.yaml` you created earlier.

For more information about the differences between `lite` and `full` dependencies, see About lite and full dependencies.

Access Tanzu Developer Portal

To access Tanzu Developer Portal, you can use the host name that you configured earlier. This host name is pointed at the shared ingress. To configure LoadBalancer for Tanzu Developer Portal, see Access Tanzu Developer Portal.

You're now ready to start using Tanzu Developer Portal. Proceed to the Getting Started topic or the Tanzu Developer Portal - Catalog Operations topic.

Exclude packages from a Tanzu Application Platform profile

To exclude packages from a Tanzu Application Platform profile:

1. Find the full subordinate (child) package name:

```
tanzu package available list --namespace tap-install
```

2. Update your `tap-values` file with a section listing the exclusions:

```
profile: PROFILE-VALUE
excluded_packages:
  - tap-gui.tanzu.vmware.com
  - service-bindings.lab.vmware.com
```

Important

If you exclude a package after performing a profile installation including that package, you cannot see the accurate package states immediately after running `tap package installed list -n tap-install`. Also, you can break package dependencies by removing a package. Allow 20 minutes to verify that all packages have reconciled correctly while troubleshooting.

Next steps

- (Optional) Install Individual Packages
- Set up developer namespaces to use your installed packages

View possible configuration settings for your package

To view possible configuration settings for a package, run:

```
tanzu package available get tap.tanzu.vmware.com/$TAP_VERSION --values-schema --namesp
ace tap-install
```

Note

The `tap.tanzu.vmware.com` package does not show all configuration settings for packages it plans to install. The package only shows top-level keys. You can view individual package configuration settings with the same `tanzu package available get` command. For example, to find the keys for Cloud Native Runtimes, you must first identify the version of the package with `tanzu package installed list -n tap-install`, which lists all the installed packages versions. Then run the command `tanzu package available get -n tap-install cnrs.tanzu.vmware.com/CNR-VERSION --values-schema` by using the package version listed for Cloud Native Runtimes.

```
profile: full

# Shared configurations go under the shared key.
shared:
  ingress_domain: tap.example.com

# ...

# For example, Cloud Native Runtimes specific values go under its name.
cnrs:
  provider: local
```

```
# For example, App Accelerator specific values go under its name.
accelerator:
  server:
    service_type: "ClusterIP"
```

Shared Keys define values that configure multiple packages. These keys are defined under the `shared` Top-level Key, as summarized in the following table:

Shared Key	Description	Optional
`ca_cert_data`	PEM-encoded certificate data to trust TLS connections with a private CA. This shared key is used by `convention_controller`, `scanning` and the Tanzu `source_controller` (not the Flux CD Source Controller).	Yes
`ingress_domain`	Domain name to be used in service routes and host names for instances of Tanzu Application Platform components.	Yes
`ingress_issuer`	A `cert-manager.io/v1/ClusterIssuer` for issuing TLS certificates to Tanzu Application Platform components. Default value: `tap-ingress-selfsigned`	Yes
`kubernetes_distribution`	Type of Kubernetes infrastructure being used. You can use this shared key in coordination with the `kubernetes_version` key. Supported value: `openshift`.	Yes
`kubernetes_version`	Kubernetes version. You can use this shared key independently or in coordination with the `kubernetes_distribution` key. Supported value: `1.24.x`, where `x` stands for the Kubernetes patch version.	Yes
`image_registry.project_path`	Project path in the container image registry server used for builder and application images.	Yes
`image_registry.username`	User name for the container image registry. Mutually exclusive with `shared.image_registry.secret.name/namespace`	Yes
`image_registry.password`	Password for the container image registry. Mutually exclusive with `shared.image_registry.secret.name/namespace`	Yes
`secret.name`	Secret name for the container image registry credentials of type `kubernetes.io/dockerconfigjson`. Mutually exclusive with `shared.image_registry.username/password`	Yes
`secret.namespace`	Secret namespace for the container image registry credentials. Mutually exclusive with `shared.image_registry.username/password`	Yes
`activateAppLiveViewSecureAccessControl`	Enable secure access connection between Application Live View components.	Yes

The following table summarizes the top-level keys used for package-specific configuration within your `tap-values.yaml`.

Package	Top-level Key
See table above.	`shared`
API Auto Registration	`api_auto_registration`
API portal	`api_portal`
Application Accelerator	`accelerator`
Application Live View	`appliveview`
Application Live View connector	`appliveview_connector`
Application Live View conventions	`appliveview-conventions`
Cartographer Conventions	`cartographer_conventions`

Package	Top-level Key
Cartographer	`cartographer`
Cloud Native Runtimes	`cnrs`
Source Controller	`source_controller`
Supply Chain	`supply_chain`
Supply Chain Basic	`ootb_supply_chain_basic`
Supply Chain Testing	`ootb_supply_chain_testing`
Supply Chain Testing Scanning	`ootb_supply_chain_testing_scanning`
Supply Chain Security Tools - Scan	`scanning`
Supply Chain Security Tools - Scan (Grype Scanner)	`grype`
Supply Chain Security Tools - Store	`metadata_store`
Build Service	`buildservice`
Tanzu Developer Portal	`tap_gui`

For information about package-specific configuration, see Install individual packages.

Install individual packages

You can install Tanzu Application Platform (commonly known as TAP) through predefined profiles or through individual packages. Use this topic to learn how to install each individual package. For more information about installing through profiles, see Components and installation profiles.

Installing individual Tanzu Application Platform packages is useful if you do not want to use a profile to install packages or if you want to install additional packages after installing a profile. Before installing the packages, be sure to complete the prerequisites, configure and verify the cluster, accept the EULA, and install the Tanzu CLI with any required plug-ins. For more information, see Prerequisites.

Install pages for individual Tanzu Application Platform packages

- Install API Auto Registration
- Install API portal
- Install Application Accelerator
- Install Application Configuration Service
- Install Application Live View
- Install Application Single Sign-On
- Install Bitnami Services
- Install cert-manager
- Install Cloud Native Runtimes
- Install Contour
- Install Crossplane
- Install default roles for Tanzu Application Platform

- Install Developer Conventions
- Install Flux CD Source Controller
- Install Out of the Box Templates
- Install Out of the Box Supply Chain with Testing
- Install Out of the Box Supply Chain with Testing and Scanning
- Install Service Bindings
- Install Services Toolkit
- Install Source Controller
- Install Spring Boot conventions
- Install Supply Chain Choreographer
- Install Supply Chain Security Tools - Store
- Install Supply Chain Security Tools - Policy Controller
- Install Supply Chain Security Tools - Scan
- Install Tanzu Developer Portal
- Install Tanzu Build Service
- Install Tekton
- Install Telemetry

Verify the installed packages

Use the following procedure to verify that the packages are installed.

1. List the installed packages by running:

   ```
   tanzu package installed list --namespace tap-install
   ```

   For example:

   ```
   $ tanzu package installed list --namespace tap-install
   \ Retrieving installed packages...
   NAME                     PACKAGE-NAME                                      PAC
   KAGE-VERSION  STATUS
   api-portal               api-portal.tanzu.vmware.com                       1.

```

Next steps

- Set up developer namespaces to use your installed packages

Set up developer namespaces to use your installed packages

This topic tells you how to set up developer namespaces to use your installed packages.

You must first enable your namespace for Tanzu Application Platform Supply Chains and then optionally apply Kubernetes RBAC for additional non-admin user access. For more information, see:

1. Enable namespace for Supply Chains.
2. (Optional) Enable non-admin users access with Kubernetes RBAC.

Enable namespace for Supply Chains

The `default` Service Account in your developer namespace requires permission to your image repositories and RoleBindings for Tanzu Application Platform `ClusterRoles`. The Namespace Provisioner watches namespaces for a specific label, then takes action to enable the namespace.

To enable the Supply Chain on your namespace, run:

```
kubectl label namespace $YOUR-NAMESPACE apps.tanzu.vmware.com/tap-ns=""
```

Where `YOUR-NAMESPACE` is your developer namespace.

(Optional) Enable non-admin users access with Kubernetes RBAC

Follow these steps to enable non-admin users by using Kubernetes RBAC to submit jobs to the Supply Chain:

1. Choose either of the following options to give developers namespace-level access and view access to appropriate cluster-level resources:

- **Option 1:** Use the Tanzu Application Platform RBAC CLI plug-in (beta).

  To use the `tanzu rbac` plug-in to grant `app-viewer` and `app-editor` roles to an identity provider group, run:

  ```
  tanzu rbac binding add -g GROUP-FOR-APP-VIEWER -n YOUR-NAMESPACE -r app-v
  iewer
  tanzu rbac binding add -g GROUP-FOR-APP-EDITOR -n YOUR-NAMESPACE -r app-e
  ditor
  ```

  Where:

  - `YOUR-NAMESPACE` is the name you give to the developer namespace.
  - `GROUP-FOR-APP-VIEWER` is the user group from the upstream identity provider that requires access to `app-viewer` resources on the current namespace and cluster.
  - `GROUP-FOR-APP-EDITOR` is the user group from the upstream identity provider that requires access to `app-editor` resources on the current namespace and cluster.

  For more information about `tanzu rbac`, see Bind a user or group to a default role.

  VMware recommends creating a user group in your identity provider's grouping system for each developer namespace and then adding the users accordingly.

  Depending on your identity provider, you might need to take further action to federate user groups appropriately with your cluster. For an example of how to set up Azure Active Directory (AD) with your cluster, see Integrating Azure Active Directory.

- **Option 2:** Use the native Kubernetes YAML.

  To apply the RBAC policy, run:

  ```
  cat <<EOF | kubectl -n YOUR-NAMESPACE apply -f -
  apiVersion: rbac.authorization.k8s.io/v1
  kind: RoleBinding
  metadata:
    name: dev-permit-app-viewer
  roleRef:
    apiGroup: rbac.authorization.k8s.io
    kind: ClusterRole
    name: app-viewer
  subjects:
    - kind: Group
      name: GROUP-FOR-APP-VIEWER
      apiGroup: rbac.authorization.k8s.io
  ---
  apiVersion: rbac.authorization.k8s.io/v1
  kind: ClusterRoleBinding
  metadata:
    name: YOUR-NAMESPACE-permit-app-viewer
  roleRef:
    apiGroup: rbac.authorization.k8s.io
    kind: ClusterRole
    name: app-viewer-cluster-access
  subjects:
    - kind: Group
      name: GROUP-FOR-APP-VIEWER
      apiGroup: rbac.authorization.k8s.io
  ---
  apiVersion: rbac.authorization.k8s.io/v1
  kind: RoleBinding
  ```

```
metadata:
  name: dev-permit-app-editor
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: app-editor
subjects:
  - kind: Group
    name: GROUP-FOR-APP-EDITOR
    apiGroup: rbac.authorization.k8s.io
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: YOUR-NAMESPACE-permit-app-editor
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: app-editor-cluster-access
subjects:
  - kind: Group
    name: GROUP-FOR-APP-EDITOR
    apiGroup: rbac.authorization.k8s.io
EOF
```

Where:

- `YOUR-NAMESPACE` is the name you give to the developer namespace.
- `GROUP-FOR-APP-VIEWER` is the user group from the upstream identity provider that requires access to `app-viewer` resources on the current namespace and cluster.
- `GROUP-FOR-APP-EDITOR` is the user group from the upstream identity provider that requires access to `app-editor` resources on the current namespace and cluster.

VMware recommends creating a user group in your identity provider's grouping system for each developer namespace and then adding the users accordingly.

Depending on your identity provider, you might need to take further action to federate user groups appropriately with your cluster. For an example of how to set up Azure Active Directory (AD) with your cluster, see Integrating Azure Active Directory.

Rather than granting roles directly to individuals, VMware recommends using your identity provider's user groups system to grant access to a group of developers. For an example of how to set up Azure AD with your cluster, see Integrating Azure Active Directory.

2. (Optional) Log in as a non-admin user, such as a developer, to see the effects of RBAC after the bindings are applied.

Next steps

- Install Tanzu Developer Tools for your VS Code

Install Tanzu Developer Tools for your VS Code

This topic tells you how to install VMware Tanzu Developer Tools for Visual Studio Code (VS Code).

Prerequisites

Before installing the extension, you must have:

- VS Code
- kubectl
- Tilt v0.30.12 or later
- Tanzu CLI and plug-ins
- A cluster with the Tanzu Application Platform Full profile or Iterate profile

If you are an app developer, someone else in your organization might have already set up the Tanzu Application Platform environment.

Docker Desktop and local Kubernetes are not prerequisites for using Tanzu Developer Tools for VS Code.

Install

To install VMware Tanzu Developer Tools for VS Code:

1. Open Visual Studio Code.
2. Open the command palette.
3. In the search box enter `Extension`.
4. Click **Extensions: Install Extensions**.
5. The **Extensions** view opens on the left side of your screen. In the search box enter `Tanzu`.
6. Click **Tanzu Developer Tools** and then click **Install**.

Configure

To configure VMware Tanzu Developer Tools for VS Code:

1. Ensure that you are targeting the correct cluster. For more information, see the Kubernetes documentation.
2. Go to **Code** > **Preferences** > **Settings** > **Extensions** > **Tanzu Developer Tools** and set the following:
    - **Confirm Apply Config**: This controls whether the extension asks to confirm user input when applying a workload.
    - **Confirm Debug Port**: This controls whether the extension asks for the debug port when running `Tanzu: Start Java Debug`.
    - **Confirm Local Port**: This controls whether the extension asks for the local port when running `Tanzu: Start Java Debug`.
    - **Confirm Delete**: This controls whether the extension asks for confirmation when deleting a workload.
    - **Enable Live Hover**: This enables Live Hover. For more information, see Integrating Live Hover by using Spring Boot Tools. Restart VS Code for this change to take effect.
    - **Source Image**: The registry location for publishing local source code. For example, `registry.io/yourapp-source`. This must include both a registry and a project name. A source image registry location is optional when Local Source Proxy is configured.
    - **Local Path**: (Optional) The path on the local file system to a directory of source code to build. This is the current directory by default.

- **Namespace**: (Optional) This is the namespace that workloads are deployed into. The namespace set in kubeconfig is the default.
- **Tracked Namespaces**: (Optional) Comma-separated list of namespaces. Resources in these namespaces appear in the Tanzu Workloads panel and the Activity panel. If empty, the namespace in the current context is the default.
- **Wait Timeout**: (Optional) This sets how long to wait for a workload to become ready.
- **Workload Type**: (Optional) This distinguishes the workload type. Examples include web and server.

Uninstall

To uninstall VMware Tanzu Developer Tools for VS Code:

1. Go to **Code** > **Preferences** > **Settings** > **Extensions**.
2. Right-click the extension and then click **Uninstall**.

Next steps

Proceed to Getting started with Tanzu Developer Tools for Visual Studio Code.

Install Tanzu Application Platform (Azure)

To install Tanzu Application Platform (commonly known as TAP) on Azure:

Step	Task	Link
1.	Review the prerequisites to ensure that you have set up everything required before beginning the installation	Prerequisites
2.	Accept Tanzu Application Platform EULAs and install the Tanzu CLI	Accept Tanzu Application Platform EULAs and installing the Tanzu CLI
3.	Create Azure Resources	Create Azure Resources
4.	Install Cluster Essentials for Tanzu	Deploy Cluster Essentials
5.	Add the Tanzu Application Platform package repository, prepare your Tanzu Application Platform profile, and install the profile to the cluster	Install the Tanzu Application Platform package and profiles
6.	(Optional) Install any additional packages that were not in the profile	Install individual packages
7.	Set up developer namespaces to use your installed packages	Set up developer namespaces to use your installed packages
8.	Install developer tools into your integrated development environment (IDE)	Install Tanzu Developer Tools for your VS Code

After installing Tanzu Application Platform on to your Kubernetes clusters, proceed with Get started with Tanzu Application Platform.

Install Tanzu Application Platform (Azure)

To install Tanzu Application Platform (commonly known as TAP) on Azure:

Step	Task	Link
1.	Review the prerequisites to ensure that you have set up everything required before beginning the installation	Prerequisites

Step	Task	Link
2.	Accept Tanzu Application Platform EULAs and install the Tanzu CLI	Accept Tanzu Application Platform EULAs and installing the Tanzu CLI
3.	Create Azure Resources	Create Azure Resources
4.	Install Cluster Essentials for Tanzu	Deploy Cluster Essentials
5.	Add the Tanzu Application Platform package repository, prepare your Tanzu Application Platform profile, and install the profile to the cluster	Install the Tanzu Application Platform package and profiles
6.	(Optional) Install any additional packages that were not in the profile	Install individual packages
7.	Set up developer namespaces to use your installed packages	Set up developer namespaces to use your installed packages
8.	Install developer tools into your integrated development environment (IDE)	Install Tanzu Developer Tools for your VS Code

After installing Tanzu Application Platform on to your Kubernetes clusters, proceed with Get started with Tanzu Application Platform.

Create Azure Resources for Tanzu Application Platform

To install Tanzu Application Platform (commonly known as TAP) within the Azure ecosystem, you must create several Azure resources. Use this topic to learn how to create:

- An Azure Kubernetes Service (AKS) cluster to install Tanzu Application Platform.
- ACR repositories for the Tanzu Application Platform container images.

Creating these resources enables Tanzu Application Platform to use an IAM role bound to a Kubernetes service account for authentication, rather than the typical username and password stored in a Kubernetes secret strategy.

This is important when using ACR because authenticating to ACR is a two-step process:

1. Retrieve a token using your Azure credentials.
2. Use the token to authenticate to the registry.

To increase security, the token has a lifetime of 12 hours. This makes storing it as a secret for a service impractical because it must be refreshed every 12 hours.

Using an IAM role on a service account mitigates the need to retrieve the token because it is handled by credential helpers within the services.

Prerequisites

Before installing Tanzu Application Platform on Azure, you need:

- **An Azure subscription:**

  You must create all of your resources within an Azure subscription and create an Azure free account.

- **Azure CLI:**

  To run CLI reference commands locally, you must install the Azure CLI. This topic uses Azure CLI to both query and configure resources in Azure, such as IAM roles. For more information, see Azure CLI documentation.

Create Azure Resource Group

1. Log in to Azure.

```
az login
az account set --subscription SUBSCRIPTION-NAME
```

2. Create a resource group with the `az group create` command.

```
az group create --name myTAPResourceGroup --location eastus
```

Create an AKS cluster

To create an AKS cluster, you can run the az aks create command with the `--enable-addons monitoring` and `--enable-msi-auth-for-monitoring` parameter to enable Azure Monitor Container insights with managed identity authentication (preview).

The following example creates a cluster named `tap-on-azure` with one node and enables a system-assigned managed identity:

```
az aks create -g myTAPResourceGroup -n tap-on-azure --enable-managed-identity --node-c
ount 6 --enable-addons monitoring --enable-msi-auth-for-monitoring --generate-ssh-keys
--node-vm-size Standard_D4ds_v4 --kubernetes-version K8S-VERSION
```

Where `K8S-VERSION` is the compatible Kubernetes version that can be retrieved by running `az aks get-versions`.

Note

You might need to increase quota for Standard DDSv4 Family vCPUs. For more information, see the Azure documentation.

After a few minutes, the command completes and returns JSON-formatted information about the cluster.

When you create an AKS cluster, a second resource group is automatically created to store the AKS resources. For more information, see Why are two resource groups created with AKS?

Connect to the AKS cluster

To manage a Kubernetes cluster, use the Kubernetes command-line client, kubectl. `kubectl` is already installed if you use Azure Cloud Shell.

1. Install `kubectl` locally by using the az aks install-cli command:

```
az aks install-cli
```

2. Configure `kubectl` to connect to your Kubernetes cluster by using the az aks get-credentials command that:
    - Downloads credentials and configures the Kubernetes CLI to use them.
    - Uses `~/.kube/config`, the default location for the Kubernetes configuration file. You can specify a different location for your Kubernetes configuration file by using the `--file` argument.

```
az aks get-credentials --resource-group myTAPResourceGroup --name tap-on-azure
```

Create the container repositories

Create the Azure Container Registry by running:

```
az acr create -n $REGISTRY_NAME -g myTAPResourceGroup --sku Standard
```

Note

Azure Container Registry (ACR) does not require that the container repositories are already created. Repositories are created automatically when images are uploaded.

Enable registry admin account

To enable push and pull to your registries, you must enable the admin user account, which is created with each registry. Run the following command to enable the admin user account:

```
az acr update -n $REGISTRY_NAME --admin-enabled true
```

There are two passwords created for each admin user account per registry. To retrieve the passwords, run the following for each registry:

```
az acr credential show --name $REGISTRY_NAME --resource-group myTAPResourceGroup
```

Expect to see the following outputs:

```
{
  "passwords": [
    {
      "name": "password",
      "value": YOUR-PASSWORD
    },
    {
      "name": "password2",
      "value": YOUR-PASSWORD-2
    }
  ],
  "username": ""
}
```

Export the username and password by running:

```
export KP_REGISTRY_USERNAME=$REGISTRY_NAME
export KP_REGISTRY_PASSWORD=YOUR-PASSWORD
```

Next steps

- Install Tanzu Application Platform package and profiles on Azure

Install Tanzu Application Platform package and profiles on Azure

This topic tells you how to install Tanzu Application Platform (commonly known as TAP) packages from your Tanzu Application Platform package repository on to Azure.

Before installing the packages, ensure you have:

- Completed the Prerequisites.
- Created Azure Resources.
- Accepted Tanzu Application Platform EULA and installed Tanzu CLI with any required plug-ins.
- Installed Cluster Essentials for Tanzu.

Relocate images to a registry

VMware recommends relocating the images from VMware Tanzu Network registry to your own container image registry before attempting installation. If you don't relocate the images, Tanzu Application Platform depends on VMware Tanzu Network for continued operation, and VMware Tanzu Network offers no uptime guarantees. The option to skip relocation is documented for evaluation and proof-of-concept only.

To relocate images from the VMware Tanzu Network registry to the ACR registry:

1. Set up environment variables for installation use by running:

   ```
   # Set tanzunet as the source registry to copy the Tanzu Application Platform pa
   ckages from.
   export IMGPKG_REGISTRY_HOSTNAME_0=registry.tanzu.vmware.com
   export IMGPKG_REGISTRY_USERNAME_0=MY-TANZUNET-USERNAME
   export IMGPKG_REGISTRY_PASSWORD_0=MY-TANZUNET-PASSWORD

   # The user's registry for copying the Tanzu Application Platform package to.
   export IMGPKG_REGISTRY_HOSTNAME_1=$INSTALL_REGISTRY_HOSTNAME
   export IMGPKG_REGISTRY_USERNAME_1=$REGISTRY_NAME
   export IMGPKG_REGISTRY_PASSWORD_1=REGISTRY-PASSWORD
   # These environment variables starting with IMGPKG_* are used by the imgpkg com
   mand only.

   # The registry from which the Tanzu Application Platform package is retrieved.
   export INSTALL_REGISTRY_HOSTNAME=$REGISTRY_NAME.azurecr.io
   export TAP_VERSION=VERSION-NUMBER
   export INSTALL_REPO=tapimages
   ```

   Where:

   - `MY-TANZUNET-USERNAME` is the user with access to the images in the VMware Tanzu Network registry `registry.tanzu.vmware.com`
   - `MY-TANZUNET-PASSWORD` is the password for `MY-TANZUNET-USERNAME`.
   - `VERSION-NUMBER` is your Tanzu Application Platform version. For example, `1.9.1`

2. Install the Carvel tool imgpkg CLI.
3. Relocate the images with the `imgpkg` CLI by running:

   ```
   imgpkg copy --concurrency 1 -b ${IMGPKG_REGISTRY_HOSTNAME_0}/tanzu-application-
   platform/tap-packages:${TAP_VERSION} --to-repo ${IMGPKG_REGISTRY_HOSTNAME_1}/
   ${INSTALL_REPO}
   ```

4. Create a namespace called `tap-install` for deploying any component packages by running:

   ```
   kubectl create ns tap-install
   ```

   This namespace keeps the objects grouped together logically.

5. Create registry secret for the VMware Tanzu Network registry by running:

```
tanzu secret registry add tap-registry \
--username ${INSTALL_REGISTRY_USERNAME} --password ${INSTALL_REGISTRY_PASSWORD}
\
--server ${INSTALL_REGISTRY_HOSTNAME} \
--export-to-all-namespaces --yes --namespace tap-install
tanzu secret registry list --namespace tap-install
```

6. Add the Tanzu Application Platform package repository to the cluster by running:

```
tanzu package repository add tanzu-tap-repository \
  --url ${INSTALL_REGISTRY_HOSTNAME}/full-deps-package-repo
  --namespace tap-install
```

7. Get the status of the Tanzu Application Platform package repository, and ensure the status updates to `Reconcile succeeded` by running:

```
tanzu package repository get tanzu-tap-repository --namespace tap-install
```

For example:

```
$ tanzu package repository get tanzu-tap-repository --namespace tap-install
- Retrieving repository tap...
NAME:          tanzu-tap-repository
VERSION:       16253001
REPOSITORY:    123456789012.dkr.acr.us-east.azure.com/tap-images
TAG:           1.9.1
STATUS:        Reconcile succeeded
REASON:
```

Note

The `VERSION` and `TAG` numbers differ from the earlier example if you are on Tanzu Application Platform v1.0.2 or earlier.

8. List the available packages by running:

```
tanzu package available list --namespace tap-install
```

For example:

```
$ tanzu package available list --namespace tap-install
/ Retrieving available packages...
  NAME                                                DISPLAY-NAME

```

Install your Tanzu Application Platform profile

The `tap.tanzu.vmware.com` package installs predefined sets of packages based on your profile settings by using the package manager installed by Tanzu Cluster Essentials. For more information about profiles, see Components and installation profiles.

Some components use `kpack` and require a repository to publish artifacts to. This registry does not have to be the same registry used for installing the Tanzu Application Platform packages. To create a registry secret and add it to a developer namespace, run:

```
export KP_REGISTRY_USERNAME=YOUR-USERNAME
export KP_REGISTRY_PASSWORD=YOUR-PASSWORD
export KP_REGISTRY_HOSTNAME=YOUR-HOSTNAME

echo $KP_REGISTRY_USERNAME
echo $KP_REGISTRY_PASSWORD
echo $KP_REGISTRY_HOSTNAME

docker login $KP_REGISTRY_HOSTNAME -u $KP_REGISTRY_USERNAME -p $KP_REGISTRY_PASSWORD

export YOUR_NAMESPACE=mydev-ns

echo $YOUR_NAMESPACE

kubectl create ns $YOUR_NAMESPACE

tanzu secret registry add registry-credentials --server $KP_REGISTRY_HOSTNAME --userna
me $KP_REGISTRY_USERNAME --password $KP_REGISTRY_PASSWORD --namespace $YOUR_NAMESPACE

kubectl get secret registry-credentials  -o jsonpath='{.data.\.dockerconfigjson}'  -n
$YOUR_NAMESPACE| base64 --decode
```

To prepare to install a profile:

1. List version information for the package by running:

```
tanzu package available list tap.tanzu.vmware.com --namespace tap-install
```

2. Create a `tap-values.yaml` file by using the Full Profile (Azure), which contains the minimum configurations required to deploy Tanzu Application Platform on Azure. The sample values file contains the necessary defaults for:
    - The meta-package, or parent Tanzu Application Platform package.
    - Subordinate packages, or individual child packages.

    Keep the values file for future configuration use.

    > **Note**
    >
    > `tap-values.yaml` is set as a Kubernetes secret, which provides secure means to read credentials for the Tanzu Application Platform components.

3. View possible configuration settings for your package

Full profile (Azure)

The following is the YAML file sample for the full-profile on Azure by using the ACR repositories you created earlier. The `profile:` field takes `full` as the default value, but you can also set it to `iterate`, `build`, `run`, or `view`. See Install multicluster Tanzu Application Platform profiles for more information.

```
cat << EOF > tap-values.yaml
shared:
  ingress_domain: YOUR_DOMAIN
  ingress_issuer: CLUSTER_ISSUER # use "" to disable SSL

  image_registry:
    project_path: ${KP_REGISTRY_HOSTNAME}/tap
    secret:
      name: registry-credentials
      namespace: ${YOUR_NAMESPACE}

ceip_policy_disclosed: true
profile: full # Can take iterate, build, run, view.

supply_chain: basic # Can take testing, testing_scanning.

ootb_templates:
  iaas_auth: true

ootb_supply_chain_basic:
  registry: # (Optional) Takes the value from the project_path under the shared.image_
registry section by default, but you can override it by setting different values.
    server: ${KP_REGISTRY_HOSTNAME}
    repository: tap-apps
  gitops:
    credentials_secret: ""

contour:
  envoy:
    service:
      type: LoadBalancer

buildservice:
  # (Optional) Takes the value from the project_path under the shared.image_registry s
ection by default, but you can override it by setting a different value.
  kp_default_repository: ${KP_REGISTRY_HOSTNAME}/buildservice
```

```
  kp_default_repository_secret:
    name: registry-credentials
    namespace: ${YOUR_NAMESPACE}

local_source_proxy:
  # (Optional) Takes the value from the project_path under the shared.image_registry s
ection by default, but you can override it by setting a different value.
  repository: "EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE"
  push_secret:
    name: "EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE-SECRET"
    namespace: "EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE-SECRET-NAMESPACE"
    create_export: true  # When set to true, the secret mentioned in this section is a
utomatically exported to Local Source Proxy's namespace.

ootb_delivery_basic:
  service_account: default

tap_gui:
  app_config:
    auth:
      allowGuestAccess: true

metadata_store:
  app_service_type: ClusterIP
  ns_for_export_app_cert: ${YOUR_NAMESPACE}

accelerator:
  server:
    service_type: "ClusterIP"

EOF
```

Where:

- `YOUR_DOMAIN` is the subdomain for the host name that you point at the `tanzu-shared-ingress` service's External IP address.

  

  Note

  You can update this field when knowing the external IP address of the ingress after the initial install of Tanzu Application Platform.

- `CLUSTER_ISSUER` is the name of the deployed `ClusterIssuer` to enable TLS on your ingress domain. You can disable TLS by using an empty string `""`.
- `YOUR_NAMESPACE` is the environment variable you defined earlier to describe the name of the developer namespace. Supply Chain Security Tools - Store exports secrets to the namespace, and Supply Chain Security Tools - Scan deploys the `ScanTemplates` there. This allows the scanning feature to run in this namespace. If there are multiple developer namespaces, use `ns_for_export_app_cert: "*"` to export the Supply Chain Security Tools - Store CA certificate to all namespaces.
- `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE` is where the developer's local source is uploaded when using Tanzu CLI to use Local Source Proxy for workload creation.
- `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE-SECRET` is the name of the secret with credentials that allow pushing to the `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE` repository.
- `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE-SECRET-NAMESPACE` is the namespace in which `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE-SECRET` is available.

Important

Installing Grype by using `tap-values.yaml` as follows is deprecated in v1.6 and will be removed in v1.8:

```
grype:
  targetImagePullSecret: registry-credentials
```

You can install Grype by using Namespace Provisioner instead.

(Optional) Configure your profile with full dependencies

When you install a profile that includes Tanzu Build Service, Tanzu Application Platform is installed with the `lite` set of dependencies. These dependencies consist of buildpacks and stacks required for application builds.

The `lite` set of dependencies do not contain all buildpacks and stacks. To use all buildpacks and stacks, you must install the `full` dependencies. For more information about the differences between `lite` and `full` dependencies, see About lite and full dependencies.

To configure `full` dependencies, add the key-value pair `exclude_dependencies: true` to your `tap-values.yaml` file under the `buildservice` section. For example:

```
buildservice:
  kp_default_repository: "KP-DEFAULT-REPO"
  kp_default_repository_secret: # Takes the value from the shared section by default,
but can be overridden by setting a different value.
    name: "KP-DEFAULT-REPO-SECRET"
    namespace: "KP-DEFAULT-REPO-SECRET-NAMESPACE"
  exclude_dependencies: true
```

After configuring `full` dependencies, you must install the dependencies after you have finished installing your Tanzu Application Platform package. See Install the full dependencies package for more information.

Tanzu Application Platform v1.6.1 supports building applications with Ubuntu v22.04 (Jammy).

Install your Tanzu Application Platform package

Follow these steps to install the Tanzu Application Platform package:

1. Install the package by running:

   ```
   tanzu package install tap -p tap.tanzu.vmware.com -v $TAP_VERSION --values-file
   tap-values.yaml -n tap-install
   ```

2. Verify the package install by running:

   ```
   tanzu package installed get tap -n tap-install
   ```

   This can take 5-10 minutes because it installs several packages on your cluster.

3. Verify that the necessary packages in the profile are installed by running:

   ```
   tanzu package installed list -A
   ```

4. If you configured `full` dependencies in your `tbs-values.yaml` file, install the `full` dependencies by following the procedure in Install full dependencies.

After installing the Full profile on your cluster, you can install the Tanzu Developer Tools for VS Code Extension to help you develop against it. For more information, see Install Tanzu Developer Tools for your VS Code.

Install the full dependencies package

If you configured `full` dependencies in your `tap-values.yaml` file in Configure your profile with full dependencies earlier, you must install the `full` dependencies package.

For more information about the differences between `lite` and `full` dependencies, see About lite and full dependencies.

To install the `full` dependencies package:

1. Get the latest version of the Tanzu Application Platform package by running:

   ```
   tanzu package available list tap.tanzu.vmware.com --namespace tap-install
   ```

2. If you have not done so already, you must exclude the default dependencies by adding the key-value pair `exclude_dependencies: true` to your `tap-values.yaml` file under the `buildservice` section. For example:

   ```
   buildservice:
     exclude_dependencies: true
   ```

3. If you have not updated your Tanzu Application Platform package installation after adding the key-value pair `exclude_dependencies: true` to your values file, perform the update by running:

   ```
   tanzu package installed update tap --namespace tap-install --values-file VALUES
   -FILE
   ```

   Where `VALUES-FILE` is the path to the `tap-values.yaml` file you edited earlier.

4. Relocate the Tanzu Build Service `full` dependencies package repository by doing one of the following:

   - Relocate the images directly for online installation:

     ```
     imgpkg copy \
       -b registry.tanzu.vmware.com/tanzu-application-platform/full-deps-packa
     ge-repo:VERSION \
       --to-repo ${INSTALL_REGISTRY_HOSTNAME}/full-deps-package-repo
     ```

     Where `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.

   - Relocate the images to an external storage device and then to the registry in the air-gapped environment:

     ```
     imgpkg copy \
       -b registry.tanzu.vmware.com/tanzu-application-platform/full-deps-packa
     ge-repo:VERSION \
       --to-tar=full-deps-package-repo.tar

     # move full-deps-package-repo.tar to environment with registry access
     imgpkg copy \
       --tar full-deps-package-repo.tar \
       --to-repo=INSTALL-REGISTRY-HOSTNAME/TARGET-REPOSITORY/full-deps-package
     -repo
     ```

Where:

- `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.
- `INSTALL-REGISTRY-HOSTNAME` is your container registry.
- `TARGET-REPOSITORY` is your target repository.

5. Add the Tanzu Build Service `full` dependencies package repository by running:

```
tanzu package repository add full-deps-package-repo \
  --url INSTALL-REGISTRY-HOSTNAME/TARGET-REPOSITORY/full-deps-package-repo:VERS
ION \
  --namespace tap-install
```

Where:

- `INSTALL-REGISTRY-HOSTNAME` is your container registry.
- `TARGET-REPOSITORY` is your target repository.
- `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.

6. Create a new `tbs-full-deps-values.yaml` and copy the `kp_default_repository` key-value pair from your `tap-values.yaml` or `tbs-values.yaml`:

```
---
 kp_default_repository: "REPO-NAME"
 kp_default_repository_secret:
   name: kp-default-repository-creds
   namespace: tap-install
```

Where `REPO-NAME` is copied from the `buildservice.kp_default_repository` field in your `tap-values.yaml` or `tbs-values.yaml`.

1. (Optional) Install the UBI builder.

   The UBI builder uses Red Hat Universal Base Image (UBI) v8 for both build and run images. This builder only supports Java and Node.js. To install the UBI builder, add the key-value pair `enable_ubi_builder: true` to your `tbs-full-deps-values.yaml`.

   ```
   ---
   enable_ubi_builder: true
   ```

2. (Optional) Install the Static builder.

   The Static builder uses Ubuntu Jammy for both build images and a minimal static run image. This builder only supports Golang. To install the Static builder, add the key-value pair `enable_static_builder: true` to your `tbs-full-deps-values.yaml`.

   ```
   ---
   enable_static_builder: true
   ```

7. Install the `full` dependencies package by running:

```
tanzu package install full-deps \
  --package full-deps.buildservice.tanzu.vmware.com \
  --version "> 0.0.0" \
  --namespace tap-install \
  --values-file VALUES-FILE
```

Where `VALUES-FILE` is the path to the `tbs-full-deps-values.yaml` you created earlier.

Access Tanzu Developer Portal

You can use the host name configured in Access Tanzu Developer Portal to access Tanzu Developer Portal. This host name is pointed at the shared ingress.

You're now ready to start using Tanzu Developer Portal. Proceed to the Getting Started topic or the Tanzu Developer Portal - Catalog Operations topic.

Next steps

- (Optional) Install Individual Packages
- Set up developer namespaces to use your installed packages

View possible configuration settings for your package

To view possible configuration settings for a package, run:

```
tanzu package available get tap.tanzu.vmware.com/$TAP_VERSION --values-schema --namesp
ace tap-install
```

Note

The `tap.tanzu.vmware.com` package does not show all configuration settings for packages it plans to install. The package only shows top-level keys. You can view individual package configuration settings with the same `tanzu package available get` command. For example, to find the keys for Cloud Native Runtimes, you must first identify the version of the package with `tanzu package installed list -n tap-install`, which lists all the installed packages versions. Then run the command `tanzu package available get -n tap-install cnrs.tanzu.vmware.com/CNR-VERSION --values-schema` by using the package version listed for Cloud Native Runtimes.

```
profile: full

# Shared configurations go under the shared key.
shared:
  ingress_domain: tap.example.com

# ...

# For example, Cloud Native Runtimes specific values go under its name.
cnrs:
  provider: local

# For example, App Accelerator specific values go under its name.
accelerator:
  server:
    service_type: "ClusterIP"
```

Shared Keys define values that configure multiple packages. These keys are defined under the `shared` Top-level Key, as summarized in the following table:

Shared Key	Description	Optional
`ca_cert_data`	PEM-encoded certificate data to trust TLS connections with a private CA. This shared key is used by `convention_controller`, `scanning` and the Tanzu `source_controller` (not the Flux CD Source Controller).	Yes

Shared Key	Description	Optional
`ingress_domain`	Domain name to be used in service routes and host names for instances of Tanzu Application Platform components.	Yes
`ingress_issuer`	A `cert-manager.io/v1/ClusterIssuer` for issuing TLS certificates to Tanzu Application Platform components. Default value: `tap-ingress-selfsigned`	Yes
`kubernetes_distribution`	Type of Kubernetes infrastructure being used. You can use this shared key in coordination with the `kubernetes_version` key. Supported value: `openshift`.	Yes
`kubernetes_version`	Kubernetes version. You can use this shared key independently or in coordination with the `kubernetes_distribution` key. Supported value: `1.24.x`, where `x` stands for the Kubernetes patch version.	Yes
`image_registry.project_path`	Project path in the container image registry server used for builder and application images.	Yes
`image_registry.username`	User name for the container image registry. Mutually exclusive with `shared.image_registry.secret.name/namespace`	Yes
`image_registry.password`	Password for the container image registry. Mutually exclusive with `shared.image_registry.secret.name/namespace`	Yes
`secret.name`	Secret name for the container image registry credentials of type `kubernetes.io/dockerconfigjson`. Mutually exclusive with `shared.image_registry.username/password`	Yes
`secret.namespace`	Secret namespace for the container image registry credentials. Mutually exclusive with `shared.image_registry.username/password`	Yes
`activateAppLiveViewSecureAccessControl`	Enable secure access connection between Application Live View components.	Yes

The following table summarizes the top-level keys used for package-specific configuration within your `tap-values.yaml`.

Package	Top-level Key
See table above.	`shared`
API Auto Registration	`api_auto_registration`
API portal	`api_portal`
Application Accelerator	`accelerator`
Application Live View	`appliveview`
Application Live View connector	`appliveview_connector`
Application Live View conventions	`appliveview-conventions`
Cartographer Conventions	`cartographer_conventions`
Cartographer	`cartographer`
Cloud Native Runtimes	`cnrs`
Source Controller	`source_controller`
Supply Chain	`supply_chain`
Supply Chain Basic	`ootb_supply_chain_basic`
Supply Chain Testing	`ootb_supply_chain_testing`
Supply Chain Testing Scanning	`ootb_supply_chain_testing_scanning`

Package	Top-level Key
Supply Chain Security Tools - Scan	`scanning`
Supply Chain Security Tools - Scan (Grype Scanner)	`grype`
Supply Chain Security Tools - Store	`metadata_store`
Build Service	`buildservice`
Tanzu Developer Portal	`tap_gui`

For information about package-specific configuration, see Install individual packages.

Install individual packages

You can install Tanzu Application Platform (commonly known as TAP) through predefined profiles or through individual packages. Use this topic to learn how to install each individual package. For more information about installing through profiles, see Components and installation profiles.

Installing individual Tanzu Application Platform packages is useful if you do not want to use a profile to install packages or if you want to install additional packages after installing a profile. Before installing the packages, be sure to complete the prerequisites, configure and verify the cluster, accept the EULA, and install the Tanzu CLI with any required plug-ins. For more information, see Prerequisites.

Install pages for individual Tanzu Application Platform packages

- Install API Auto Registration
- Install API portal
- Install Application Accelerator
- Install Application Configuration Service
- Install Application Live View
- Install Application Single Sign-On
- Install Bitnami Services
- Install cert-manager
- Install Cloud Native Runtimes
- Install Contour
- Install Crossplane
- Install default roles for Tanzu Application Platform
- Install Developer Conventions
- Install Flux CD Source Controller
- Install Out of the Box Templates
- Install Out of the Box Supply Chain with Testing
- Install Out of the Box Supply Chain with Testing and Scanning
- Install Service Bindings
- Install Services Toolkit

- Install Source Controller
- Install Spring Boot conventions
- Install Supply Chain Choreographer
- Install Supply Chain Security Tools - Store
- Install Supply Chain Security Tools - Policy Controller
- Install Supply Chain Security Tools - Scan
- Install Tanzu Developer Portal
- Install Tanzu Build Service
- Install Tekton
- Install Telemetry

Verify the installed packages

Use the following procedure to verify that the packages are installed.

1. List the installed packages by running:

   ```
   tanzu package installed list --namespace tap-install
   ```

   For example:

   ```
   $ tanzu package installed list --namespace tap-install
   \ Retrieving installed packages...
   NAME                     PACKAGE-NAME                                        PAC
   KAGE-VERSION  STATUS
   api-portal               api-portal.tanzu.vmware.com                         1.
   0.3           Reconcile succeeded

Next steps

- Set up developer namespaces to use your installed packages

Set up developer namespaces to use your installed packages

This topic tells you how to set up developer namespaces by using the legacy manual process. For more information about how to automatically set up your developer namespaces, see Namespace Provisioner.

Additional configuration for testing and scanning

If you plan to install or have already installed Out of the Box Supply Chains with Testing and Scanning, you can use Namespace Provisioner to set up the required resources. For more information, see Customize installation in the Namespace Provisioner documentation for configuration steps.

Legacy namespace setup

You can choose either one of the following two approaches to create a `Workload` for your application by using the registry credentials specified, add credentials and Role-Based Access Control (RBAC) rules to the namespace that you plan to create the `Workload` in:

- Enable single user access.
- Enable additional users access with Kubernetes RBAC.

Enable single user access

Run the following command to add secrets, a service account to execute the supply chain, and RBAC rules to authorize the service account to the developer namespace:

```
cat <<EOF | kubectl -n YOUR-NAMESPACE apply -f -
apiVersion: v1
kind: Secret
metadata:
  name: tap-registry
  annotations:
    secretgen.carvel.dev/image-pull-secret: ""
type: kubernetes.io/dockerconfigjson
data:
  .dockerconfigjson: e30K

---
apiVersion: v1
kind: ServiceAccount
metadata:
  name: default
```

```
secrets:
  - name: registry-credentials
imagePullSecrets:
  - name: registry-credentials
  - name: tap-registry

---
apiVersion: rbac.authorization.k8s.io/v1
kind: Role
metadata:
  name: default
rules:
- apiGroups: [source.toolkit.fluxcd.io]
  resources: [gitrepositories]

  kind: Role
  name: default
subjects:
```

```
  - kind: ServiceAccount
    name: default
```

Where `YOUR-NAMESPACE` is your developer namespace.

Enable additional users access with Kubernetes RBAC

Follow these steps to enable additional users by using Kubernetes RBAC to submit jobs to the Supply Chain:

1. Enable single user access.
2. Choose either of the following options to give developers namespace-level access and view access to appropriate cluster-level resources:
    - **Option 1:** Use the Tanzu Application Platform RBAC CLI plug-in (beta).

      To use the `tanzu rbac` plug-in to grant `app-viewer` and `app-editor` roles to an identity provider group, run:

      ```
      tanzu rbac binding add -g GROUP-FOR-APP-VIEWER -n YOUR-NAMESPACE -r app-v
      iewer
      tanzu rbac binding add -g GROUP-FOR-APP-EDITOR -n YOUR-NAMESPACE -r app-e
      ditor
      ```

      Where:

        - `YOUR-NAMESPACE` is the name you give to the developer namespace.
        - `GROUP-FOR-APP-VIEWER` is the user group from the upstream identity provider that requires access to `app-viewer` resources on the current namespace and cluster.
        - `GROUP-FOR-APP-EDITOR` is the user group from the upstream identity provider that requires access to `app-editor` resources on the current namespace and cluster.

      For more information about `tanzu rbac`, see Bind a user or group to a default role.

      VMware recommends creating a user group in your identity provider's grouping system for each developer namespace and then adding the users accordingly.

      Depending on your identity provider, you might need to take further action to federate user groups appropriately with your cluster. For an example of how to set up Azure Active Directory (AD) with your cluster, see Integrating Azure Active Directory.

    - **Option 2:** Use the native Kubernetes YAML.

      To apply the RBAC policy, run:

      ```
      cat <<EOF | kubectl -n YOUR-NAMESPACE apply -f -
      apiVersion: rbac.authorization.k8s.io/v1
      kind: RoleBinding
      metadata:
        name: dev-permit-app-viewer
      roleRef:
        apiGroup: rbac.authorization.k8s.io
        kind: ClusterRole
        name: app-viewer
      subjects:
        - kind: Group
          name: GROUP-FOR-APP-VIEWER
          apiGroup: rbac.authorization.k8s.io
      ---
      ```

```
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: YOUR-NAMESPACE-permit-app-viewer
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: app-viewer-cluster-access
subjects:
  - kind: Group
    name: GROUP-FOR-APP-VIEWER
    apiGroup: rbac.authorization.k8s.io
---
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: dev-permit-app-editor
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: app-editor
subjects:
  - kind: Group
    name: GROUP-FOR-APP-EDITOR
    apiGroup: rbac.authorization.k8s.io
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: YOUR-NAMESPACE-permit-app-editor
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: app-editor-cluster-access
subjects:
  - kind: Group
    name: GROUP-FOR-APP-EDITOR
    apiGroup: rbac.authorization.k8s.io
EOF
```

Where:

- `YOUR-NAMESPACE` is the name you give to the developer namespace.
- `GROUP-FOR-APP-VIEWER` is the user group from the upstream identity provider that requires access to `app-viewer` resources on the current namespace and cluster.
- `GROUP-FOR-APP-EDITOR` is the user group from the upstream identity provider that requires access to `app-editor` resources on the current namespace and cluster.

VMware recommends creating a user group in your identity provider's grouping system for each developer namespace and then adding the users accordingly.

Depending on your identity provider, you might need to take further action to federate user groups appropriately with your cluster. For an example of how to set up Azure Active Directory (AD) with your cluster, see Integrating Azure Active Directory.

Rather than granting roles directly to individuals, VMware recommends using your identity provider's user groups system to grant access to a group of developers. For an example of how to set up Azure AD with your cluster, see Integrating Azure Active Directory.

3. (Optional) Log in as a non-admin user, such as a developer, to see the effects of RBAC after the bindings are applied.

Next steps

- Install Tanzu Developer Tools for your VS Code

Install Tanzu Developer Tools for your VS Code

This topic tells you how to install VMware Tanzu Developer Tools for Visual Studio Code (VS Code).

Prerequisites

Before installing the extension, you must have:

- VS Code
- kubectl
- Tilt v0.30.12 or later
- Tanzu CLI and plug-ins
- A cluster with the Tanzu Application Platform Full profile or Iterate profile

If you are an app developer, someone else in your organization might have already set up the Tanzu Application Platform environment.

Docker Desktop and local Kubernetes are not prerequisites for using Tanzu Developer Tools for VS Code.

Install

To install VMware Tanzu Developer Tools for VS Code:

1. Open Visual Studio Code.
2. Open the command palette.
3. In the search box enter `Extension`.
4. Click **Extensions: Install Extensions**.
5. The **Extensions** view opens on the left side of your screen. In the search box enter `Tanzu`.
6. Click **Tanzu Developer Tools** and then click **Install**.

Configure

To configure VMware Tanzu Developer Tools for VS Code:

1. Ensure that you are targeting the correct cluster. For more information, see the Kubernetes documentation.
2. Go to **Code** > **Preferences** > **Settings** > **Extensions** > **Tanzu Developer Tools** and set the following:
    - **Confirm Apply Config**: This controls whether the extension asks to confirm user input when applying a workload.
    - **Confirm Debug Port**: This controls whether the extension asks for the debug port when running `Tanzu: Start Java Debug`.

- **Confirm Local Port**: This controls whether the extension asks for the local port when running `Tanzu: Start Java Debug`.
- **Confirm Delete**: This controls whether the extension asks for confirmation when deleting a workload.
- **Enable Live Hover**: This enables Live Hover. For more information, see Integrating Live Hover by using Spring Boot Tools. Restart VS Code for this change to take effect.
- **Source Image**: The registry location for publishing local source code. For example, `registry.io/yourapp-source`. This must include both a registry and a project name. A source image registry location is optional when Local Source Proxy is configured.
- **Local Path**: (Optional) The path on the local file system to a directory of source code to build. This is the current directory by default.
- **Namespace**: (Optional) This is the namespace that workloads are deployed into. The namespace set in kubeconfig is the default.
- **Tracked Namespaces**: (Optional) Comma-separated list of namespaces. Resources in these namespaces appear in the Tanzu Workloads panel and the Activity panel. If empty, the namespace in the current context is the default.
- **Wait Timeout**: (Optional) This sets how long to wait for a workload to become ready.
- **Workload Type**: (Optional) This distinguishes the workload type. Examples include web and server.

Uninstall

To uninstall VMware Tanzu Developer Tools for VS Code:

1. Go to **Code** > **Preferences** > **Settings** > **Extensions**.
2. Right-click the extension and then click **Uninstall**.

Next steps

Proceed to Getting started with Tanzu Developer Tools for Visual Studio Code.

Install Tanzu Application Platform (OpenShift)

To install Tanzu Application Platform (commonly known as TAP) on your OpenShift clusters with internet access:

Step	Task	Link
1.	Review the prerequisites to ensure you have met all requirements before installing.	Prerequisites
2.	Accept Tanzu Application Platform EULAs and install the Tanzu CLI.	Accept Tanzu Application Platform EULAs and installing the Tanzu CLI
3.	Install Cluster Essentials for Tanzu.	Deploy Cluster Essentials
4.	Add the Tanzu Application Platform package repository, prepare your Tanzu Application Platform profile, and install the profile to the cluster.	Install the Tanzu Application Platform package and profiles
5.	(Optional) Install any additional packages that were not in the profile.	Install individual packages

Step	Task	Link
6.	Set up developer namespaces to use your installed packages.	Set up developer namespaces to use your installed packages
7.	Install developer tools into your integrated development environment (IDE).	Install Tanzu Developer Tools for your VS Code

After installing Tanzu Application Platform on to your OpenShift clusters, proceed with Get started with Tanzu Application Platform.

Install Tanzu Application Platform (OpenShift)

To install Tanzu Application Platform (commonly known as TAP) on your OpenShift clusters with internet access:

Step	Task	Link
1.	Review the prerequisites to ensure you have met all requirements before installing.	Prerequisites
2.	Accept Tanzu Application Platform EULAs and install the Tanzu CLI.	Accept Tanzu Application Platform EULAs and installing the Tanzu CLI
3.	Install Cluster Essentials for Tanzu.	Deploy Cluster Essentials
4.	Add the Tanzu Application Platform package repository, prepare your Tanzu Application Platform profile, and install the profile to the cluster.	Install the Tanzu Application Platform package and profiles
5.	(Optional) Install any additional packages that were not in the profile.	Install individual packages
6.	Set up developer namespaces to use your installed packages.	Set up developer namespaces to use your installed packages
7.	Install developer tools into your integrated development environment (IDE).	Install Tanzu Developer Tools for your VS Code

After installing Tanzu Application Platform on to your OpenShift clusters, proceed with Get started with Tanzu Application Platform.

Install Tanzu Application Platform on your OpenShift clusters

This topic tells you how to install Tanzu Application Platform (commonly known as TAP) packages on your OpenShift clusters.

Before installing the packages, ensure you have:

- Completed the Prerequisites.
- Configured and verified the cluster.
- Accepted Tanzu Application Platform EULA and installed Tanzu CLI with any required plug-ins.

Relocate images to a registry

VMware recommends relocating the images from VMware Tanzu Network registry to your own container image registry before attempting installation. If you don't relocate the images, Tanzu Application Platform will depend on VMware Tanzu Network for continued operation, and VMware Tanzu Network offers no uptime guarantees. The option to skip relocation is documented for evaluation and proof-of-concept only.

The supported registries are Harbor, Azure Container Registry, Google Container Registry, and Quay.io. See the following documentation for a registry to learn how to set it up:

- Harbor documentation
- Google Container Registry documentation
- Quay.io documentation

To relocate images from the VMware Tanzu Network registry to your registry:

1. Set up environment variables for installation use by running:

   ```
   # Set tanzunet as the source registry to copy Tanzu Application Platform packag
   es from.
   export IMGPKG_REGISTRY_HOSTNAME_0=registry.tanzu.vmware.com
   export IMGPKG_REGISTRY_USERNAME_0=MY-TANZUNET-USERNAME
   export IMGPKG_REGISTRY_PASSWORD_0=MY-TANZUNET-PASSWORD

   # The user's registry for copying the Tanzu Application Platform package to.
   export IMGPKG_REGISTRY_HOSTNAME_1=MY-REGISTRY
   export IMGPKG_REGISTRY_USERNAME_1=MY-REGISTRY-USER
   export IMGPKG_REGISTRY_PASSWORD_1=MY-REGISTRY-PASSWORD
   # These environment variables starting with IMGPKG_* are used by the imgpkg com
   mand only.

   # The registry from which the Tanzu Application Platform package is retrieved.
   export INSTALL_REGISTRY_USERNAME="${IMGPKG_REGISTRY_USERNAME_1}"
   export INSTALL_REGISTRY_PASSWORD="${IMGPKG_REGISTRY_PASSWORD_1}"
   export INSTALL_REGISTRY_HOSTNAME=MY-REGISTRY
   export TAP_VERSION=VERSION-NUMBER
   export INSTALL_REPO=TARGET-REPOSITORY
   ```

   Where:

   - `MY-REGISTRY-USER` is the user with write access to `MY-REGISTRY`.
   - `MY-REGISTRY-PASSWORD` is the password for `MY-REGISTRY-USER`.
   - `MY-REGISTRY` is your own container registry.
   - `MY-TANZUNET-USERNAME` is the user with access to the images in the VMware Tanzu Network registry `registry.tanzu.vmware.com`
   - `MY-TANZUNET-PASSWORD` is the password for `MY-TANZUNET-USERNAME`.
   - `VERSION-NUMBER` is your Tanzu Application Platform version. For example, `1.9.1`.
   - `TARGET-REPOSITORY` is your target repository, a folder/repository on `MY-REGISTRY` that serves as the location for the installation files for Tanzu Application Platform.

2. Install the Carvel tool imgpkg CLI.
3. Relocate the images with the `imgpkg` CLI by running:

   ```
   imgpkg copy -b registry.tanzu.vmware.com/tanzu-application-platform/tap-package
   s:${TAP_VERSION} --to-repo ${INSTALL_REGISTRY_HOSTNAME}/${INSTALL_REPO}/tap-pac
   kages
   ```

4. Create a namespace called `tap-install` for deploying any component packages by running:

   ```
   kubectl create ns tap-install
   ```

   This namespace keeps the objects grouped together logically.

5. Create a registry secret by running:

```
tanzu secret registry add tap-registry \
  --username ${INSTALL_REGISTRY_USERNAME} --password ${INSTALL_REGISTRY_PASSWOR
D} \
  --server ${INSTALL_REGISTRY_HOSTNAME} \
  --export-to-all-namespaces --yes --namespace tap-install
```

6. (Optional) Create a registry secret for your writable image repository used for:
    - Tanzu Build Service Dependencies
    - Workloads when using the `shared.image_registry` key

```
tanzu secret registry add image-registry-creds \
  --server "${REGISTRY_HOSTNAME}" \
  --username "${REGISTRY_USERNAME}" \
  --password "${REGISTRY_PASSWORD}" \
  --namespace tap-install
```

Where:

- `REGISTRY_HOSTNAME` is the host name for the registry that contains your writable repository. Examples:
    - Harbor has the form `--server "my-harbor.io"`.
    - Docker Hub has the form `--server "index.docker.io"`.
    - Google Cloud Registry has the form `--server "gcr.io"`.
- `REGISTRY_USERNAME` and `REGISTRY_PASSWORD` are the user name and password for the user that can write to the repository used in the following step. For Google Cloud Registry, use `_json_key` as the user name and the contents of the service account JSON file for the password.

Note

If using the same repository as `tap-registry`, you can skip this step and use the `tap-registry` secret in your `tap-values.yaml` instead of `image-registry-creds`.

7. Add the Tanzu Application Platform package repository to the cluster by running:

```
tanzu package repository add tanzu-tap-repository \
  --url ${INSTALL_REGISTRY_HOSTNAME}/${INSTALL_REPO}/tap-packages:$TAP_VERSION
\
  --namespace tap-install
```

8. Get the status of the Tanzu Application Platform package repository, and ensure the status updates to `Reconcile succeeded` by running:

```
tanzu package repository get tanzu-tap-repository --namespace tap-install
```

For example:

```
$ tanzu package repository get tanzu-tap-repository --namespace tap-install
- Retrieving repository tap...
NAME:          tanzu-tap-repository
VERSION:       16253001
REPOSITORY:    tapmdc.azurecr.io/mdc/1.4.0/tap-packages
TAG:           1.9.1
```

```
STATUS:        Reconcile succeeded
REASON:
```

Note

The `VERSION` and `TAG` numbers differ from the earlier example if you are on Tanzu Application Platform v1.0.2 or earlier.

9. List the available packages by running:

```
tanzu package available list --namespace tap-install
```

For example:

```
$ tanzu package available list --namespace tap-install
/ Retrieving available packages...
  NAME                                                DISPLAY-NAME

Install your Tanzu Application Platform profile

The `tap.tanzu.vmware.com` package installs predefined sets of packages based on your profile settings. This is done by using the package manager installed by Tanzu Cluster Essentials.

For more information about profiles, see Components and installation profiles.

To prepare to install a profile:

1. List version information for the package by running:

   ```
   tanzu package available list tap.tanzu.vmware.com --namespace tap-install
   ```

2. Create a `tap-values.yaml` file by using the Full Profile sample in the following section as a guide. These samples have the minimum configuration required to deploy Tanzu Application Platform. The sample values file contains the necessary defaults for:

   - The meta-package, or parent Tanzu Application Platform package.
   - Subordinate packages, or individual child packages.

   Keep the values file for future configuration use.

   

   Note

   `tap-values.yaml` is set as a Kubernetes secret, which provides secure means to read credentials for Tanzu Application Platform components.

3. View possible configuration settings for your package

Full profile

The following is the YAML file sample for the full-profile. The `profile:` field takes `full` as the default value, but you can also set it to `iterate`, `build`, `run` or `view`. Refer to Install multicluster Tanzu Application Platform profiles for more information.

```
shared:
  ingress_domain: "INGRESS-DOMAIN"
  image_registry:
    project_path: "SERVER-NAME/REPO-NAME"
    secret:
      name: image-registry-creds
      namespace: tap-install
  kubernetes_distribution: "openshift" # To be passed only for OpenShift. Defaults to
"".
  kubernetes_version: "K8S-VERSION"
  ca_cert_data: | # To be passed if using custom certificates.
      -----BEGIN CERTIFICATE-----

  app_service_type: ClusterIP # Defaults to LoadBalancer. If shared.ingress_domain is
set earlier, this must be set to ClusterIP.
```

Important

Installing Grype by using `tap-values.yaml` as follows is deprecated in v1.6 and will be removed in v1.8:

```
grype:
  targetImagePullSecret: "TARGET-REGISTRY-CREDENTIALS-SECRET"
```

You can install Grype by using Namespace Provisioner instead.

Where:

- `INGRESS-DOMAIN` is the subdomain for the host name that you point at the `tanzu-shared-ingress` service's External IP address.
- `KP-DEFAULT-REPO` is a writable repository in your registry. Tanzu Build Service dependencies are written to this location. Examples:
  - Harbor has the form `kp_default_repository: "my-harbor.io/my-project/build-service"`.
  - Docker Hub has the form `kp_default_repository: "my-dockerhub-user/build-service"` or `kp_default_repository: "index.docker.io/my-user/build-service"`.
  - Google Cloud Registry has the form `kp_default_repository: "gcr.io/my-project/build-service"`.
- `K8S-VERSION` is the Kubernetes version used by your OpenShift cluster. It must be in the form of `1.26.3`, `1.27.x` or `1.28.x`, where `x` stands for the patch version. Examples:
  - Red Hat OpenShift Container Platform v4.13 uses the Kubernetes version `1.26.3`.
  - Red Hat OpenShift Container Platform v4.14 uses the Kubernetes version `1.27.6`.
  - Red Hat OpenShift Container Platform v4.15 uses the Kubernetes version `1.28.5`.
- `SERVER-NAME` is the host name of the registry server. Examples:
  - Harbor has the form `server: "my-harbor.io"`.
  - Docker Hub has the form `server: "index.docker.io"`.
  - Google Cloud Registry has the form `server: "gcr.io"`.
- `REPO-NAME` is where workload images are stored in the registry. If this key is passed through the shared section earlier and AWS ECR registry is used, you must ensure that the `SERVER-NAME/REPO-NAME/buildservice` and `SERVER-NAME/REPO-NAME/workloads` exist. AWS ECR expects the paths to be pre-created. Images are written to `SERVER-NAME/REPO-NAME/workload-name`. Examples:
  - Harbor has the form `repository: "my-project/supply-chain"`.
  - Docker Hub has the form `repository: "my-dockerhub-user"`.
  - Google Cloud Registry has the form `repository: "my-project/supply-chain"`.
- `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE` is where the developer's local source is uploaded when using Tanzu CLI to use Local Source Proxy for workload creation.

  If an AWS ECR registry is being used, ensure that the repository already exists. AWS ECR expects the repository path to already exist. This destination is represented as `REGISTRY-SERVER/REPOSITORY-PATH`. For more information, see Install Local Source Proxy.
- `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE-SECRET` is the name of the secret with credentials that allow pushing to the `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE` repository.
- `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE-SECRET-NAMESPACE` is the namespace in which `EXTERNAL-REGISTRY-FOR-LOCAL-SOURCE-SECRET` is available.
- `GIT-SOURCE-CREDENTIAL-SECRET-NAME` is the name of the Kubernetes secret in the developer namespace that supplies the Git credentials for the supply chain to fetch source code from.

This field is only required if you use a private repository. See Git authentication for more information.

- `GITOPS-CREDENTIAL-SECRET-NAME` is the name of the Kubernetes secret in the developer namespace that supplies the Git credentials for the supply chain to push configuration to. See Git authentication for more information.
- `GIT-CATALOG-URL` is the path to the `catalog-info.yaml` catalog definition file. You can download either a blank or populated catalog file from the Tanzu Application Platform product page. Otherwise, you can use a Backstage-compliant catalog you've already built and posted on the Git infrastructure.
- `MY-DEV-NAMESPACE` is the name of the developer namespace. SCST - Store exports secrets to the namespace, and SCST - Scan deploys the `ScanTemplates` there. This allows the scanning feature to run in this namespace. If there are multiple developer namespaces, use `ns_for_export_app_cert: "*"` to export the SCST - Store CA certificate to all namespaces.
- `TARGET-REGISTRY-CREDENTIALS-SECRET` is the name of the secret that contains the credentials to pull an image from the registry for scanning.

Tanzu Application Platform is part of VMware's CEIP program where data is collected to help improve the customer experience. By setting `ceip_policy_disclosed` to `true` (not a string), you acknowledge the program is disclosed to you and you are aware data collection is happening. This field must be set for the installation to be completed. See Opt out of telemetry collection for more information.

If you use custom CA certificates, you must provide one or more PEM-encoded CA certificates under the `ca_cert_data` key. If you configured `shared.ca_cert_data`, Tanzu Application Platform component packages inherit that value by default.

If you use AWS, the default settings creates a classic LoadBalancer. To use the Network LoadBalancer instead of the classic LoadBalancer for ingress, add the following to your `tap-values.yaml`:

```
contour:
  infrastructure_provider: aws
  envoy:
    service:
      aws:
        LBType: nlb
```

(Optional) Additional Build Service configurations

The following tasks are optional during the Tanzu Application Platform installation process:

- (Optional) Configure your profile with full dependencies
- (Optional) Configure your profile with the Jammy stack only

(Optional) Configure your profile with full dependencies

When you install a profile that includes Tanzu Build Service, Tanzu Application Platform is installed with the `lite` set of dependencies. These dependencies consist of buildpacks and stacks required for application builds.

The `lite` set of dependencies do not contain all buildpacks and stacks. To use all buildpacks and stacks, you must install the `full` dependencies. For more information about the differences between `lite` and `full` dependencies, see About lite and full dependencies.

To configure `full` dependencies, add the key-value pair `exclude_dependencies: true` to your `tap-values.yaml` file under the `buildservice` section. For example:

```
buildservice:
  ...
  exclude_dependencies: true
  ...
```

After configuring `full` dependencies, you must install the dependencies after you have finished installing your Tanzu Application Platform package. See Install the full dependencies package for more information.

(Optional) Configure your profile with the Jammy stack only

Tanzu Application Platform v1.5.0 supports building applications with both the Ubuntu v22.04 (Jammy) and v18.04 (Bionic) stack. For more information, see Bionic and Jammy stacks.

To install Tanzu Application Platform with Jammy as the only available stack, include the `stack_configuration: jammy-only` field under the `buildservice:` section in `tap-values.yaml`.

Security Context Constraints

Security Context Constraints (SCC) define a set of rules that a pod must satisfy to be created. Tanzu Application Platform components use the built-in nonroot-v2 or restricted-v2 SCC.

In Red Hat OpenShift, SCC are used to restrict privileges for pods. In Tanzu Application Platform v1.4 there is no custom SCC.

Tanzu Application Platform packages reconcile without any issues when using OpenShift v4.11 with restricted-v2 or nonroot-v2.

Install your Tanzu Application Platform package

Follow these steps to install the Tanzu Application Platform package:

1. Install the package by running:

   ```
   tanzu package install tap -p tap.tanzu.vmware.com -v $TAP_VERSION --values-file
   tap-values.yaml -n tap-install
   ```

2. Verify the package install by running:

   ```
   tanzu package installed get tap -n tap-install
   ```

   This can take 5-10 minutes because it installs several packages on your cluster.

3. Verify that the necessary packages in the profile are installed by running:

   ```
   tanzu package installed list -A
   ```

4. If you configured `full` dependencies in your `tbs-values.yaml` file, install the `full` dependencies by following the procedure in Install full dependencies.

After installing the Full profile on your cluster, you can install the Tanzu Developer Tools for VS Code Extension to help you develop against it. For instructions, see Install Tanzu Developer Tools for your VS Code.

Note

You can run the following command after reconfiguring the profile to reinstall the Tanzu Application Platform:

```
tanzu package installed update tap -p tap.tanzu.vmware.com -v $TAP_VERSION  --values-f
ile tap-values.yaml -n tap-install
```

Install the full dependencies package

If you configured `full` dependencies in your `tap-values.yaml` file in Configure your profile with full dependencies earlier, you must install the `full` dependencies package.

For more information about the differences between `lite` and `full` dependencies, see About lite and full dependencies.

To install the `full` dependencies package:

1. Get the latest version of the Tanzu Application Platform package by running:

   ```
   tanzu package available list tap.tanzu.vmware.com --namespace tap-install
   ```

2. If you have not done so already, you must exclude the default dependencies by adding the key-value pair `exclude_dependencies: true` to your `tap-values.yaml` file under the `buildservice` section. For example:

   ```
   buildservice:
     exclude_dependencies: true
   ```

3. If you have not updated your Tanzu Application Platform package installation after adding the key-value pair `exclude_dependencies: true` to your values file, perform the update by running:

   ```
   tanzu package installed update tap --namespace tap-install --values-file VALUES
   -FILE
   ```

   Where `VALUES-FILE` is the path to the `tap-values.yaml` file you edited earlier.

4. Relocate the Tanzu Build Service `full` dependencies package repository by doing one of the following:

   - Relocate the images directly for online installation:

     ```
     imgpkg copy \
       -b registry.tanzu.vmware.com/tanzu-application-platform/full-deps-packa
     ge-repo:VERSION \
       --to-repo ${INSTALL_REGISTRY_HOSTNAME}/full-deps-package-repo
     ```

     Where `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.

   - Relocate the images to an external storage device and then to the registry in the air-gapped environment:

     ```
     imgpkg copy \
       -b registry.tanzu.vmware.com/tanzu-application-platform/full-deps-packa
     ge-repo:VERSION \
       --to-tar=full-deps-package-repo.tar

     # move full-deps-package-repo.tar to environment with registry access
     imgpkg copy \
       --tar full-deps-package-repo.tar \
       --to-repo=INSTALL-REGISTRY-HOSTNAME/TARGET-REPOSITORY/full-deps-package
     -repo
     ```

     Where:

- `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.
- `INSTALL-REGISTRY-HOSTNAME` is your container registry.
- `TARGET-REPOSITORY` is your target repository.

5. Add the Tanzu Build Service `full` dependencies package repository by running:

```
tanzu package repository add full-deps-package-repo \
  --url INSTALL-REGISTRY-HOSTNAME/TARGET-REPOSITORY/full-deps-package-repo:VERS
ION \
  --namespace tap-install
```

Where:

- `INSTALL-REGISTRY-HOSTNAME` is your container registry.
- `TARGET-REPOSITORY` is your target repository.
- `VERSION` is the version of the Tanzu Application Platform package you retrieved earlier.

6. Create a new `tbs-full-deps-values.yaml` and copy the `kp_default_repository` key-value pair from your `tap-values.yaml` or `tbs-values.yaml`:

```
---
 kp_default_repository: "REPO-NAME"
 kp_default_repository_secret:
   name: kp-default-repository-creds
   namespace: tap-install
```

Where `REPO-NAME` is copied from the `buildservice.kp_default_repository` field in your `tap-values.yaml` or `tbs-values.yaml`.

1. (Optional) Install the UBI builder.

   The UBI builder uses Red Hat Universal Base Image (UBI) v8 for both build and run images. This builder only supports Java and Node.js. To install the UBI builder, add the key-value pair `enable_ubi_builder: true` to your `tbs-full-deps-values.yaml`.

   ```
   ---
   enable_ubi_builder: true
   ```

2. (Optional) Install the Static builder.

   The Static builder uses Ubuntu Jammy for both build images and a minimal static run image. This builder only supports Golang. To install the Static builder, add the key-value pair `enable_static_builder: true` to your `tbs-full-deps-values.yaml`.

   ```
   ---
   enable_static_builder: true
   ```

7. Install the `full` dependencies package by running:

```
tanzu package install full-deps \
  --package full-deps.buildservice.tanzu.vmware.com \
  --version "> 0.0.0" \
  --namespace tap-install \
  --values-file VALUES-FILE
```

Where `VALUES-FILE` is the path to the `tbs-full-deps-values.yaml` you created earlier.

Access Tanzu Developer Portal

To access Tanzu Developer Portal, you can use the host name that you configured earlier. This host name is pointed at the shared ingress. To configure LoadBalancer for Tanzu Developer Portal, see Access Tanzu Developer Portal.

You're now ready to start using Tanzu Developer Portal. Proceed to the Getting Started topic or the Tanzu Developer Portal - Catalog Operations topic.

Exclude packages from a Tanzu Application Platform profile

To exclude packages from a Tanzu Application Platform profile:

1. Find the full subordinate (child) package name:

   ```
   tanzu package available list --namespace tap-install
   ```

2. Update your `tap-values` file with a section listing the exclusions:

   ```
   profile: PROFILE-VALUE
   excluded_packages:
     - tap-gui.tanzu.vmware.com
     - service-bindings.lab.vmware.com
   ```

Important

If you exclude a package after performing a profile installation including that package, you cannot see the accurate package states immediately after running `tap package installed list -n tap-install`. Also, you can break package dependencies by removing a package. Allow 20 minutes to verify that all packages have reconciled correctly while troubleshooting.

View possible configuration settings for your package

To view possible configuration settings for a package, run:

```
tanzu package available get tap.tanzu.vmware.com/$TAP_VERSION --values-schema --namesp
ace tap-install
```

Note

The `tap.tanzu.vmware.com` package does not show all configuration settings for packages it plans to install. The package only shows top-level keys. You can view individual package configuration settings with the same `tanzu package available get` command. For example, to find the keys for Cloud Native Runtimes, you must first identify the version of the package with `tanzu package installed list -n tap-install`, which lists all the installed packages versions. Then run the command `tanzu package available get -n tap-install cnrs.tanzu.vmware.com/CNR-VERSION --values-schema` by using the package version listed for Cloud Native Runtimes.

```
profile: full

# Shared configurations go under the shared key.
shared:
  ingress_domain: tap.example.com

# ...

# For example, Cloud Native Runtimes specific values go under its name.
cnrs:
  provider: local

# For example, App Accelerator specific values go under its name.
accelerator:
  server:
    service_type: "ClusterIP"
```

Shared Keys define values that configure multiple packages. These keys are defined under the `shared` Top-level Key, as summarized in the following table:

Shared Key	Description	Optional
`ca_cert_data`	PEM-encoded certificate data to trust TLS connections with a private CA. This shared key is used by `convention_controller`, `scanning` and the Tanzu `source_controller` (not the Flux CD Source Controller).	Yes
`ingress_domain`	Domain name to be used in service routes and host names for instances of Tanzu Application Platform components.	Yes
`ingress_issuer`	A `cert-manager.io/v1/ClusterIssuer` for issuing TLS certificates to Tanzu Application Platform components. Default value: `tap-ingress-selfsigned`	Yes
`kubernetes_distribution`	Type of Kubernetes infrastructure being used. You can use this shared key in coordination with the `kubernetes_version` key. Supported value: `openshift`.	Yes
`kubernetes_version`	Kubernetes version. You can use this shared key independently or in coordination with the `kubernetes_distribution` key. Supported value: `1.24.x`, where `x` stands for the Kubernetes patch version.	Yes
`image_registry.project_path`	Project path in the container image registry server used for builder and application images.	Yes
`image_registry.username`	User name for the container image registry. Mutually exclusive with `shared.image_registry.secret.name/namespace`	Yes
`image_registry.password`	Password for the container image registry. Mutually exclusive with `shared.image_registry.secret.name/namespace`	Yes
`secret.name`	Secret name for the container image registry credentials of type `kubernetes.io/dockerconfigjson`. Mutually exclusive with `shared.image_registry.username/password`	Yes
`secret.namespace`	Secret namespace for the container image registry credentials. Mutually exclusive with `shared.image_registry.username/password`	Yes
`activateAppLiveViewSecureAccessControl`	Enable secure access connection between Application Live View components.	Yes

The following table summarizes the top-level keys used for package-specific configuration within your `tap-values.yaml`.

Package	Top-level Key
See table above.	`shared`
API Auto Registration	`api_auto_registration`

Package	Top-level Key
API portal	`api_portal`
Application Accelerator	`accelerator`
Application Live View	`appliveview`
Application Live View connector	`appliveview_connector`
Application Live View conventions	`appliveview-conventions`
Cartographer Conventions	`cartographer_conventions`
Cartographer	`cartographer`
Cloud Native Runtimes	`cnrs`
Source Controller	`source_controller`
Supply Chain	`supply_chain`
Supply Chain Basic	`ootb_supply_chain_basic`
Supply Chain Testing	`ootb_supply_chain_testing`
Supply Chain Testing Scanning	`ootb_supply_chain_testing_scanning`
Supply Chain Security Tools - Scan	`scanning`
Supply Chain Security Tools - Scan (Grype Scanner)	`grype`
Supply Chain Security Tools - Store	`metadata_store`
Build Service	`buildservice`
Tanzu Developer Portal	`tap_gui`

For information about package-specific configuration, see Install individual packages.

Install individual packages

You can install Tanzu Application Platform (commonly known as TAP) through predefined profiles or through individual packages. Use this topic to learn how to install each individual package. For more information about installing through profiles, see Components and installation profiles.

Installing individual Tanzu Application Platform packages is useful if you do not want to use a profile to install packages or if you want to install additional packages after installing a profile. Before installing the packages, be sure to complete the prerequisites, configure and verify the cluster, accept the EULA, and install the Tanzu CLI with any required plug-ins. For more information, see Prerequisites.

Install pages for individual Tanzu Application Platform packages

- Install API Auto Registration
- Install API portal
- Install Application Accelerator
- Install Application Configuration Service
- Install Application Live View
- Install Application Single Sign-On

- Install Bitnami Services
- Install cert-manager
- Install Cloud Native Runtimes
- Install Contour
- Install Crossplane
- Install default roles for Tanzu Application Platform
- Install Developer Conventions
- Install Flux CD Source Controller
- Install Out of the Box Templates
- Install Out of the Box Supply Chain with Testing
- Install Out of the Box Supply Chain with Testing and Scanning
- Install Service Bindings
- Install Services Toolkit
- Install Source Controller
- Install Spring Boot conventions
- Install Supply Chain Choreographer
- Install Supply Chain Security Tools - Store
- Install Supply Chain Security Tools - Policy Controller
- Install Supply Chain Security Tools - Scan
- Install Tanzu Developer Portal
- Install Tanzu Build Service
- Install Tekton
- Install Telemetry

Verify the installed packages

Use the following procedure to verify that the packages are installed.

1. List the installed packages by running:

   ```
   tanzu package installed list --namespace tap-install
   ```

   For example:

   ```
   $ tanzu package installed list --namespace tap-install
   \ Retrieving installed packages...
   NAME                     PACKAGE-NAME                                    PAC
   KAGE-VERSION  STATUS
   api-portal               api-portal.tanzu.vmware.com                     1.
   0.3           Reconcile succeeded
   app-accelerator          accelerator.apps.tanzu.vmware.com               1.
   0.0           Reconcile succeeded
   app-live-view            appliveview.tanzu.vmware.com                    1.
   0.2           Reconcile succeeded
   appliveview-conventions  build.appliveview.tanzu.vmware.com              1.
   0.2           Reconcile succeeded
   cartographer             cartographer.tanzu.vmware.com                   0.
   1.0           Reconcile succeeded
   ```

```

Next steps

- Set up developer namespaces to use your installed packages

Set up developer namespaces to use your installed packages

For details about how to automatically set up your developer namespaces, see Provision developer namespaces in Namespace Provisioner.

Additional configuration for testing and scanning

If you plan to install or have already installed Out of the Box Supply Chains with Testing and Scanning, you can use Namespace Provisioner to set up the required resources. For more information, see Customize installation in the Namespace Provisioner documentation for configuration steps.

Legacy namespace setup

To use the legacy manual process for setting up developer namespaces, see Legacy namespace setup.

Next steps

- Install Tanzu Developer Tools for your VS Code

Install Tanzu Developer Tools for your VS Code

This topic tells you how to install VMware Tanzu Developer Tools for Visual Studio Code (VS Code).

Prerequisites

Before installing the extension, you must have:

- VS Code
- kubectl
- Tilt v0.30.12 or later
- Tanzu CLI and plug-ins
- A cluster with the Tanzu Application Platform Full profile or Iterate profile

If you are an app developer, someone else in your organization might have already set up the Tanzu Application Platform environment.

Docker Desktop and local Kubernetes are not prerequisites for using Tanzu Developer Tools for VS Code.

Install

To install VMware Tanzu Developer Tools for VS Code:

1. Open Visual Studio Code.
2. Open the command palette.
3. In the search box enter `Extension`.
4. Click **Extensions: Install Extensions**.
5. The **Extensions** view opens on the left side of your screen. In the search box enter `Tanzu`.
6. Click **Tanzu Developer Tools** and then click **Install**.

Configure

To configure VMware Tanzu Developer Tools for VS Code:

1. Ensure that you are targeting the correct cluster. For more information, see the Kubernetes documentation.
2. Go to **Code** > **Preferences** > **Settings** > **Extensions** > **Tanzu Developer Tools** and set the following:
    - **Confirm Apply Config**: This controls whether the extension asks to confirm user input when applying a workload.
    - **Confirm Debug Port**: This controls whether the extension asks for the debug port when running `Tanzu: Start Java Debug`.
    - **Confirm Local Port**: This controls whether the extension asks for the local port when running `Tanzu: Start Java Debug`.
    - **Confirm Delete**: This controls whether the extension asks for confirmation when deleting a workload.
    - **Enable Live Hover**: This enables Live Hover. For more information, see Integrating Live Hover by using Spring Boot Tools. Restart VS Code for this change to take effect.

- **Source Image**: The registry location for publishing local source code. For example, `registry.io/yourapp-source`. This must include both a registry and a project name. A source image registry location is optional when Local Source Proxy is configured.
- **Local Path**: (Optional) The path on the local file system to a directory of source code to build. This is the current directory by default.
- **Namespace**: (Optional) This is the namespace that workloads are deployed into. The namespace set in kubeconfig is the default.
- **Tracked Namespaces**: (Optional) Comma-separated list of namespaces. Resources in these namespaces appear in the Tanzu Workloads panel and the Activity panel. If empty, the namespace in the current context is the default.
- **Wait Timeout**: (Optional) This sets how long to wait for a workload to become ready.
- **Workload Type**: (Optional) This distinguishes the workload type. Examples include web and server.

Uninstall

To uninstall VMware Tanzu Developer Tools for VS Code:

1. Go to **Code** > **Preferences** > **Settings** > **Extensions**.
2. Right-click the extension and then click **Uninstall**.

Next steps

Proceed to Getting started with Tanzu Developer Tools for Visual Studio Code.

Custom Security Context Constraint details for Tanzu Application Platform

Custom Security Context Constraint (commonly known as SCC) details for Tanzu Application Platform (commonly known as TAP) components are as follows:

- Application Accelerator on OpenShift cluster
- Application Live View on OpenShift
- Application Single Sign-On for OpenShift cluster
- Contour for OpenShift cluster
- Developer Conventions for OpenShift cluster
- Tanzu Build Service for OpenShift cluster

Application Accelerator on OpenShift

On OpenShift clusters, Application Accelerator must run with a custom SecurityContextConstraint (SCC) to enable compliance with restricted Kubernetes pod security standards. Tanzu Application Platform configures the following SCC for Application Accelerator when you configure the `kubernetes_distribution: openshift` key in the `tap-values.yaml` file.

Specification follows:

```
#@ load("@ytt:data", "data")
#@ load("@ytt:assert", "assert")
```

```
#@ kubernetes_distribution = data.values.kubernetes_distribution
#@ validDistributions = [None, "", "openshift"]
#@ if kubernetes_distribution not in validDistributions:
#@   assert.fail("{} not in {}".format(kubernetes_distribution, validDistributions))
#@ end

#@ if kubernetes_distribution == "openshift":
---
apiVersion: rbac.authorization.k8s.io/v1
kind: Role
metadata:
  name: accelerator-system-nonroot-scc
  namespace: accelerator-system
rules:
- apiGroups:
  - security.openshift.io
  resourceNames:
  - nonroot
  resources:
  - securitycontextconstraints
  verbs:
  - use
---
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: accelerator-system-nonroot-scc
  namespace: accelerator-system
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: Role
  name: accelerator-system-nonroot-scc
subjects:
- apiGroup: rbac.authorization.k8s.io
  kind: Group
  name: system:serviceaccounts:accelerator-system
#@ end
```

Application Live View on OpenShift

Application Live View must run with a custom SecurityContextConstraint (SCC) to enable compliance with restricted Kubernetes Pod Security Standards on OpenShift. Tanzu Application Platform configures the following SCC for Application Live View back end, Application Live View connector, and Application Live View convention service when you configure the `kubernetes_distribution: openshift` key in the `tap-values.yaml` file.

The following is a `SecurityContextConstraints` specification for Application Live View connector:

```
---
apiVersion: security.openshift.io/v1
kind: SecurityContextConstraints
metadata:
  name: appliveview-connector-restricted-with-seccomp
allowHostDirVolumePlugin: false
allowHostIPC: false
allowHostNetwork: false
allowHostPID: false
allowHostPorts: false
allowPrivilegeEscalation: false
allowPrivilegedContainer: false
allowedCapabilities: null
defaultAddCapabilities: null
fsGroup:
  type: MustRunAs
```

```
priority: null
readOnlyRootFilesystem: false
requiredDropCapabilities:
  - ALL
runAsUser:
  type: MustRunAsNonRoot
seLinuxContext:
  type: MustRunAs
supplementalGroups:
  type: RunAsAny
volumes:
  - configMap
  - downwardAPI
  - emptyDir
  - persistentVolumeClaim
  - projected
  - secret
seccompProfiles:
  - runtime/default
```

The preceding `SecurityContextConstraints` specification is applicable to Application Live View back end and Application Live View convention service as well.

Application Single Sign-On for OpenShift cluster

On OpenShift clusters, AppSSO must run with a custom SecurityContextConstraint (SCC) to enable compliance with restricted Kubernetes Pod Security Standards. Tanzu Application Platform configures the following SCC for AppSSO controller and its `AuthServer` managed resources when you configure the `kubernetes_distribution: openshift` key in the `tap-values.yaml` file.

Specification follows:

```
---
kind: SecurityContextConstraints
apiVersion: security.openshift.io/v1
metadata:
  name: appsso-scc
allowHostDirVolumePlugin: false
allowHostIPC: false
allowHostNetwork: false
allowHostPID: false
allowHostPorts: false
allowPrivilegeEscalation: false
allowPrivilegedContainer: false
allowedCapabilities: null
defaultAddCapabilities: null
fsGroup:
  type: MustRunAs
priority: null
readOnlyRootFilesystem: false
requiredDropCapabilities:
  - KILL
  - MKNOD
  - SETUID
  - SETGID
runAsUser:
  type: MustRunAsNonRoot
seLinuxContext:
  type: MustRunAs
volumes:
  - configMap
  - downwardAPI
  - emptyDir
  - persistentVolumeClaim
```

```
  - projected
  - secret
seccompProfiles:
  - 'runtime/default'
```

AppSSO controller's `ServiceAccount` is given the following additional permissions, including a `use` permission for AppSSO SCC, so `AuthServer` can use the custom SCC:

```
- apiGroups:
    - security.openshift.io
  resources:
    - securitycontextconstraints
  verbs:
    - "get"
    - "list"
    - "watch"
```

```
- apiGroups:
    - security.openshift.io
  resourceNames:
    - appsso-scc
  resources:
    - securitycontextconstraints
  verbs:
    - "use"
```

Contour for OpenShift cluster

On OpenShift clusters, Contour must run with a custom SecurityContextConstraint (SCC) to enable compliance with restricted Kubernetes Pod Security Standards. Tanzu Application Platform configures the following SCC for the service accounts in the `tanzu-system-ingress` namespace, which applies to Contour's controller and Envoy pods, when you configure the `kubernetes_distribution: openshift` key in the `tap-values.yaml` file.

Specification follows:

```
apiVersion: security.openshift.io/v1
kind: SecurityContextConstraints
metadata:
  annotations:
    include.release.openshift.io/ibm-cloud-managed: "true"
    include.release.openshift.io/self-managed-high-availability: "true"
    include.release.openshift.io/single-node-developer: "true"
    kubernetes.io/description: nonroot provides all features of the restricted SCC
      but allows users to run with any non-root UID.  The user must specify the UID
      or it must be specified on the by the manifest of the container runtime. On
      top of the legacy 'nonroot' SCC, it also requires to drop ALL capabilities and
      does not allow privilege escalation binaries. It will also default the seccomp
      profile to runtime/default if unset, otherwise this seccomp profile is required.
  name: contour-seccomp-nonroot-v2
allowHostDirVolumePlugin: false
allowHostIPC: false
allowHostNetwork: false
allowHostPID: false
allowHostPorts: false
allowPrivilegeEscalation: false
allowPrivilegedContainer: false
allowedCapabilities:
- NET_BIND_SERVICE
defaultAddCapabilities: null
fsGroup:
```

```
  type: RunAsAny
groups: []
priority: null
readOnlyRootFilesystem: false
requiredDropCapabilities:
- ALL
runAsUser:
  type: MustRunAsNonRoot
seLinuxContext:
  type: MustRunAs
seccompProfiles:
- runtime/default
supplementalGroups:
  type: RunAsAny
users: []
volumes:
- configMap
- downwardAPI
- emptyDir
- persistentVolumeClaim
- projected
- secret
```

The SCC is bound to the service accounts by using the following Role and RoleBinding:

```
---
apiVersion: rbac.authorization.k8s.io/v1
kind: Role
metadata:
  name: contour-seccomp-nonroot-v2
  namespace: tanzu-system-ingress
rules:
- apiGroups:
  - security.openshift.io
  resourceNames:
  - contour-seccomp-nonroot-v2
  resources:
  - securitycontextconstraints
  verbs:
  - use
---
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: contour-seccomp-nonroot-v2
  namespace: tanzu-system-ingress
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: Role
  name: contour-seccomp-nonroot-v2
subjects:
- apiGroup: rbac.authorization.k8s.io
  kind: Group
  name: system:serviceaccounts:tanzu-system-ingress
```

Developer Conventions for OpenShift cluster

On OpenShift clusters, Developer Conventions must run with a custom SecurityContextConstraint (SCC) to enable compliance with restricted Kubernetes pod security standards. Tanzu Application Platform configures the following SCC for the Developer Convention's webhook when you configure the `kubernetes_distribution: openshift` key in the `tap-values.yaml` file.

Specification follows:

```
---
apiVersion: security.openshift.io/v1
kind: SecurityContextConstraints
metadata:
  name: developer-conventions-scc
allowHostDirVolumePlugin: false
allowHostIPC: false
allowHostNetwork: false
allowHostPID: false
allowHostPorts: false
allowPrivilegeEscalation: false
allowPrivilegedContainer: false
defaultAddCapabilities: null
fsGroup:
  type: RunAsAny
priority: null
readOnlyRootFilesystem: false
requiredDropCapabilities: null
runAsUser:
  type: MustRunAsNonRoot
seLinuxContext:
  type: MustRunAs
supplementalGroups:
  type: RunAsAny
volumes:
  - secret
seccompProfiles: []
groups:
  - system:serviceaccounts:developer-conventions
```

Tanzu Build Service for OpenShift cluster

On OpenShift clusters Tanzu Build Service must run with a custom Security Context Constraint (SCC) to enable compliance. Tanzu Application Platform configures the following SCC for Tanzu Build Service when you configure the `kubernetes_distribution: openshift` key in the `tap-values.yaml` file.

```
---
kind: SecurityContextConstraints
apiVersion: security.openshift.io/v1
metadata:
  name: tbs-restricted-scc-with-seccomp
allowHostDirVolumePlugin: false
allowHostIPC: false
allowHostNetwork: false
allowHostPID: false
allowHostPorts: false
allowPrivilegeEscalation: false
allowPrivilegedContainer: false
allowedCapabilities:
  - NET_BIND_SERVICE
defaultAddCapabilities: null
fsGroup:
  type: RunAsAny
groups: []
priority: null
readOnlyRootFilesystem: false
requiredDropCapabilities:
  - ALL
runAsUser:
  type: MustRunAsNonRoot
seLinuxContext:
  type: MustRunAs
```

```
seccompProfiles:
  - runtime/default
supplementalGroups:
  type: RunAsAny
users: []
volumes:
  - configMap
  - downwardAPI
  - emptyDir
  - persistentVolumeClaim
  - projected
  - secret
```

It also applies the following RBAC to allow Tanzu Build Service services to use the SCC:

```
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  labels:
    apps.tanzu.vmware.com/aggregate-to-workload: "true"
  annotations:
    rbac.authorization.kubernetes.io/autoupdate: "true"
  name: system:tbs:scc:restricted-with-seccomp
rules:
  - apiGroups:
      - security.openshift.io
    resourceNames:
      - tbs-restricted-scc-with-seccomp
    resources:
      - securitycontextconstraints
    verbs:
      - use
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: system:tbs:scc:restricted-with-seccomp
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: system:tbs:scc:restricted-with-seccomp
subjects:
  - kind: ServiceAccount
    namespace: build-service
    name: dependency-updater-serviceaccount
  - kind: ServiceAccount
    namespace: build-service
    name: dependency-updater-controller-serviceaccount
  - kind: ServiceAccount
    namespace: build-service
    name: secret-syncer-service-account
  - kind: ServiceAccount

```

Install Tanzu Application Platform (GitOps)

GitOps is a set of practices and principles to manage Kubernetes infrastructure and application deployments using Git as the single source of truth. It promotes declarative configurations and automated workflows to ensure consistency, reliability, and traceability for your application deployments.

The key components involved in implementing GitOps with Kubernetes include:

- **Git as the single source of truth**: The desired state is stored in a Git repository. To change the cluster state, you must change it in the Git repository instead of modifying it directly on the cluster.
- **Declarative configuration**: GitOps follows a declarative approach, where the desired state is defined in the declarative configuration files.
- **Pull-based synchronization**: GitOps follows a pull-based model. Kubernetes cluster periodically pulls the desired state from the Git repository. This approach ensures that the cluster is always in sync with the desired configuration.

Caution

Tanzu Application Platform (GitOps) is currently in beta and is intended for evaluation and test purposes only. Do not use in a production environment.

How Tanzu RI supports GitOps

The Tanzu GitOps Reference Implementation (RI) is built upon Carvel, which shares the same packaging APIs as the Tanzu Application Platform. Carvel packaging APIs support all the GitOps features and enables a native GitOps flow.

- All the packaging APIs are declarative in nature.
- Among many options to fetch the manifest to be deployed, it can also pull the content from the Git repository, making Git the source of truth.
- Packages installed are reconciled every time after the SyncPeriod expires (10 minutes by default). As part of the reconciliation, it fetches the manifest from the Git repository and when the desired state is different from the actual state on Kubernetes, it converges the resources to their desired state declared in Git.

GitOps benefits

GitOps offers the following benefits:

- **Compliance and auditing capabilities**: In GitOps, Git is the single source of truth, enabling auditors to access a complete audit trail of all configuration changes.

- **Disaster recovery**: Disaster recovery involves an organization's efforts to restore access and function to its IT infrastructure. With all configurations securely stored in Git, disaster recovery becomes as straightforward as reapplying the desired configuration version.
- **Repeatable**: Running Tanzu CLI commands with environment variables or configuration files on a local machine is no longer required. Instead, all the necessary configurations and service accounts for access are configured in a shared Git repository. This approach allows any operator to make edits to a file, and the system's behavior remains independent of their local environment.

GitOps install paths

Choose one of the following install paths to install Tanzu Application Platform on your Kubernetes clusters through GitOps:

Note

To decide which approach to use, see Choosing SOPS or ESO.

GitOps with Secrets OPerationS (SOPS)

Applies to the scenario when you want a simple instance and store sensitive data encrypted in your Git repo:

Step	Task	Link
1.	Review the prerequisites to ensure you have met all requirements before installing.	Prerequisites
2.	Accept Tanzu Application Platform EULAs and install the Tanzu CLI.	Accept Tanzu Application Platform EULAs and installing the Tanzu CLI
3.	Install Cluster Essentials for Tanzu*.	Deploy Cluster Essentials
4.	Install Tanzu Application Platform.	Install Tanzu Application Platform through Gitops with Secrets OPerationS (SOPS)
5.	(Optional) Install any additional packages that were not in the profile.	Install individual packages
6.	Set up developer namespaces to use your installed packages.	Set up developer namespaces to use your installed packages
7.	Install developer tools into your integrated development environment (IDE).	Install Tanzu Developer Tools for your VS Code

GitOps with External Secrets Operator (ESO)

AWS Secrets Manager

Applies to the scenario when you want to store sensitive data in AWS Secrets Manager:

Step	Task	Link
1.	Review the prerequisites to ensure you have met all requirements before installing.	Prerequisites
2.	Accept Tanzu Application Platform EULAs and install the Tanzu CLI.	Accept Tanzu Application Platform EULAs and installing the Tanzu CLI
3.	Create AWS Resources such as EKS cluster and roles)	Create AWS Resources

Step	Task	Link
4.	Install Cluster Essentials for Tanzu*.	Deploy Cluster Essentials
5.	Install Tanzu Application Platform.	Install Tanzu Application Platform through GitOps using AWS Secrets Manager
6.	(Optional) Install any additional packages that were not in the profile.	Install individual packages
7.	Set up developer namespaces to use your installed packages.	Set up developer namespaces to use your installed packages
8.	Install developer tools into your integrated development environment (IDE).	Install Tanzu Developer Tools for your VS Code

HashiCorp Vault

Applies to the scenario when you want to store sensitive data in HashiCorp Vault:

Step	Task	Link
1.	Review the prerequisites to ensure you have met all requirements before installing.	Prerequisites
2.	Accept Tanzu Application Platform EULAs and install the Tanzu CLI.	Accept Tanzu Application Platform EULAs and installing the Tanzu CLI
3.	Install Cluster Essentials for Tanzu*.	Deploy Cluster Essentials
4.	Install Tanzu Application Platform.	Install Tanzu Application Platform through GitOps using HashiCorp Vault
5.	(Optional) Install any additional packages that were not in the profile.	Install individual packages
6.	Set up developer namespaces to use your installed packages.	Set up developer namespaces to use your installed packages
7.	Install developer tools into your integrated development environment (IDE).	Install Tanzu Developer Tools for your VS Code

** When you use a VMware Tanzu Kubernetes Grid cluster, there is no need to install Cluster Essentials because the contents of Cluster Essentials are already installed on your cluster.*

After installing Tanzu Application Platform on to your Kubernetes clusters, proceed with Get started with Tanzu Application Platform.

Install Tanzu Application Platform (GitOps)

GitOps is a set of practices and principles to manage Kubernetes infrastructure and application deployments using Git as the single source of truth. It promotes declarative configurations and automated workflows to ensure consistency, reliability, and traceability for your application deployments.

Install Tanzu Application Platform through GitOps with External Secrets Operator (ESO)

Caution

Tanzu Application Platform (GitOps) is currently in beta and is intended for evaluation and test purposes only. Do not use in a production environment.

This topic tells you how to install Tanzu Application Platform (commonly known as TAP) through GitOps with secrets managed externally in AWS Secrets Manager.

Select a secrets manager for external secret storage:

- AWS Secrets Manager
- HashiCorp Vault

Important

Tanzu GitOps Reference Implementation (RI) does not support changing the secrets management strategy for a cluster.

Install Tanzu Application Platform through GitOps with AWS Secrets Manager

Caution

Tanzu Application Platform (GitOps) is currently in beta and is intended for evaluation and test purposes only. Do not use in a production environment.

This topic tells you how to install Tanzu Application Platform (commonly known as TAP) through GitOps with secrets managed externally in AWS Secrets Manager. To decide which approach to use, see Choosing Secrets OPerationS (SOPS) or External Secrets Operator (ESO).

Tanzu GitOps Reference Implementation (RI) does not support changing the secrets management strategy for a cluster, for example, SOPS to ESO. However, changing between AWS Secrets Manager and HashiCorp Vault is supported. The External Secrets Operator integration in this release of Tanzu GitOps RI is verified to support AWS Elastic Kubernetes Service (EKS) cluster with

AWS Secrets Manager. Other combinations of Kubernetes distribution and ESO providers are not verified.

Prerequisites

Before installing Tanzu Application Platform, ensure you have:

- Completed the Prerequisites.
- Created AWS Resources.
- Accepted Tanzu Application Platform EULA and installed Tanzu CLI with any required plug-ins.
- Installed Cluster Essentials for Tanzu.
- Installed eksctl CLI.

Relocate images to a registry

VMware recommends relocating the images from VMware Tanzu Network registry to your own container image registry before attempting installation. If you don't relocate the images, Tanzu Application Platform depends on VMware Tanzu Network for continued operation, and VMware Tanzu Network offers no uptime guarantees. The option to skip relocation is documented for evaluation and proof-of-concept only.

The supported registries are Harbor, Azure Container Registry, Google Container Registry, and Quay.io. See the following the documentation for instructions on setting up a registry:

- Harbor documentation
- Google Container Registry documentation
- Quay.io documentation

To relocate images from the VMware Tanzu Network registry to your registry:

1. Set up environment variables for installation use by running:

   ```
   export IMGPKG_REGISTRY_HOSTNAME_0=registry.tanzu.vmware.com
   export IMGPKG_REGISTRY_USERNAME_0=MY-TANZUNET-USERNAME
   export IMGPKG_REGISTRY_PASSWORD_0=MY-TANZUNET-PASSWORD
   export IMGPKG_REGISTRY_HOSTNAME_1=MY-REGISTRY
   export IMGPKG_REGISTRY_USERNAME_1=MY-REGISTRY-USER
   export IMGPKG_REGISTRY_PASSWORD_1=MY-REGISTRY-PASSWORD
   export INSTALL_REGISTRY_USERNAME=MY-REGISTRY-USER
   export INSTALL_REGISTRY_PASSWORD=MY-REGISTRY-PASSWORD
   export INSTALL_REGISTRY_HOSTNAME=MY-REGISTRY
   export TAP_VERSION=VERSION-NUMBER
   export INSTALL_REPO=TARGET-REPOSITORY
   ```

   Where:

   - `MY-REGISTRY-USER` is the user with write access to `MY-REGISTRY`.
   - `MY-REGISTRY-PASSWORD` is the password for `MY-REGISTRY-USER`.
   - `MY-REGISTRY` is your own container registry.
   - `MY-TANZUNET-USERNAME` is the user with access to the images in the VMware Tanzu Network registry `registry.tanzu.vmware.com`.
   - `MY-TANZUNET-PASSWORD` is the password for `MY-TANZUNET-USERNAME`.
   - `VERSION-NUMBER` is your Tanzu Application Platform version. For example, `1.9.1`.

- `TARGET-REPOSITORY` is your target repository, a folder or repository on `MY-REGISTRY` that serves as the location for the installation files for Tanzu Application Platform.

VMware recommends using a JSON key file to authenticate with Google Container Registry. In this case, the value of `INSTALL_REGISTRY_USERNAME` is `_json_key` and the value of `INSTALL_REGISTRY_PASSWORD` is the content of the JSON key file. For more information about how to generate the JSON key file, see Google Container Registry documentation.

2. Install the Carvel tool `imgpkg` CLI.

   To query for the available versions of Tanzu Application Platform on VMWare Tanzu Network Registry, run:

   ```
   imgpkg tag list -i registry.tanzu.vmware.com/tanzu-application-platform/tap-packages | sort -V
   ```

3. Relocate the images with the `imgpkg` CLI by running:

   ```
   imgpkg copy -b registry.tanzu.vmware.com/tanzu-application-platform/tap-packages:${TAP_VERSION} --to-repo ${INSTALL_REGISTRY_HOSTNAME}/${INSTALL_REPO}/tap-packages
   ```

(Optional) Install Tanzu Application Platform in an air-gapped environment

Complete the following steps if you install Tanzu Application Platform in an air-gapped environment:

1. Relocate the Tanzu Build Service images to your registry:

   ```
   imgpkg copy -b registry.tanzu.vmware.com/tanzu-application-platform/full-tbs-deps-package-repo:VERSION --to-repo ${INSTALL_REGISTRY_HOSTNAME}/${INSTALL_REPO}/full-tbs-deps-package-repo
   ```

   Where `VERSION` is the version of Tanzu Build Service. You can retrieve this value by running `kubectl get package -n tap-install | grep buildservice`

2. Configure custom certificate authorities for Tanzu Developer Portal.
3. Host a `grype` database in the air-gapped environment. For more information, see Use vulnerability scanning in offline and air-gapped environments.

Create a new Git repository

Follow these steps to create a new Git repository:

1. In a hosted Git service, for example, GitHub or GitLab, create a new repository.

   This version of Tanzu GitOps RI supports authenticating to a hosted Git repository by using SSH and Basic Authentication.

2. Initialize a new Git repository:

   ```
   mkdir -p $HOME/tap-gitops
   cd $HOME/tap-gitops

   git init
   git remote add origin git@github.com:my-organization/tap-gitops.git
   ```

3. Set up the authentication method:

SSH
Create a read-only deploy key for this new repository (recommended) or SSH key for an account with read access to this repository. The private portion of this key is referred to as `GIT_SSH_PRIVATE_KEY`.

Basic Authentication
Have a user name with read access to the Git repository and password or personal access token for the same user.

Important

Only use one of `ssh` or `Basic Authentication`, not both.

Download and unpack Tanzu GitOps Reference Implementation (RI)

Follow these steps to download and unpack Tanzu GitOps Reference Implementation (RI):

1. Sign in to VMware Tanzu Network.
2. Go to the Tanzu Application Platform product page.
3. Select **Release 1.9.1** from the release drop-down menu.
4. Click **Tanzu GitOps Reference Implementation**.
5. Unpack the downloaded TGZ file into the `$HOME/tap-gitops` directory by running:

   ```
   tar -xvf tanzu-gitops-ri-*.tgz -C $HOME/tap-gitops
   ```

6. Commit the initial state:

   ```
   cd $HOME/tap-gitops

   git add . && git commit -m "Initialize Tanzu GitOps RI"
   git push -u origin
   ```

Create your cluster configuration

Follow these steps to create your cluster configuration:

1. Seed configuration for a cluster by using the provided convenience script:

   ```
   cd $HOME/tap-gitops

   ./setup-repo.sh CLUSTER-NAME aws-secrets-manager
   ```

   Where:

   - `CLUSTER-NAME` is the name for your cluster. Typically, this is the same as your EKS cluster's name, the name of the cluster as it appears in `eksctl get clusters`
   - `aws-secrets-manager` selects the AWS Secrets Manager external Secret Store.

   For example, if the name of your cluster is `iterate-green`:

   ```
   cd $HOME/tap-gitops
   ```

```
./setup-repo.sh iterate-green aws-secrets-manager
```

This script creates the directory `clusters/iterate-green/` and copies in the configuration required to sync this Git repository with the cluster and installing Tanzu Application Platform.

2. Commit and push:

```
git add . && git commit -m 'Add "iterate-green" cluster'
git push
```

Saving the base configuration in an initial commit makes it easier to review customizations in the future.

Customize your cluster configuration

Configuring the Tanzu Application Platform installation involves setting up two components:

- An installation of Tanzu Application Platform.
- An instance of Tanzu Sync, the component that implements the GitOps workflow, fetching configuration from Git and applying it to the cluster.

Follow these steps to customize your Tanzu Application Platform cluster configuration:

1. Navigate to the created directory:

```
cd clusters/CLUSTER-NAME
```

For example, if the name of your cluster is `iterate-green`:

```
cd clusters/iterate-green
```

2. Define the following environment variables:

```
export AWS_ACCOUNT_ID=MY-AWS-ACCOUNT-ID
export AWS_REGION=AWS-REGION
export CLUSTER_NAME=CLUSTER-NAME
export TAP_PKGR_REPO=TAP-PACKAGE-OCI-REPOSITORY
```

Where:

- `MY-AWS-ACCOUNT-ID` is your AWS account ID as it appears in the output of `aws sts get-caller-identity`.
- `AWS-REGION` is the region where the Secrets Manager is and the EKS cluster was created.
- `CLUSTER-NAME` is the name of the target cluster as it appears in the output of `eksctl get clusters`.
- `TAP-PACKAGE-OCI-REPOSITORY` is the fully-qualified path to the OCI repository hosting the Tanzu Application Platform images. If they are relocated to a different registry as described in Relocate images to a registry, the value is `${INSTALL_REGISTRY_HOSTNAME}/${INSTALL_REPO}/tap-packages`.

Grant read access to secret data

AWS Secrets Manager secrets store all sensitive configurations, which are accessed by both Tanzu Sync and the Tanzu Application Platform installation.

Follow these steps to configure the IAM Role for a Service Account:

1. In AWS Identity and Access Manager, create two IAM Policies, one to read the Tanzu Sync secrets and another to read the Tanzu Application Platform installation secrets, by using the supplied script:

   ```
   tanzu-sync/scripts/setup/create-policies.sh
   ```

2. Create two IAM Role-to-Service Account pairs for your cluster, one for Tanzu Sync and another for the Tanzu Application Platform installation, by using the supplied script:

   ```
   tanzu-sync/scripts/setup/create-irsa.sh
   ```

   For example, if the name of the EKS cluster is `iterate-green` using the defaults, there are two IAM roles in the AWS account:

   ```
   $ aws iam list-roles --query 'Roles[?starts_with(RoleName,`iterate-green`)]'
   [
       {
           "RoleName": "iterate-green--tanzu-sync-secrets",
           ...
       },
       {
           "RoleName": "iterate-green--tap-install-secrets",
           ...
       }
   ]
   ```

Generate the default configuration

You can use the following script to generate the default configuration for both Tanzu Sync and Tanzu Application Platform installation:

```
tanzu-sync/scripts/configure.sh
```

The following sections tell you how to edit the configuration values to suit your specific needs.

Review and store Tanzu Sync config

Configuration for Tanzu is stored in two locations:

- Sensitive configuration is stored in AWS Secrets Manager.
- Non-sensitive configuration are stored in YAML files in the Git repository.

Follow these steps to create the sensitive configuration and review the non-sensitive configuration:

1. Save the credentials that Tanzu Sync uses to authenticate with the Git repository.

   SSH
   Create a secret named `dev/CLUSTER-NAME/tanzu-sync/sync-git/ssh` containing the following information as plaintext:

   ```
   {
     "privatekey": "... (private key portion here) ...",
     "knownhosts": "... (known_hosts for git host here) ..."
   }
   ```

   Where `CLUSTER-NAME` is the name as it appears in `eksctl get clusters`.

   For example, if the Git repository is hosted on GitHub, and the private key created in Create a new Git repository is stored in the file `~/.ssh/id_ed25519`:

```
aws secretsmanager create-secret \
  --name dev/${CLUSTER_NAME}/tanzu-sync/sync-git/ssh \
  --secret-string "$(cat <<EOF
{
  "privatekey": "$(cat ~/.ssh/id_ed25519 | awk '{printf "%s\\n", $0}')",
  "knownhosts": "$(ssh-keyscan github.com | awk '{printf "%s\\n", $0}')"
}
EOF
)"
```

Where:

- The content of `~/.ssh/id_ed25519` is the private portion of the SSH key.
- `ssh-keyscan` obtains the public keys for the SSH host.
- `awk '{printf "%s\n", $0}'` converts a multiline string into a single-line string with embedded newline chars (`\n`). JSON does not support multiline strings.

Basic Authentication

Create a secret named `dev/CLUSTER-NAME/tanzu-sync/sync-git/basic_auth` containing the following information as plaintext:

```
{
  "username": "... (username) ...",
  "password": "... (password) ..."
}
```

Where:

- `CLUSTER-NAME` is the name as it appears in `eksctl get clusters`.
- `username` is the username of a user account with read access to the Git repository.
- `password` is the password or personal access token for the user.

2. To securely store the authentication credentials required for accessing the OCI registry that hosts the Tanzu Application Platform images, create a secret called `dev/CLUSTER-NAME/tanzu-sync/install-registry-dockerconfig`. This secret contains the following information in plaintext:

```
{
  "auths": {
    "MY-REGISTRY": {
      "username": "MY-REGISTRY-USER",
      "password": "MY-REGISTRY-PASSWORD"
    }
  }
}
```

Where:

- `CLUSTER-NAME` is the name as it appears in `eksctl get clusters`
- `MY-REGISTRY-USER` is the user with write access to `MY-REGISTRY`.
- `MY-REGISTRY-PASSWORD` is the password for `MY-REGISTRY-USER`.
- `MY-REGISTRY` is the container registry where the Tanzu Application Platform images are located.

For example:

```
aws secretsmanager create-secret \
   --name dev/${CLUSTER_NAME}/tanzu-sync/install-registry-dockerconfig \
   --secret-string "$(cat <<EOF
{
 "auths": {
   "${INSTALL_REGISTRY_HOSTNAME}": {
     "username": "${INSTALL_REGISTRY_USERNAME}",
     "password": "${INSTALL_REGISTRY_PASSWORD}"
   }
 }
}
EOF
)"
```

3. Review the hosted Git URL and branch used by Tanzu Sync.

   This configuration was generated by the `configure.sh` script. It reported:

   ```
   ...
   wrote non-sensitive Tanzu Sync configuration to: tanzu-sync/app/values/tanzu-sy
   nc.yaml
   ...
   ```

   For example, for the `iterate-green` cluster, if the Git repository is hosted on GitHub under `my-organization/tap-gitops` and is on the `main` branch, `tanzu-sync.yaml` contains the following information:

   ```
   ---
   git:
    url: git@github.com:my-organization/tap-gitops.git
    ref: origin/main
    sub_path: clusters/iterate-green/cluster-config
   ```

   You can review and edit these values as needed.

4. Review the integration with External Secrets Operator.

   This configuration was generated by the `configure.sh` script. It reported:

   ```
   ...
   wrote ESO configuration for Tanzu Sync to: tanzu-sync/app/values/tanzu-sync-aws
   -secrets-manager-values.yaml
   ...
   ```

   For example, for the `iterate-green` cluster, if the AWS account is `665100000000`, `tanzu-sync-aws-secrets-manager-values.yaml` contains the following information:

   ```
   ---
   secrets:
    eso:
      aws:
        region: us-west-2
        tanzu_sync_secrets:
          role_arn: arn:aws:iam::665100000000:role/iterate-green--tanzu-sync-secre
   ts
      remote_refs:
        sync_git:
        # TO DO: Fill in your configuration for ssh or basic authentication here.
   See tanzu-sync/app/config/.tanzu-managed/schema--eso.yaml for details.
        install_registry_dockerconfig:
          dockerconfigjson:
            key: dev/iterate-green/tanzu-sync/install-registry-dockerconfig
   ```

Where:

- `role_arn` is the IAM role that grants permission to Tanzu Sync to read secrets specific to Tanzu Sync. This role was created in the Grant read access to secret data section.
- `install_registry_dockerconfig` contains the AWS Secrets Manager secret name that contains the Docker config authentication to the OCI registry hosting the Tanzu Application Platform images created earlier.

5. Replace any `TO DO` sections from line 10 in the earlier example with the relevant values.

   Configuration example for SSH authentication:

```
---
secrets:
 eso:
  aws:
    region: us-west-2
    tanzu_sync_secrets:
      role_arn: arn:aws:iam::665100000000:role/iterate-green--tanzu-sync-secret
s
  remote_refs:
    sync_git:
      ssh:
        private_key:
          key: dev/iterate-green/tanzu-sync/sync-git/ssh
          property: privatekey
        known_hosts:
          key: dev/iterate-green/tanzu-sync/sync-git/ssh
          property: knownhosts
    install_registry_dockerconfig:
      dockerconfigjson:
        key: dev/iterate-green/tanzu-sync/install-registry-dockerconfig
```

   Configuration example for basic authentication:

```
---
secrets:
 eso:
  aws:
    region: us-west-2
    tanzu_sync_secrets:
      role_arn: arn:aws:iam::665100000000:role/iterate-green--tanzu-sync-secret
s
  remote_refs:
    sync_git:
      basic_auth:
        username:
          key: dev/iterate-green/tanzu-sync/sync-git/basic_auth
          property: username
        password:
          key: dev/iterate-green/tanzu-sync/sync-git/basic_auth
          property: password
    install_registry_dockerconfig:
      dockerconfigjson:
        key: dev/iterate-green/tanzu-sync/install-registry-dockerconfig
```

6. Commit the Tanzu Sync configuration.

   For example, for the “iterate-green” cluster, run:

```
git add tanzu-sync/
git commit -m 'Configure Tanzu Sync on "iterate-green"'
```

Review and store the Tanzu Application Platform installation config

Configuration for the Tanzu Application Platform installation is stored in two places:

- Sensitive configuration is stored in AWS Secrets Manager.
- Non-sensitive configuration is stored in YAML files in the Git repository.

Follow these steps to create the sensitive configuration and review the non-sensitive configuration:

1. Create a secret named `dev/${CLUSTER_NAME}/tap/sensitive-values.yaml` that stores the sensitive data such as username, password, private key from the `tap-values.yaml` file:

   ```
   aws secretsmanager create-secret \
      --name dev/${CLUSTER_NAME}/tap/sensitive-values.yaml \
      --secret-string "$(cat <<EOF
   ---
   # this document is intentionally initially blank.
   EOF
   )"
   ```

   You can start with an empty document and edit it later on as described in the Configure and push the Tanzu Application Platform values section.

2. Review the integration with External Secrets Operator.

   This configuration was generated by the `configure.sh` script. It reported:

   ```
   ...
   wrote AWS Secrets Manager configuration for TAP Install to: cluster-config/valu
   es/tap-install-aws-secrets-manager-values.yaml
   ...
   ```

   For example, for the `iterate-green` cluster, if the AWS account is `665100000000`, `tap-install-aws-secrets-manager-values.yaml` contains the following information:

   ```
   ---
   tap_install:
    secrets:
      eso:
        aws:
          region: us-west-2
          tap_install_secrets:
            role_arn: arn:aws:iam:665100000000:iterate-green--tap-install-secrets
        remote_refs:
          tap_sensitive_values:
            sensitive_tap_values_yaml:
              key: dev/iterate-green/tap/sensitive-values.yaml
   ```

   Where:

   - `role_arn` is the IAM role that grants permission to the Tanzu Application Platform installation to read its associated secrets. This role was created in the Grant read access to secret data section.
   - `sensitive_tap_values_yaml.key` is the AWS Secrets Manager secret name that contains the sensitive data from the `tap-values.yaml` file for this cluster in a YAML format.

3. (Optional) Update Tanzu Application Platform to use the latest patch:

   Update the Tanzu Application Platform version in `GIT-REPO-ROOT/clusters/CLUSTER-NAME/cluster-config/values/tap-install-values.yaml`:

```
tap_install:
    ...
    version:
        package_repo_bundle_tag: "1.9.1" # Populate these values with the lates
t patch version.
        package_version: "1.9.1"
```

Where:

- `package_repo_bundle_tag` is the version of Tanzu Application Platform you want to upgrade to.
- `package_version` is the version of Tanzu Application Platform you want to upgrade to. This version must match `package_repo_bundle_tag`.

Note

Tanzu GitOps RI does not provide a separate artifact for each patch version within a minor line. For example, Tanzu Application Platform v1.6.x only contains the v1.6.1 GitOps artifact.

4. Commit the Tanzu Application Platform installation configuration.

   For example, for the `iterate-green` cluster, run:

```
git add cluster-config/
git commit -m 'Configure installer for TAP 1.6.1 on "iterate-green"'
```

Configure and push the Tanzu Application Platform values

The configuration for the Tanzu Application Platform is divided into two separate locations:

- Sensitive configuration is stored in a AWS Secrets Manager secret created as described in the Review and store Tanzu Application Platform installation config section.
- Non-sensitive configuration is stored in a plain YAML file `cluster-config/values/tap-values.yaml`

Follow these steps to split the Tanzu Application Platform values:

1. Create the `cluster-config/values/tap-values.yaml` file by using the Full Profile (AWS), which contains the minimum configurations required to deploy Tanzu Application Platform on AWS.

   The Tanzu Application Platform values are input configurations to the Tanzu Application Platform installation and are placed under the `tap_install.values` path.

```
tap_install:
  values:
    # Tanzu Application Platform values go here.
    shared:
      ingress_domain: "INGRESS-DOMAIN"
    ceip_policy_disclosed: true
...
```

   To install Tanzu Application Platform in an offline environment, you must configure `Tanzu Build Service` and `Grype` to work in an air-gapped environment:

```
---
tap_install:
```

```
  values:
    ...
    buildservice:
      exclude_dependencies: true
    grype:
      db:
        dbUpdateUrl: INTERNAL-VULN-DB-URL
```

Where `INTERNAL-VULN-DB-URL` is the URL that points to the internal file server.

For more information, see Components and installation profiles.

2. Review the contents of `tap-values.yaml` and move all the sensitive values into the AWS Secrets Store secret created in the Review and store Tanzu Application Platform installation config section.

   For example, if the `iterate-green` cluster is configured with the basic Out of the Box Supply Chain, this might include a passphrase for that supply chain's GitOps flow:

   ```
   ---
   tap_install:
    values:
      ...
      ootb_supply_chain_basic:
        registry:
          server: "SERVER-NAME"
          repository: "REPO-NAME"
        gitops:
          ssh_secret: "SSH-SECRET-KEY"
      ...
   ```

   To maintain the secrecy of `ootb_supply_chain_basic.gitops.ssh_secret`, move this value from the `tap-values.yaml` file:

   ```
   ---
   tap_install:
    values:
      ...
      ootb_supply_chain_basic:
        registry:
          server: "SERVER-NAME"
          repository: "REPO-NAME"
      ...
   ```

   Add it to the AWS Secrets Store secret named `dev/iterate-green/tap/sensitive-values.yaml`, by default, without the `tap_install.values` root:

   ```
   ---
   ...
   ootb_supply_chain_basic:
    gitops:
      ssh_secret: "SSH-SECRET-KEY"
   ...
   ```

   To update the secret value, follow the instructions in Modify an AWS Secrets Manager secret.

   When moving values, you must omit the `tap_install.values` root, but keep the remaining structure. All of the parent keys, such as `ootb_supply_chain_basic.gitops` and `ssh_secret`, must be copied to the sensitive value YAML.

3. Commit and push the Tanzu Application Platform values:

```
git add cluster-config/
git commit -m "Configure initial values for TAP 1.6.1"
git push
```

Tanzu Sync fetches configuration from the hosted clone of the Git repository. For changes to take effect on the cluster, they must be pushed to that clone of the Git repository.

Deploy Tanzu Sync

Deploying Tanzu Sync starts the GitOps workflow that initiates the Tanzu Application Platform installation.

After deployed, Tanzu Sync periodically polls the Git repository for changes. The following deployment process is only required once per cluster:

1. Install the Carvel tools `kapp` and `ytt` onto your `$PATH`:

   ```
   sudo cp $HOME/tanzu-cluster-essentials/kapp /usr/local/bin/kapp
   sudo cp $HOME/tanzu-cluster-essentials/ytt /usr/local/bin/ytt
   ```

   This step is required to ensure the successful deployment of the `tanzu-sync` app.

2. Ensure the Kubernetes cluster context is set to the EKS cluster.

   1. List the existing contexts:

      ```
      kubectl config get-contexts
      ```

   2. Set the context to the cluster that you want to deploy:

      ```
      kubectl config use-context CONTEXT-NAME
      ```

      Where `CONTEXT-NAME` can be retrieved from the outputs of the previous step.

3. Bootstrap the deployment.

   External Secrets Operator is installed from the package included in the Tanzu Application Platform package repository. That repository must be fetched from the OCI registry initially.

   1. Set the following environment variables:

      ```
      export INSTALL_REGISTRY_HOSTNAME=MY-REGISTRY
      export INSTALL_REGISTRY_USERNAME=MY-REGISTRY-USER
      export INSTALL_REGISTRY_PASSWORD=MY-REGISTRY-PASSWORD
      ```

      Where:

      - `MY-REGISTRY` is your container registry.
      - `MY-REGISTRY-USER` is the user with read access to `MY-REGISTRY`.
      - `MY-REGISTRY-PASSWORD` is the password for `MY-REGISTRY-USER`.

   2. Create a secret containing credentials to fetch from that OCI registry by using the provided script:

      ```
      tanzu-sync/scripts/bootstrap.sh
      ```

      These credentials are used exactly once to install the External Secrets Operator (ESO) package.

4. Install Tanzu Sync and start the GitOps workflow by deploying it to the cluster using `kapp` and `ytt`.

```
tanzu-sync/scripts/deploy.sh
```

Depending on the profile and components included, it may take 5-10 minutes for the Tanzu Application Platform to install. During this time, `kapp` waits for the deployment of Tanzu Sync to reconcile successfully. This is normal.

You can track the progress of the installation by watching the installation of those packages in a separate terminal window:

```
watch kubectl get pkgi -n tap-install
```

Install Tanzu Application Platform through GitOps with HashiCorp Vault

Caution

Tanzu Application Platform (GitOps) is currently in beta and is intended for evaluation and test purposes only. Do not use in a production environment.

This topic tells you how to install Tanzu Application Platform (commonly known as TAP) through GitOps with secrets managed in an external secrets store. To decide which approach to use, see Choosing Secrets OPerationS (SOPS) or External Secrets Operator (ESO).

Tanzu GitOps Reference Implementation (RI) does not support changing the secrets management strategy for a cluster, for example, SOPS to ESO. However, changing between AWS Secrets Manager and HashiCorp Vault is supported. The External Secrets Operator integration in this release of Tanzu GitOps RI is verified to support Kubernetes integration with HashiCorp Vault.

Prerequisites

Before installing Tanzu Application Platform, ensure you have:

- Completed the Prerequisites.
- Accepted Tanzu Application Platform EULA and installed Tanzu CLI with any required plug-ins.
- Installed Cluster Essentials for Tanzu.
- Installed eksctl CLI.

Relocate images to a registry

VMware recommends relocating the images from VMware Tanzu Network registry to your own container image registry before attempting installation. If you don't relocate the images, Tanzu Application Platform depends on VMware Tanzu Network for continued operation, and VMware Tanzu Network offers no uptime guarantees. The option to skip relocation is documented for evaluation and proof-of-concept only.

The supported registries are Harbor, Azure Container Registry, Google Container Registry, and Quay.io. See the following the documentation for instructions on setting up a registry:

- Harbor documentation
- Google Container Registry documentation
- Quay.io documentation

To relocate images from the VMware Tanzu Network registry to your registry:

1. Set up environment variables for installation use by running:

   ```
   export IMGPKG_REGISTRY_HOSTNAME_0=registry.tanzu.vmware.com
   export IMGPKG_REGISTRY_USERNAME_0=MY-TANZUNET-USERNAME
   export IMGPKG_REGISTRY_PASSWORD_0=MY-TANZUNET-PASSWORD
   export IMGPKG_REGISTRY_HOSTNAME_1=MY-REGISTRY
   export IMGPKG_REGISTRY_USERNAME_1=MY-REGISTRY-USER
   export IMGPKG_REGISTRY_PASSWORD_1=MY-REGISTRY-PASSWORD
   export INSTALL_REGISTRY_USERNAME=MY-REGISTRY-USER
   export INSTALL_REGISTRY_PASSWORD=MY-REGISTRY-PASSWORD
   export INSTALL_REGISTRY_HOSTNAME=MY-REGISTRY
   export TAP_VERSION=VERSION-NUMBER
   export INSTALL_REPO=TARGET-REPOSITORY
   ```

   Where:

   - `MY-REGISTRY-USER` is the user with write access to `MY-REGISTRY`.
   - `MY-REGISTRY-PASSWORD` is the password for `MY-REGISTRY-USER`.
   - `MY-REGISTRY` is your own container registry.
   - `MY-TANZUNET-USERNAME` is the user with access to the images in the VMware Tanzu Network registry `registry.tanzu.vmware.com`.
   - `MY-TANZUNET-PASSWORD` is the password for `MY-TANZUNET-USERNAME`.
   - `VERSION-NUMBER` is your Tanzu Application Platform version. For example, `1.9.1`.
   - `TARGET-REPOSITORY` is your target repository, a folder or repository on `MY-REGISTRY` that serves as the location for the installation files for Tanzu Application Platform.

   VMware recommends using a JSON key file to authenticate with Google Container Registry. In this case, the value of `INSTALL_REGISTRY_USERNAME` is `_json_key` and the value of `INSTALL_REGISTRY_PASSWORD` is the content of the JSON key file. For more information about how to generate the JSON key file, see Google Container Registry documentation.

2. Install the Carvel tool `imgpkg` CLI.

   To query for the available versions of Tanzu Application Platform on VMWare Tanzu Network Registry, run:

   ```
   imgpkg tag list -i registry.tanzu.vmware.com/tanzu-application-platform/tap-pac
   kages | sort -V
   ```

3. Relocate the images with the `imgpkg` CLI by running:

   ```
   imgpkg copy -b registry.tanzu.vmware.com/tanzu-application-platform/tap-package
   s:${TAP_VERSION} --to-repo ${INSTALL_REGISTRY_HOSTNAME}/${INSTALL_REPO}/tap-pac
   kages
   ```

(Optional) Install Tanzu Application Platform in an air-gapped environment

Complete the following steps if you install Tanzu Application Platform in an air-gapped environment:

1. Relocate the Tanzu Build Service images to your registry:

   ```
   imgpkg copy -b registry.tanzu.vmware.com/tanzu-application-platform/full-tbs-de
   ps-package-repo:VERSION --to-repo ${INSTALL_REGISTRY_HOSTNAME}/${INSTALL_REPO}/
   ```

```
full-tbs-deps-package-repo
```

Where:

- `VERSION` is the version of Tanzu Build Service. You can retrieve this value by running `kubectl get package -n tap-install | grep buildservice`

2. Configure custom certificate authorities for Tanzu Developer Portal.
3. Host a `grype` database in the air-gapped environment. For more information, see Use vulnerability scanning in offline and air-gapped environments.

Create a new Git repository

1. In a hosted Git service, for example, GitHub or GitLab, create a new repository.

   This version of Tanzu GitOps RI supports authenticating to a hosted Git repository by using SSH as well as Basic Authentication.

2. Initialize a new Git repository:

```
mkdir -p $HOME/tap-gitops
cd $HOME/tap-gitops

git init
git remote add origin git@github.com:my-organization/tap-gitops.git
```

3. Set up the authentication method.

SSH
Create a read-only deploy key for this new repository (recommended) or SSH key for an account with read access to this repository. The private portion of this key is referred to as `GIT_SSH_PRIVATE_KEY`.

Basic Authentication
Have a username with read access to the Git repository and password or personal access token for the same user.

Important

Only use one of `ssh` or `Basic Authentication`, not both.

Download and unpack Tanzu GitOps Reference Implementation (RI)

1. Sign in to VMware Tanzu Network.
2. Go to the Tanzu Application Platform product page.
3. Select **Release 1.9.1** from the release drop-down menu.
4. Click **Tanzu GitOps Reference Implementation**.
5. Unpack the downloaded TGZ file into the `$HOME/tap-gitops` directory by running:

```
tar -xvf tanzu-gitops-ri-*.tgz -C $HOME/tap-gitops
```

6. Commit the initial state:

```
cd $HOME/tap-gitops

git add . && git commit -m "Initialize Tanzu GitOps RI"
git push -u origin
```

Create cluster configuration

1. Seed configuration for a cluster using Vault through the provided convenience script:

   ```
   cd $HOME/tap-gitops

   ./setup-repo.sh CLUSTER-NAME vault
   ```

   Where:

   - `CLUSTER-NAME` is the name for your cluster. Typically, this is the same as your EKS cluster's name, the name of the cluster as it appears in `eksctl get clusters`.
   - `vault` selects the Vault external Secret Store.

   For example, if the name of your cluster is `iterate-green`:

   ```
   cd $HOME/tap-gitops

   ./setup-repo.sh iterate-green vault
   ```

   This script creates the directory `clusters/iterate-green/` and copies in the configuration required to sync this Git repository with the cluster and installing Tanzu Application Platform.

2. Commit and push:

   ```
   git add . && git commit -m 'Add "iterate-green" cluster'
   git push
   ```

   Saving the base configuration in an initial commit makes it easier to review customizations in the future.

Customize cluster configuration

Configuring the Tanzu Application Platform installation involves setting up two components:

- An installation of Tanzu Application Platform.
- An instance of Tanzu Sync, the component that implements the GitOps workflow, fetching configuration from Git and applying it to the cluster.

Follow these steps to customize your Tanzu Application Platform cluster configuration:

1. Navigate to the created directory:

   ```
   cd clusters/CLUSTER-NAME
   ```

   For example, if the name of your cluster is `iterate-green`:

   ```
   cd clusters/iterate-green
   ```

2. Define the following environment variables:

   ```
   export VAULT_ADDR=MY-VAULT-ADDR
   export CLUSTER_NAME=CLUSTER-NAME
   ```

```
export TAP_PKGR_REPO=TAP-PACKAGE-OCI-REPOSITORY
```

Where:

- `MY-VAULT-ADDR` is the accessible URL of your vault instance (Vault must be reachable by the Kubernetes cluster).
- `CLUSTER-NAME` is the name of the target cluster.
- `TAP-PACKAGE-OCI-REPOSITORY` is the fully-qualified path to the OCI repository hosting the Tanzu Application Platform images. If they are relocated to a different registry as described in Relocate images to a registry, the value is `${INSTALL_REGISTRY_HOSTNAME}/${INSTALL_REPO}/tap-packages`.

Connect Vault to a Kubernetes cluster

Tanzu GitOps RI uses the Vault Kubernetes authentication method for establishing trust between the Kubernetes cluster and Vault, see Vault Kubernetes auth for more. This authentication method uses the Kubernetes Control Plane TokenReview API to authenticate the Kubernetes service accounts with Vault. For this reason, the clusters control plane must be able to communicate over the network to the Vault instance.

To configure Kubernetes authentication for Vault, you can create a new Kubernetes authentication engine instance on Vault and two IAM Roles by using the supplied script:

```
tanzu-sync/scripts/setup/create-kubernetes-auth.sh
```

Important

- If you use an Enterprise Vault Server with namespaces, run `export VAULT_NAMESPACE=MY-VAULT-NAMESPACE` before using the script.
- If you use token to access server, run `export VAULT_TOKEN=MY-VAULT-TOKEN` before using the script.

This creates a new vault Kubernetes authentication instance using the information for the current context in your `KUBECONFIG`.

Example:

```
vault write auth/iterate-green/config \
  kubernetes_host="MY-KUBERNETES-API-URL" \
  kubernetes_ca_cert="MY-KUBERNETES-CA-CERT" \
  ttl=1h
```

Grant read access to secret data

Vault secrets store all sensitive configurations, which are accessed by both Tanzu Sync and the Tanzu Application Platform installation.

Follow these steps to configure Roles in Vault:

1. Create two Policies, one to read the Tanzu Sync secrets and another to read the Tanzu Application Platform installation secrets, by using the supplied script:

   ```
   tanzu-sync/scripts/setup/create-policies.sh
   ```

2. Create two Roles, one to read the Tanzu Sync secrets and another to read the Tanzu Application Platform installation secrets, by using the supplied script:

```
tanzu-sync/scripts/setup/create-roles.sh
```

Generate default configuration

You can use the following script to generate default configuration for both Tanzu Sync and Tanzu Application Platform installation:

```
tanzu-sync/scripts/configure.sh
```

The following sections tell you how to edit the configuration values to suit your specific needs.

Review and store Tanzu Sync config

Configuration for Tanzu is stored in two locations:

- Sensitive configuration is stored in Vault.
- Non-sensitive configuration are stored in YAML files in the Git repository.

Follow these steps to create the sensitive configuration and review the non-sensitive configuration:

Important

You must enable a key-value secret engine named `secret`.

1. Save the credentials that Tanzu Sync uses to authenticate with the Git repository. There are two supported authentication methods:

   SSH
   Create a secret named `secret/dev/CLUSTER-NAME/tanzu-sync/sync-git/ssh` containing the following information as plaintext:

   ```
   {
     "privatekey": "... (private key portion here) ...",
     "knownhosts": "... (known_hosts for git host here) ..."
   }
   ```

   Where `CLUSTER-NAME` is the name of your cluster.

   For example, if the Git repository is hosted on GitHub, and the private key created in Create a new Git repository is stored in the file `~/.ssh/id_ed25519`:

   ```
   export GIT_SSH_PRIVATE_KEY_FILE=~/.ssh/id_ed25519
   export GIT_KNOWN_HOSTS=$(ssh-keyscan github.com)
   printf '%s\n'  "$(cat <<EOF
   {
       "privatekey": "$(cat $GIT_SSH_PRIVATE_KEY_FILE | awk '{printf "%s\\n",
   $0}')",
       "knownhosts": "$(echo $GIT_KNOWN_HOSTS | awk '{printf "%s\\n", $0}')"
   }
   EOF
   )" | vault kv put secret/dev/${CLUSTER_NAME}/tanzu-sync/sync-git/ssh -
   ```

   Where:

   - The content of `~/.ssh/id_ed25519` is the private portion of the SSH key.
   - `ssh-keyscan` obtains the public keys for the SSH host.

- `awk '{printf "%s\\n", $0}'` converts a multiline string into a single-line string with embedded newline chars (`\n`). JSON does not support multiline strings.

Basic Authentication

Create a secret named `secret/dev/CLUSTER-NAME/tanzu-sync/sync-git/basic_auth` containing the following information as plaintext:

```
{
  "username": "... (username) ...",
  "password": "... (password) ..."
}
```

Where:

- `CLUSTER-NAME` is the name of your cluster.
- `username` is the username of a user account with read access to the Git repository.
- `password` is the password or personal access token for the user.

2. To securely store the authentication credentials required for accessing the OCI registry hosting the Tanzu Application Platform images, create a secret called `dev/CLUSTER-NAME/tanzu-sync/install-registry-dockerconfig`. This secret contains the following information in plaintext:

```
{
  "auths": {
    "MY-REGISTRY": {
      "username": "MY-REGISTRY-USER",
      "password": "MY-REGISTRY-PASSWORD"
    }
  }
}
```

Where:

- `CLUSTER-NAME` is the name of your cluster.
- `MY-REGISTRY-USER` is the user with write access to `MY-REGISTRY`.
- `MY-REGISTRY-PASSWORD` is the password for `MY-REGISTRY-USER`.
- `MY-REGISTRY` is the container registry where the Tanzu Application Platform images are located.

For example:

```
printf '%s\n'  "$(cat <<EOF
{
  "auths": {
      "${INSTALL_REGISTRY_HOSTNAME}": {
          "username": "${INSTALL_REGISTRY_USERNAME}",
          "password": "${INSTALL_REGISTRY_PASSWORD}"
      }
  }
}
EOF
)" | vault kv put secret/dev/${CLUSTER_NAME}/tanzu-sync/install-registry-docker
config -
```

3. Review the hosted Git URL and branch used by Tanzu Sync.

   This configuration was generated by the `configure.sh` script. It reported:

```
...
wrote non-sensitive Tanzu Sync configuration to: tanzu-sync/app/values/tanzu-sy
nc.yaml
...
```

For example, for the `iterate-green` cluster, if the Git repository is hosted on GitHub at `my-organization/tap-gitops` on the `main` branch, `tanzu-sync.yaml` contains the following information:

```
---
git:
 url: git@github.com:my-organization/tap-gitops.git
 ref: origin/main
 sub_path: clusters/iterate-green/cluster-config
```

You can review and edit these values as needed.

4. Review the integration with External Secrets Operator.

   This configuration was generated by the `configure.sh` script. It reported:

   ```
   ...
   wrote ESO configuration for Tanzu Sync to: tanzu-sync/app/values/tanzu-sync-vau
   lt-values.yaml
   ...
   ```

   For example, for the `iterate-green` cluster, if the Vault URL is `https://vault.example.com`, `tanzu-sync-vault-values.yaml` contains the following information:

   ```
   ---
   secrets:
    eso:
     vault:
       server: https://vault.example.com
       namespace: ""
       auth:
         kubernetes:
           mountPath: iterate-green
           role: iterate-green--tanzu-sync-secrets
     remote_refs:
       sync_git:
       # TO DO: Fill in your configuration for ssh or basic authentication here. S
   ee tanzu-sync/app/config/.tanzu-managed/schema--eso.yaml for details.
       install_registry_dockerconfig:
         dockerconfigjson:
           key: secret/dev/iterate-green/tanzu-sync/install-registry-dockerconfig
   ```

   Where:

   - `kubernetes.role` is the IAM role that grants permission to Tanzu Application Platform installation to read its associated secrets. This role was created in the Grant read access to secret data section.
   - `install_registry_dockerconfig` contains the Vault secret name that contains the Docker config authentication to the OCI registry hosting the Tanzu Application Platform images created earlier.

5. Replace any `TO DO` sections from line 12 in the earlier example with the relevant values.

   Configuration example for SSH authentication:

   ```
   ---
   secrets:
   ```

```
 eso:
  vault:
    server: https://vault.example.com
    namespace: ""
    auth:
      kubernetes:
        mountPath: iterate-green
        role: iterate-green--tanzu-sync-secrets
  remote_refs:
    sync_git:
      ssh:
        private_key:
          key: secret/dev/iterate-green/tanzu-sync/sync-git/ssh
          property: privatekey
        known_hosts:
          key: secret/dev/iterate-green/tanzu-sync/sync-git/ssh
          property: knownhosts
    install_registry_dockerconfig:
      dockerconfigjson:
        key: secret/dev/iterate-green/tanzu-sync/install-registry-dockerconfig
```

Configuration example for basic authentication:

```
---
secrets:
 eso:
  vault:
    server: https://vault.example.com
    namespace: ""
    auth:
      kubernetes:
        mountPath: iterate-green
        role: iterate-green--tanzu-sync-secrets
  remote_refs:
    sync_git:
      basic_auth:
        username:
          key: secret/dev/iterate-green/tanzu-sync/sync-git/basic_auth
          property: username
        password:
          key: secret/dev/iterate-green/tanzu-sync/sync-git/basic_auth
          property: password
    install_registry_dockerconfig:
      dockerconfigjson:
        key: secret/dev/iterate-green/tanzu-sync/install-registry-dockerconfig
```

6. (Optional) Update Tanzu Application Platform to use the latest patch:

   Update the Tanzu Application Platform version in `GIT-REPO-ROOT/clusters/CLUSTER-NAME/cluster-config/values/tap-install-values.yaml`:

```
tap_install:
    ...
    version:
        package_repo_bundle_tag: "1.9.1" # Populate these values with the lates
t patch version.
        package_version: "1.9.1"
```

   Where:

   - `package_repo_bundle_tag` is the version of Tanzu Application Platform you want to upgrade to.
   - `package_version` is the version of Tanzu Application Platform you want to upgrade to. This version must match `package_repo_bundle_tag`.

> **Note**
>
> Tanzu Application Platform (GitOps) does not provide a separate artifact for each patch version within a minor line. For example, Tanzu Application Platform v1.6.x only contains the v1.6.1 GitOps artifact.

7. Commit the Tanzu Sync configuration.

   For example, for the “iterate-green” cluster, run:

   ```
   git add tanzu-sync/
   git commit -m 'Configure Tanzu Sync on "iterate-green"'
   ```

Review and store the Tanzu Application Platform installation config

Configuration for the Tanzu Application Platform installation is stored in two places:

- Sensitive configuration is stored in Vault.
- Non-sensitive configuration is stored in YAML files in the Git repository.

Follow these steps to create the sensitive configuration and review the non-sensitive configuration:

1. Create a secret named `secret/dev/${CLUSTER_NAME}/tap/sensitive-values.yaml` that stores the sensitive data such as username, password, private key from the `tap-values.yaml` file:

   ```
   printf '%s\n'  "$(cat <<EOF
   ---
   # this document is intentionally initially blank.
   EOF
   )" | vault kv put secret/dev/${CLUSTER_NAME}/tap/sensitive-values.yaml -
   ```

   You can start with an empty document and edit it later on as described in the Configure and push the Tanzu Application Platform values section.

   Vault does not support storing YAML files, all secrets must be in `key-value` format. You must convert your sensitive-values YAML file to `json` before storage.

2. Review the integration with External Secrets Operator.

   This configuration was generated by the `configure.sh` script. It reported:

   ```
   ...
   wrote Vault configuration for TAP Install to: cluster-config/values/tap-install
   -vault-values.yaml
   ...
   ```

   For example, for the `iterate-green` cluster `tap-install-vault-values.yaml` contains the following information:

   ```
   ---
   tap_install:
    secrets:
      eso:
       vault:
         server: https://vault.example.com
         namespace: ""
         auth:
           kubernetes:
             mountPath: iterate-green
             role: iterate-green--tap-install-secrets
   ```

```
    remote_refs:
      tap_sensitive_values:
        sensitive_tap_values_yaml:
          key: secret/dev/iterate-green/tap/sensitive-values.yaml
```

Where:

- `kubernetes.role` is the IAM role that grants permission to Tanzu Application Platform installation to read its associated secrets. This role was created in the Grant read access to secret data section.
- `sensitive_tap_values_yaml.key` is the Vault secret name that contains the sensitive data from the `tap-values.yaml` file for this cluster in a YAML format.

3. Commit the Tanzu Application Platform installation configuration.

   For example, for the `iterate-green` cluster, run:

   ```
   git add cluster-config/
   git commit -m 'Configure installer for TAP 1.6.1 on "iterate-green"'
   ```

Configure and push the Tanzu Application Platform values

The configuration for the Tanzu Application Platform is divided into two separate locations:

- Sensitive configuration is stored in a Vault secret created in the Review and store Tanzu Application Platform installation config section.
- Non-sensitive configuration is stored in a plain YAML file `cluster-config/values/tap-values.yaml`

Follow these steps to split the Tanzu Application Platform values:

1. Create the file `cluster-config/values/tap-values.yaml` by using the Full Profile sample as a guide:

   The Tanzu Application Platform values are input configurations to the Tanzu Application Platform installation and are placed under the `tap_install.values` path.

   ```
   tap_install:
     values:
       # Tanzu Application Platform values go here.
       shared:
         ingress_domain: "INGRESS-DOMAIN"
       ceip_policy_disclosed: true
   ...
   ```

   To install Tanzu Application Platform in an offline environment, you must configure `Tanzu Build Service` and `Grype` to work in an air-gapped environment:

   ```
   ---
   tap_install:
     values:
       ...
       buildservice:
         exclude_dependencies: true
       grype:
         db:
           dbUpdateUrl: INTERNAL-VULN-DB-URL
   ```

   Where `INTERNAL-VULN-DB-URL` is the URL that points to the internal file server.

   For more information, see Components and installation profiles.

2. Review the contents of `tap-values.yaml` and move all the sensitive values into the Vault secret created in the Review and store Tanzu Application Platform installation config section.

   For example, if the `iterate-green` cluster is configured with the basic Out of the Box Supply Chain, this might include a passphrase for that supply chain's GitOps flow:

   ```
   ---
   tap_install:
    values:
      ...
      ootb_supply_chain_basic:
        registry:
          server: "SERVER-NAME"
          repository: "REPO-NAME"
        gitops:
          ssh_secret: "SSH-SECRET-KEY"
      ...
   ```

   To maintain the secrecy of `ootb_supply_chain_basic.gitops.ssh_secret`, move this value from the `tap-values.yaml` file:

   ```
   ---
   tap_install:
    values:
      ...
      ootb_supply_chain_basic:
        registry:
          server: "SERVER-NAME"
          repository: "REPO-NAME"
      ...
   ```

   Add it to the Vault secret named `secret/dev/iterate-green/tap/sensitive-values.yaml`, by default, without the `tap_install.values` root:

   ```
   ---
   ...
   ootb_supply_chain_basic:
    gitops:
      ssh_secret: "SSH-SECRET-KEY"
   ...
   ```

   When moving values, you must omit the `tap_install.values` root, but keep the remaining structure. All of the parent keys, such as `ootb_supply_chain_basic.gitops` and `ssh_secret`, must be copied to the sensitive value YAML.

3. Commit and push the Tanzu Application Platform values:

   ```
   git add cluster-config/
   git commit -m "Configure initial values for TAP 1.6.1"
   git push
   ```

   Tanzu Sync fetches configuration from the hosted clone of the Git repository. For changes to take effect on the cluster, they must be pushed to that clone of the Git repository.

Deploy Tanzu Sync

Deploying Tanzu Sync starts the GitOps workflow that initiates the Tanzu Application Platform installation.

After deployed, Tanzu Sync periodically polls the Git repository for changes. The following deployment process is only required once per cluster:

1. Install the Carvel tools `kapp` and `ytt` onto your `$PATH`:

   ```
   sudo cp $HOME/tanzu-cluster-essentials/kapp /usr/local/bin/kapp
   sudo cp $HOME/tanzu-cluster-essentials/ytt /usr/local/bin/ytt
   ```

   This step is required to ensure the successful deployment of the `tanzu-sync` app.

2. Ensure the Kubernetes cluster context is set to the correct cluster.

   1. List the existing contexts:

      ```
      kubectl config get-contexts
      ```

   2. Set the context to the cluster that you want to deploy:

      ```
      kubectl config use-context CONTEXT-NAME
      ```

      Where `CONTEXT-NAME` can be retrieved from the outputs of the previous step.

3. Bootstrap the deployment.

   External Secrets Operator is installed from the package included in the Tanzu Application Platform package repository. That repository must be fetched from the OCI registry initially.

   1. Set the following environment variables:

      ```
      export INSTALL_REGISTRY_HOSTNAME=MY-REGISTRY
      export INSTALL_REGISTRY_USERNAME=MY-REGISTRY-USER
      export INSTALL_REGISTRY_PASSWORD=MY-REGISTRY-PASSWORD
      ```

      Where:

      - `MY-REGISTRY` is your container registry.
      - `MY-REGISTRY-USER` is the user with read access to `MY-REGISTRY`.
      - `MY-REGISTRY-PASSWORD` is the password for `MY-REGISTRY-USER`.

   2. Create a secret containing credentials to fetch from that OCI registry by using the provided script:

      ```
      tanzu-sync/scripts/bootstrap.sh
      ```

      These credentials are used exactly once to install the External Secrets Operator (ESO) package.

4. Install Tanzu Sync and start the GitOps workflow by deploying it to the cluster using `kapp` and `ytt`.

   ```
   tanzu-sync/scripts/deploy.sh
   ```

   Depending on the profile and components included, it may take 5-10 minutes for the Tanzu Application Platform to install. During this time, `kapp` waits for the deployment of Tanzu Sync to reconcile successfully. This is normal.

   You can track the progress of the installation by watching the installation of those packages in a separate terminal window:

   ```
   watch kubectl get pkgi -n tap-install
   ```

Install Tanzu Application Platform through Gitops with Secrets OPerationS (SOPS)

This topic tells you how to install Tanzu Application Platform (commonly known as TAP) through GitOps with secrets managed in a Git repository.

Caution

- Tanzu Application Platform (GitOps) is currently in beta and is intended for evaluation and test purposes only. Do not use in a production environment.
- Tanzu GitOps Reference Implementation (RI) does not support changing the secrets management strategy for a cluster.

Prerequisites

Before installing Tanzu Application Platform, you need:

- **SOPS CLI** to view and edit SOPS encrypted files. To install the SOPS CLI, see SOPS documentation in GitHub.
- **Age CLI** to create an encryption key used to encrypt and decrypt sensitive data. To install the Age CLI, see age documentation in GitHub.
- Completed the Prerequisites.
- Accepted Tanzu Application Platform EULA and installed Tanzu CLI with any required plug-ins.
- Installed Cluster Essentials for Tanzu.

Relocate images to a registry

VMware recommends relocating the images from VMware Tanzu Network registry to your own container image registry before attempting installation. If you don't relocate the images, Tanzu Application Platform depends on VMware Tanzu Network for continued operation, and VMware Tanzu Network offers no uptime guarantees. The option to skip relocation is documented for evaluation and proof-of-concept only.

The supported registries are Harbor, Azure Container Registry, Google Container Registry, and Quay.io. See the following documentation for a registry to learn how to set it up:

- Harbor documentation
- Google Container Registry documentation
- Quay.io documentation

To relocate images from the VMware Tanzu Network registry to your registry:

1. Set up environment variables for installation use by running:

```
# Set tanzunet as the source registry to copy the Tanzu Application Platform pa
ckages from.
export IMGPKG_REGISTRY_HOSTNAME_0=registry.tanzu.vmware.com
export IMGPKG_REGISTRY_USERNAME_0=MY-TANZUNET-USERNAME
export IMGPKG_REGISTRY_PASSWORD_0=MY-TANZUNET-PASSWORD

# The user's registry for copying the Tanzu Application Platform package to.
export IMGPKG_REGISTRY_HOSTNAME_1=MY-REGISTRY
export IMGPKG_REGISTRY_USERNAME_1=MY-REGISTRY-USER
```

```
export IMGPKG_REGISTRY_PASSWORD_1=MY-REGISTRY-PASSWORD
# These environment variables starting with IMGPKG_* are used by the imgpkg com
mand only.

# The registry from which the Tanzu Application Platform package is retrieved.
export INSTALL_REGISTRY_USERNAME=MY-REGISTRY-USER
export INSTALL_REGISTRY_PASSWORD=MY-REGISTRY-PASSWORD
export INSTALL_REGISTRY_HOSTNAME=MY-REGISTRY
export TAP_VERSION=VERSION-NUMBER
export INSTALL_REPO=TARGET-REPOSITORY
```

Where:

- `MY-REGISTRY-USER` is the user with write access to `MY-REGISTRY`.
- `MY-REGISTRY-PASSWORD` is the password for `MY-REGISTRY-USER`.
- `MY-REGISTRY` is your own container image registry.
- `MY-TANZUNET-USERNAME` is the user with access to the images in the VMware Tanzu Network registry `registry.tanzu.vmware.com`.
- `MY-TANZUNET-PASSWORD` is the password for `MY-TANZUNET-USERNAME`.
- `VERSION-NUMBER` is your Tanzu Application Platform version. For example, `1.9.1`.
- `TARGET-REPOSITORY` is your target repository, a folder or repository on `MY-REGISTRY` that serves as the location for the installation files for Tanzu Application Platform.

VMware recommends using a JSON key file to authenticate with Google Container Registry. In this case, the value of `INSTALL_REGISTRY_USERNAME` is `_json_key` and the value of `INSTALL_REGISTRY_PASSWORD` is the content of the JSON key file. For more information about how to generate the JSON key file, see Google Container Registry documentation.

2. Install the Carvel tool `imgpkg` CLI.

   To query for the available versions of Tanzu Application Platform on VMWare Tanzu Network Registry, run:

   ```
   imgpkg tag list -i registry.tanzu.vmware.com/tanzu-application-platform/tap-pac
   kages | sort -V
   ```

3. Relocate the images with the `imgpkg` CLI by running:

   ```
   imgpkg copy -b registry.tanzu.vmware.com/tanzu-application-platform/tap-package
   s:${TAP_VERSION} --to-repo ${INSTALL_REGISTRY_HOSTNAME}/${INSTALL_REPO}/tap-pac
   kages
   ```

(Optional) Install Tanzu Application Platform in an air-gapped environment

Complete the following steps if you install Tanzu Application Platform in an air-gapped environment:

1. Relocate the Tanzu Build Service images to your registry:

   ```
   imgpkg copy -b registry.tanzu.vmware.com/tanzu-application-platform/full-tbs-de
   ps-package-repo:VERSION --to-repo ${INSTALL_REGISTRY_HOSTNAME}/${INSTALL_REPO}/
   full-tbs-deps-package-repo
   ```

   Where `VERSION` is the version of Tanzu Build Service. You can retrieve this value by running `kubectl get package -n tap-install | grep buildservice`

2. Host a `grype` database in the air-gapped environment. For more information, see Use vulnerability scanning in offline and air-gapped environments.

Create a new Git repository

Follow these steps to create a new Git repository and set up the authentication:

1. In a hosted Git service, for example, GitHub or GitLab, create a new repository.

   This version of Tanzu GitOps RI supports authenticating to a hosted Git repository by using SSH and Basic Authentication.

2. Initialize a new Git repository:

```
mkdir -p $HOME/tap-gitops
cd $HOME/tap-gitops

git init
git remote add origin git@github.com:my-organization/tap-gitops.git
```

3. Set up the authentication method.

   SSH
   Create a read-only deploy key for this new repository (recommended) or SSH key for an account with read access to this repository. The private portion of this key is called `GIT_SSH_PRIVATE_KEY`.

   Basic Authentication
   Have a user name with read access to the Git repository and password or personal access token for the same user.

Important

Only use one of `ssh` or `Basic Authentication`, not both.

Download and unpack Tanzu GitOps Reference Implementation (RI)

1. Sign in to VMware Tanzu Network.
2. Go to the Tanzu Application Platform product page.
3. Select **Release 1.9.1** from the release drop-down menu.
4. Click **Tanzu GitOps Reference Implementation**.
5. Unpack the downloaded TGZ file into the `$HOME/tap-gitops` directory by running:

```
tar xvf tanzu-gitops-ri-*.tgz -C $HOME/tap-gitops
```

6. Commit the initial state:

```
cd $HOME/tap-gitops

git add . && git commit -m "Initialize Tanzu GitOps RI"
git push -u origin
```

Create cluster configuration

1. Seed configuration for a cluster using SOPS:

   ```
   cd $HOME/tap-gitops

   ./setup-repo.sh CLUSTER-NAME sops
   ```

   Where:

   - `CLUSTER-NAME` the name of your cluster.
   - `sops` selects the Secrets OPerationS-based secrets management variant.

   Example:

   ```
   cd $HOME/tap-gitops

   ./setup-repo.sh full-tap-cluster sops
   Created cluster configuration in ./clusters/full-tap-cluster.
   ...
   ```

   This script creates the directory `clusters/full-tap-cluster/` and copies in the configuration required to sync this Git repository with the cluster and installing Tanzu Application Platform.

2. Commit and push:

   ```
   git add . && git commit -m "Add full-tap-cluster"
   git push
   ```

Configure Tanzu Application Platform

Tanzu Sync Reference Implementation (RI) splits the values configuration of Tanzu Application Platform into two categories:

- Sensitive TAP values, for example, credentials, encryptions keys and so on.
- Non-sensitive TAP values, for example, packages to exclude, namespace configuration and so on.

The following sections describe how to create these values files.

Prepare the sensitive Tanzu Application Platform values

Follow these steps to prepare the sensitive Tanzu Application Platform values:

1. Generate Age public or secrets keys:

   

   Note

   Skip this step if you already have an Age key to encrypt or decrypt secrets.

   ```
   mkdir -p $HOME/tmp-enc
   chmod 700 $HOME/tmp-enc
   cd $HOME/tmp-enc

   age-keygen -o key.txt

   cat key.txt
   ```

```
# created: 2023-02-08T10:55:35-07:00
# public key: age1ql3z7hjy54pw3hyww5ayyfg7zqgvc7w3j2elw8zmrj2kg5sfn9aqmcac8p
AGE-SECRET-KEY-my-secret-key
```

2. Create a plain YAML file `tap-sensitive-values.yaml` outside of your Git repository that contains a placeholder for the sensitive portion of the Tanzu Application Platform values:

   ```
   ---
   tap_install:
     sensitive_values:
   ```

3. Encrypt `tap-sensitive-values.yaml` with Age using SOPS:

   ```
   export SOPS_AGE_RECIPIENTS=$(cat key.txt | grep "# public key: " | sed 's/# pub
   lic key: //')
   sops --encrypt tap-sensitive-values.yaml > tap-sensitive-values.sops.yaml
   ```

   Where:

   - `grep` is used to find the line containing the public key portion of the generated secret.
   - `sed` is used to extract the public key from the line found by `grep`.

4. (Optional) Verify the encrypted file can be decrypted:

   ```
   export SOPS_AGE_KEY_FILE=key.txt
   sops --decrypt tap-sensitive-values.sops.yaml
   ```

   (Optional) Verify the encrypted file can be edited directly by using SOPS:

   ```
   sops tap-sensitive-values.sops.yaml
   ```

5. Move the sensitive Tanzu Application Platform values into the cluster config:

   ```
   mv tap-sensitive-values.sops.yaml GIT-REPO-ROOT/clusters/CLUSTER-NAME/cluster-c
   onfig/values/
   ```

   Example:

   ```
   mv tap-sensitive-values.sops.yaml $HOME/tap-gitops/clusters/full-tap-cluster/cl
   uster-config/values/
   ```

6. (Optional) Retain the Age identity key file in a safe and secure place such as a password manager, and purge the scratch space:

   ```
   mv key.txt SAFE-LOCATION/
   export SOPS_AGE_KEY_FILE=SAFE-LOCATION/key.txt
   rm -rf $HOME/tmp-enc
   ```

Prepare the non-sensitive Tanzu Application Platform values

Create a plain YAML file `GIT-REPO-ROOT/clusters/CLUSTER-NAME/cluster-config/values/tap-non-sensitive-values.yaml` by using the Full Profile sample as a guide:

Example:

```
---
tap_install:
```

```
  values:
    ceip_policy_disclosed: true
    excluded_packages:
    - policy.apps.tanzu.vmware.com
...
```

To install Tanzu Application Platform in an offline environment, you must configure `Tanzu Build Service` and `Grype` to work in an air-gapped environment:

```
---
tap_install:
  values:
    ...
    buildservice:
      exclude_dependencies: true
    grype:
      db:
        dbUpdateUrl: INTERNAL-VULN-DB-URL
```

Where `INTERNAL-VULN-DB-URL` is the URL that points to the internal file server.

For more information, see Components and installation profiles.

Update the sensitive Tanzu Application Platform values

After filling in the non-sensitive values, follow these steps to extract the sensitive values into `tap-sensitive-values.sops.yaml` that you prepared earlier:

1. Open an editor through SOPS to edit the encrypted sensitive values file:

   ```
   sops GIT-REPO-ROOT/clusters/CLUSTER-NAME/cluster-config/values/tap-sensitive-values.sops.yaml
   ```

   Example:

   ```
   sops $HOME/tap-gitops/clusters/full-tap-cluster/cluster-config/values/tap-sensitive-values.sops.yaml
   ```

2. Add the sensitive values:

   Example of the container registry credentials using basic authentication:

   ```
   ---
   tap_install:
    sensitive_values:
      shared:
        image_registry:
          project_path: "example.com/my-project/tap"
          username: "my_username"
          password: "my_password"
   ```

   Example of the container registry credentials using Google Container Registry:

   ```
   ---
   tap_install:
    sensitive_values:
     shared:
       image_registry:
          project_path: "gcr.io/my-project/tap"
          username: "_json_key"
          password: |
            {
              "type": "service_account",
   ```

```
            "project_id": "my-project",
            "private_key_id": "my-private-key-id",
            "private_key": "-----BEGIN PRIVATE KEY-----\n.........\n-----END PR
IVATE KEY-----\n",
            ...
          }
```

Prepare the sensitive Tanzu Sync values

Follow these steps to prepare the sensitive Tanzu Sync values:

1. Create a plain YAML file `tanzu-sync-values.yaml` outside of your Git repository that contains a placeholder for the sensitive portion of Tanzu Sync values:

   ```
   ---
   secrets:
       sops:
   ```

2. Encrypt `tanzu-sync-values.yaml` with Age using SOPS:

   ```
   export SOPS_AGE_RECIPIENTS=$(cat key.txt | grep "# public key: " | sed 's/# pub
   lic key: //')
   sops --encrypt tanzu-sync-values.yaml > tanzu-sync-values.sops.yaml
   ```

   Where:

   - `grep` is used to find the line containing the public key portion of the generated secret.
   - `sed` is used to extract the public key from the line found by `grep`.

3. Move the encrypted sensitive Tanzu Application Platform values into the Tanzu Sync config:

   ```
   mv tanzu-sync-values.sops.yaml GIT-REPO-ROOT/clusters/CLUSTER-NAME/tanzu-sync/a
   pp/sensitive-values/tanzu-sync-values.sops.yaml
   ```

   Example:

   ```
   mv tanzu-sync-values.sops.yaml $HOME/tap-gitops/clusters/full-tap-cluster/tanzu
   -sync/app/sensitive-values/tanzu-sync-values.sops.yaml
   ```

Update the sensitive Tanzu Sync values

Follow these steps to populate `tap-sensitive-values.sops.yaml` with credentials:

1. Open an editor and use SOPS to edit the encrypted sensitive values file:

   ```
   sops GIT-REPO-ROOT/clusters/CLUSTER-NAME/tanzu-sync/app/sensitive-values/tanzu-
   sync-values.sops.yaml
   ```

   Example:

   ```
   sops $HOME/tap-gitops/clusters/full-tap-cluster/tanzu-sync/app/sensitive-value
   s/tanzu-sync-values.sops.yaml
   ```

2. Add the sensitive values:

   Configuration example for the Git SSH authentication:

   ```
   ---
   secrets:
   ```

```
    sops:
        age_key: |
            AGE-KEY
        registry:
            hostname: MY-REGISTRY
            username: MY-REGISTRY-USER
            password: MY-REGISTRY-PASSWORD
        git:
            ssh:
                private_key: |
                    PRIVATE-KEY
                known_hosts: |
                    HOST-LIST
```

Configuration example for the Git basic authentication:

```
---
secrets:
    sops:
        age_key: |
            AGE-KEY
        registry:
            hostname: MY-REGISTRY
            username: MY-REGISTRY-USER
            password: MY-REGISTRY-PASSWORD
        git:
            basic_auth:
                username: MY-GIT-USERNAME
                password: MY-GIT-PASSWORD
```

Where:

- `AGE-KEY` is the contents of the Age key generated earlier.
- `MY-REGISTRY` is your container image registry.
- `MY-REGISTRY-USER` is the user with read access to `MY-REGISTRY`.
- `MY-REGISTRY-PASSWORD` is the password for `MY-REGISTRY-USER`.
- `PRIVATE-KEY` is the contents of an SSH private key file with read access to your Git repository. Only applies when you use `ssh`.
- `HOST-LIST` is the list of known hosts for Git host service. Only applies when you use `ssh`.
- `MY-GIT-USERNAME` is the user with read access to your Git repository. Only applies when you use `basic authentication`.
- `MY-GIT-PASSWORD` is the password for `MY-GIT-USERNAME`. Only applies when you use `basic authentication`.

You can find the schema for Tanzu Sync credentials in `GIT-REPO-ROOT/clusters/CLUSTER-NAME/tanzu-sync/app/config/.tanzu-managed/schema--sops.yaml`

Generate Tanzu Application Platform installation and Tanzu Sync configuration

Follow these steps to generate the Tanzu Application Platform installation and Tanzu Sync configuration:

1. Set up environment variables by running:

```
export TAP_PKGR_REPO=TAP-PACKAGE-OCI-REPOSITORY
export SOPS_AGE_KEY=AGE-KEY
```

Where:

- `TAP-PACKAGE-OCI-REPOSITORY` is the fully-qualified path to the OCI repository hosting the Tanzu Application Platform images. If the images are relocated as described in Relocate images to a registry, this value is `${INSTALL_REGISTRY_HOSTNAME}/${INSTALL_REPO}/tap-packages`.
- `AGE-KEY` is the contents of the Age key generated earlier.

Example of the Git repo hosted on GitHub:

```
export TAP_PKGR_REPO=registry.tanzu.vmware.com/tanzu-application-platform/tap-p
ackages
export SOPS_AGE_KEY=$(cat $HOME/tmp-enc/key.txt)
```

2. Generate the Tanzu Application Platform install and the Tanzu Sync configuration files by using the provided script:

```
cd GIT-REPO-ROOT/clusters/CLUSTER-NAME

./tanzu-sync/scripts/configure.sh
```

Example:

```
cd $HOME/tap-gitops/clusters/full-tap-cluster

./tanzu-sync/scripts/configure.sh
```

3. (Optional) Update Tanzu Application Platform to use the latest patch:

Update the Tanzu Application Platform version in `GIT-REPO-ROOT/clusters/CLUSTER-NAME/cluster-config/values/tap-install-values.yaml`:

```
tap_install:
    ...
    version:
        package_repo_bundle_tag: "1.9.1" # Populate these values with the lates
t patch version.
        package_version: "1.9.1"
```

Where:

- `package_repo_bundle_tag` is the version of Tanzu Application Platform you want to upgrade to.
- `package_version` is the version of Tanzu Application Platform you want to upgrade to. This version must match `package_repo_bundle_tag`.

Note

Tanzu GitOps RI does not provide a separate artifact for each patch version within a minor line. For example, Tanzu Application Platform v1.6.x only contains the v1.6.1 GitOps artifact.

4. Commit the generated configured to Git repository:

```
git add cluster-config/ tanzu-sync/
git commit -m "Configure install of TAP 1.6.1"
git push
```

Deploy Tanzu Sync

Follow these steps to deploy Tanzu Sync:

1. Install the Carvel tools `kapp` and `ytt` onto your `$PATH`:

   ```
   sudo cp $HOME/tanzu-cluster-essentials/kapp /usr/local/bin/kapp
   sudo cp $HOME/tanzu-cluster-essentials/ytt /usr/local/bin/ytt
   ```

2. Set the Kubernetes cluster context.
   1. List the existing contexts:

      ```
      kubectl config get-contexts
      ```

   2. Set the context to the cluster that you want to deploy:

      ```
      kubectl config use-context CONTEXT-NAME
      ```

      Where `CONTEXT-NAME` can be retrieved from the outputs of the previous step.

3. Deploy the Tanzu Sync component:

   ```
   cd GIT-REPO-ROOT/clusters/CLUSTER-NAME

   ./tanzu-sync/scripts/deploy.sh
   ```

   Example:

   ```
   cd $HOME/tap-gitops/clusters/full-tap-cluster

   ./tanzu-sync/scripts/deploy.sh
   ```

   

   Note

   Depending on the profile and components included, it may take 5-10 minutes for Tanzu Application Platform to install. During this time, `kapp` waits for the deployment of Tanzu Sync to reconcile successfully. This is normal.

Install individual packages

You can install Tanzu Application Platform (commonly known as TAP) through predefined profiles or through individual packages. Use this topic to learn how to install each individual package. For more information about installing through profiles, see Components and installation profiles.

Installing individual Tanzu Application Platform packages is useful if you do not want to use a profile to install packages or if you want to install additional packages after installing a profile. Before installing the packages, be sure to complete the prerequisites, configure and verify the cluster, accept the EULA, and install the Tanzu CLI with any required plug-ins. For more information, see Prerequisites.

Install pages for individual Tanzu Application Platform packages

- Install API Auto Registration
- Install API portal
- Install Application Accelerator
- Install Application Configuration Service
- Install Application Live View
- Install Application Single Sign-On
- Install Bitnami Services
- Install cert-manager
- Install Cloud Native Runtimes
- Install Contour
- Install Crossplane
- Install default roles for Tanzu Application Platform
- Install Developer Conventions
- Install Flux CD Source Controller
- Install Out of the Box Templates
- Install Out of the Box Supply Chain with Testing
- Install Out of the Box Supply Chain with Testing and Scanning
- Install Service Bindings
- Install Services Toolkit
- Install Source Controller
- Install Spring Boot conventions
- Install Supply Chain Choreographer
- Install Supply Chain Security Tools - Store
- Install Supply Chain Security Tools - Policy Controller
- Install Supply Chain Security Tools - Scan
- Install Tanzu Developer Portal
- Install Tanzu Build Service
- Install Tekton
- Install Telemetry

Verify the installed packages

Use the following procedure to verify that the packages are installed.

1. List the installed packages by running:

   ```
   tanzu package installed list --namespace tap-install
   ```

   For example:

```
$ tanzu package installed list --namespace tap-install
\ Retrieving installed packages...
NAME                     PACKAGE-NAME                                      PAC
KAGE-VERSION  STATUS
api-portal               api-portal.tanzu.vmware.com                       1.

```

Next steps

- Set up developer namespaces to use your installed packages

Set up developer namespaces to use your installed packages

For details about how to automatically set up your developer namespaces, see Provision developer namespaces in Namespace Provisioner.

Additional configuration for testing and scanning

If you plan to install or have already installed Out of the Box Supply Chains with Testing and Scanning, you can use Namespace Provisioner to set up the required resources. For more

information, see Customize installation in the Namespace Provisioner documentation for configuration steps.

Legacy namespace setup

To use the legacy manual process for setting up developer namespaces, see Legacy namespace setup.

Next steps

- Install Tanzu Developer Tools for your VS Code

Install Tanzu Developer Tools for your VS Code

This topic tells you how to install VMware Tanzu Developer Tools for Visual Studio Code (VS Code).

Prerequisites

Before installing the extension, you must have:

- VS Code
- kubectl
- Tilt v0.30.12 or later
- Tanzu CLI and plug-ins
- A cluster with the Tanzu Application Platform Full profile or Iterate profile

If you are an app developer, someone else in your organization might have already set up the Tanzu Application Platform environment.

Docker Desktop and local Kubernetes are not prerequisites for using Tanzu Developer Tools for VS Code.

Install

To install VMware Tanzu Developer Tools for VS Code:

1. Open Visual Studio Code.
2. Open the command palette.
3. In the search box enter `Extension`.
4. Click **Extensions: Install Extensions**.
5. The **Extensions** view opens on the left side of your screen. In the search box enter `Tanzu`.
6. Click **Tanzu Developer Tools** and then click **Install**.

Configure

To configure VMware Tanzu Developer Tools for VS Code:

1. Ensure that you are targeting the correct cluster. For more information, see the Kubernetes documentation.
2. Go to **Code** > **Preferences** > **Settings** > **Extensions** > **Tanzu Developer Tools** and set the following:

- **Confirm Apply Config**: This controls whether the extension asks to confirm user input when applying a workload.
- **Confirm Debug Port**: This controls whether the extension asks for the debug port when running `Tanzu: Start Java Debug`.
- **Confirm Local Port**: This controls whether the extension asks for the local port when running `Tanzu: Start Java Debug`.
- **Confirm Delete**: This controls whether the extension asks for confirmation when deleting a workload.
- **Enable Live Hover**: This enables Live Hover. For more information, see Integrating Live Hover by using Spring Boot Tools. Restart VS Code for this change to take effect.
- **Source Image**: The registry location for publishing local source code. For example, `registry.io/yourapp-source`. This must include both a registry and a project name. A source image registry location is optional when Local Source Proxy is configured.
- **Local Path**: (Optional) The path on the local file system to a directory of source code to build. This is the current directory by default.
- **Namespace**: (Optional) This is the namespace that workloads are deployed into. The namespace set in kubeconfig is the default.
- **Tracked Namespaces**: (Optional) Comma-separated list of namespaces. Resources in these namespaces appear in the Tanzu Workloads panel and the Activity panel. If empty, the namespace in the current context is the default.
- **Wait Timeout**: (Optional) This sets how long to wait for a workload to become ready.
- **Workload Type**: (Optional) This distinguishes the workload type. Examples include web and server.

Uninstall

To uninstall VMware Tanzu Developer Tools for VS Code:

1. Go to **Code** > **Preferences** > **Settings** > **Extensions**.
2. Right-click the extension and then click **Uninstall**.

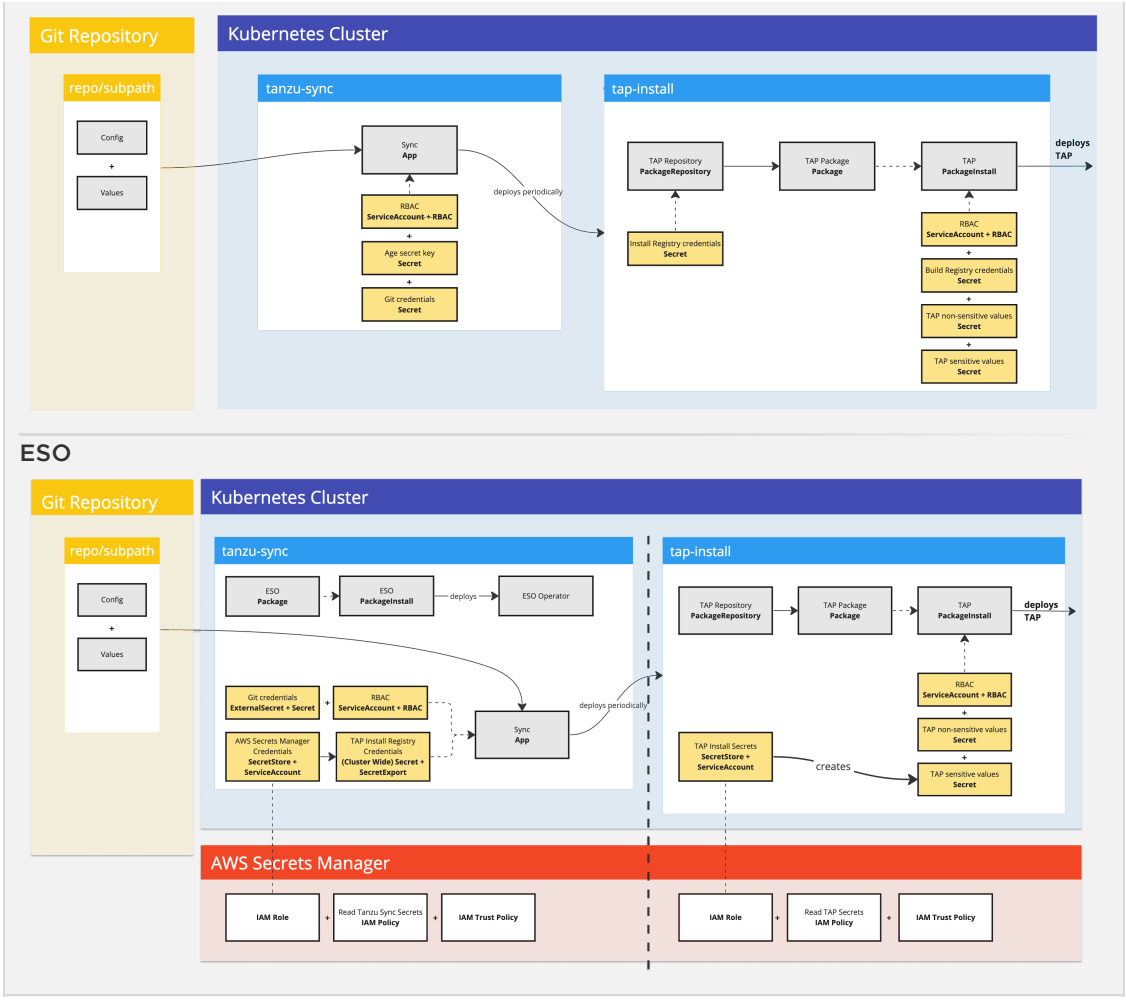
Next steps

Proceed to Getting started with Tanzu Developer Tools for Visual Studio Code.

Tanzu GitOps RI Reference Documentation

The following diagrams shows you the components that are installed as part of Tanzu GitOps Reference Implementation (RI) and how they work together to automate the installation of Tanzu Application Platform (commonly known as TAP):

SOPS



Caution

Tanzu Application Platform (GitOps) is currently in beta and is intended for evaluation and test purposes only. Do not use in a production environment.

Tanzu Sync Carvel Application

Tanzu Sync consists of a Carvel application named `sync` that is installed in the `tanzu-sync` namespace. The sync application:

1. Fetches a Git repository that contains configuration for Tanzu Application Platform.
2. Templates with `ytt` a set of resources and data values.
3. Deploys with `kapp` a set of resources to install Tanzu Application Platform, with any other user specified configuration in the Git Repository.

Choosing Secrets OPerationS (SOPS) or External Secrets Operator (ESO)

The following table outlines the Kubernetes distributions and secret management solutions that SOPS and ESO support:

Choose	IaaS	Secrets Manager
SOPS	Any IaaS supported by Tanzu Application Platform	N/A
ESO	AWS EKS	AWS Secrets Manager
ESO	Azure, GKE and AWS EKS are supported by Tanzu Application Platform	Vault

Note

Future release will include additional Secrets Managers for ESO.

The following table describes a few common use cases and scenarios for SOPS and ESO:

I want ...	SOPS	ESO
Sensitive data encrypted inside the Git repository.		
Sensitive data to be stored outside the Git repository.		
Minimal setup. No external secret storage system		
To manage sensitive data myself. For example, storing keys, rotation and usage auditing.)		
To utilize sensitive data management. For example, storage, rotation and usage auditing by a third-party solution.		

Git Repository structure

Tanzu Sync Application fetches our deployable content from a Git repository that must match the following structure:

Git repository for a cluster named `full-tap-cluster`:

```
├── .catalog
│   ├── tanzu-sync
│   │   └── 0.0.3
│   └── tap-install
│       └── 1.5.0
├── README.md
├── clusters
│   └── full-tap-cluster
│       ├── README.md
│       ├── cluster-config
│       │   ├── config
│       │   │   └── tap-install
│       │   │       └── .tanzu-managed
│       │   └── values
│       └── tanzu-sync
│           ├── app
│           │   ├── config
│           │   │   └── .tanzu-managed
│           │   └── values
│           ├── bootstrap
│           └── scripts
└── setup-repo.sh
```

Where:

- `.catalog`: VMware supplied directory of resources and configuration to install Tanzu Sync and Tanzu Application Platform.

    - `tanzu-sync`: Contains the Carvel Packaging App which supports a GitOps workflow for fetching, templating and deploying the `clusters/full-tap-cluster/cluster-config` directory of this repository.
    - `tap-install`: Contains the configuration to install Tanzu Application Platform.
- `clusters/full-tap-cluster`
    - `cluster-config`
        - `config`: Contains the Tanzu Application Platform installation configuration. This directory can be extended to include any desired resources managed through GitOps to your cluster.
        - `.tanzu-managed`: Contains VMware managed Kubernetes resource files to install Tanzu Application Platform. Do not alter this value.
        - `values`: Contains the plain YAML data files which configure the application.
    - `tanzu-sync`
        - `app`: Contains the main Carvel Packaging App that runs on the cluster. It fetches, templates and deploys your Tanzu Application Platform installation from `clusters/full-tap-cluster/cluster-config`.
        - `bootstrap`: Contains secret provider specific bootstrapping if required.
        - `scripts`: Contains helper scripts to assist with the configuration and deployment of Tanzu GitOps RI.

Configuration of Tanzu Sync without helper scripts

1. The following plain YAML values files are required to run Tanzu Sync:
    - Tanzu Sync App:

      `clusters/full-tap-cluster/tanzu-sync/app/values/values.yaml` adhering to the following schema:

      ```
      #@data/values-schema
      #@overlay/match-child-defaults missing_ok=True
      ---
      git:
        url: ""
        ref: ""
        sub_path: ""

      tap_package_repository:
        oci_repository: ""
      ```

      Example:

      ```
      ---
      git:
        url: git@github.com:my-org/gitops-tap.git
        ref: origin/main
        sub_path: clusters/full-tap-cluster/cluster-config

      tap_package_repository:
        oci_repository: registry.example.com/tanzu-application-platform/tap-pac
      kages
      ```
    - Tanzu Application Platform Install:

      `clusters/full-tap-cluster/cluster-config/config/values/install-values.yaml` adhering to the following schema:

```
#@data/values-schema
#@overlay/match-child-defaults missing_ok=True
---
tap_install:
  package_repository:
    oci_repository: ""
  #@schema/type any=True
  values: {}
```

Example:

```
tap_install:
  package_repository:
    oci_repository: registry.example.com/tanzu-application-platform/tap-p
ackages
  values:
    shared:
      ingress_domain: example.vmware.com
    ceip_policy_disclosed: true
```

`clusters/full-tap-cluster/cluster-config/config/values/sensitive-values.sops.yaml` adhering to the following schema:

```
#@data/values-schema
#@overlay/match-child-defaults missing_ok=True
---
tap_install:
  #@schema/nullable
  #@schema/validation not_null=True
  #@schema/type any=True
  sensitive_values: {}
```

Example:

```
tap_install:
  sensitive_values:
    shared:
      image_registry:
        project_path: example.registry.com/my-project/my-user/tap
        username: my-username
        password: my-password
```

2. The following is used to deploy the application by using `kapp`:

```
kapp deploy --app tanzu-sync --file <(ytt \
    --file tanzu-sync/app/config \
    --file cluster-config/config/tap-install/.tanzu-managed/version.yaml \
    --data-values-file tanzu-sync/app/values/ \
    --data-value secrets.sops.age_key=$(cat $HOME/key.txt) \
    --data-value secrets.sops.registry.hostname="hostname" \
    --data-value secrets.sops.registry.username="foo@example.com" \
    --data-value secrets.sops.registry.password="password" \
    --data-value secrets.sops.git.ssh.private_key=$(cat $HOME/.ssh/my_private_k
ey) \
    --data-value secrets.sops.git.ssh.known_hosts=$(ssh-keyscan github.com) \
)
```

Tanzu Sync Scripts

Caution

The provided scripts are intended to help set up your Git repository to work with a GitOps approach, they are subject to change or removal between releases.

VMware provides a set of convenience bash scripts in `clusters/MY-CLUSTER/tanzu-sync/scripts` to help you set up your Git repository and configure the values as described in the previous section:

- `setup-repo.sh`: Populates a Git repository with the structure described in the Git Repository structure section.
- `configure.sh`: Generates the values files described in the Configuration of values without helper scripts section.
- `deploy.sh`: A light wrapper around a simple `kapp deploy` given the data values from the previous section and sensitive values which must not be stored on disk.

Customize your package installation

You can customize your package configuration that is not exposed through data values by using annotations and ytt overlays.

You can customize a package that was installed manually or that was installed by using a Tanzu Application Platform profile.

Customize a package that was manually installed

To customize a package that was installed manually:

1. Create a `secret.yml` file with a `Secret` that contains your ytt overlay. For example:

   ```
   apiVersion: v1
   kind: Secret
   metadata:
    name: tap-overlay
    namespace: tap-install
   stringData:
    custom-package-overlay.yml: |
      CUSTOM-OVERLAY
   ```

   For more information about ytt overlays, see the Carvel documentation.

2. Apply the `Secret` to your cluster by running:

   ```
   kubectl apply -f secret.yml
   ```

3. Update your `PackageInstall` to include the `ext.packaging.carvel.dev/ytt-paths-from-secret-name.x` annotation to reference your new overlay `Secret`. For example:

   ```
   apiVersion: packaging.carvel.dev/v1alpha1
   kind: PackageInstall
   metadata:
    name: PACKAGE-NAME
    namespace: tap-install
    annotations:
      ext.packaging.carvel.dev/ytt-paths-from-secret-name: tap-overlay
   ...
   ```

   Note

> You can suffix the extension annotation with `.x`, where `x` is a number, to apply multiple overlays. For more information, see the Carvel documentation.

Customize a package that was installed by using a profile

To add an overlay to a package that was installed by using a Tanzu Application Platform profile:

1. Create a `Secret` with your ytt overlay. For more information about ytt overlays, see the Carvel documentation.
2. Update your values file to include a `package_overlays` field:

   ```
   package_overlays:
   - name: PACKAGE-NAME
     secrets:
     - name: SECRET-NAME
   ```

   Where `PACKAGE-NAME` is the target package for the overlay. For example, `tap-gui`.
3. Update Tanzu Application Platform by running:

   ```
   tanzu package installed update tap -p tap.tanzu.vmware.com -v 1.9.1  --values-f
   ile tap-values.yaml -n tap-install
   ```

For information about Tanzu Application Platform profiles, see Installing Tanzu Application Platform package and profiles.

Upgrade Tanzu Application Platform

This document tells you how to upgrade your Tanzu Application Platform (commonly known as TAP).

You can perform a fresh install of Tanzu Application Platform by following the instructions in Installing Tanzu Application Platform.

Prerequisites

Before you upgrade Tanzu Application Platform:

- Verify that you meet all the prerequisites and resource requirements of the target Tanzu Application Platform version. If the target Tanzu Application Platform version does not support your existing Kubernetes version, VMware recommends upgrading to a supported version before proceeding with the upgrade.
- For information about installing your Tanzu Application Platform, see Install your Tanzu Application Platform profile.
- Ensure that Tanzu CLI is updated to the version recommended by the target Tanzu Application Platform version. For information about installing or updating the Tanzu CLI and plug-ins, see Install or update the Tanzu CLI and plug-ins.
- For information about Tanzu Developer Portal considerations, see Tanzu Developer Portal Considerations.
- Verify all packages are reconciled by running `tanzu package installed list -A`.
- To avoid the temporary warning state that is described in Update the new package repository, upgrade to Cluster Essentials v1.9. For more information about the upgrade

procedures, see the Cluster Essentials documentation.

- The previously deprecated field `scanning.metadataStore.url` is removed from the values for installing or upgrading Tanzu Application Platform v1.7 and later. This field must not present in the `tap-non-sensitive-values.yaml` file when performing the upgrade.
- Note that this upgrade will update all workloads and pods that are using service bindings. This is done automatically after upgrading to 1.7 or later and requires no user action.
- All pods with service bindings are recreated concurrently at the time of the upgrade. You must have sufficient Kubernetes resources in your clusters to support the pod rollout.
- If you manually created a secret to configure the Metadata Store CA Certificate for Supply Chain Security Tools (SCST) - Scan, you must configure this certificate in Tanzu Application Platform values file before upgrading. For more information, see v1.9.0 Breaking changes: Supply Chain Security Tools - Scan.

Supported upgrade paths

Tanzu Application Platform v1.9 supports upgrading from the following versions:

- v1.8.x long-term support release
- v1.7.x long-term support release

Update the new package repository

Follow these steps to update the new package repository:

1. Relocate the latest version of Tanzu Application Platform images by following step 1 through step 6 in Relocate images to a registry.

   Important

   Make sure to update the `TAP_VERSION` to the target version of Tanzu Application Platform you are migrating to. For example, `1.9.1`.

2. Add the target version of the Tanzu Application Platform package repository by running:

   Cluster Essentials 1.2 or above

   ```
   tanzu package repository add tanzu-tap-repository \
   --url ${INSTALL_REGISTRY_HOSTNAME}/${INSTALL_REPO}/tap-packages:$TAP_VERSION
   \
   --namespace tap-install
   ```

   Cluster Essentials 1.1 or 1.0

   ```
   tanzu package repository update tanzu-tap-repository \
   --url ${INSTALL_REGISTRY_HOSTNAME}/TARGET-REPOSITORY/tap-packages:${TAP_VERSI
   ON} \
   --namespace tap-install
   ```

   Expect to see the installed Tanzu Application Platform packages in a temporary “Reconcile Failed” state, following a “Package not found” warning. These warnings will disappear after you upgrade the installed Tanzu Application Platform packages to version 1.2.0.

3. Verify you have added the new package repository by running:

   ```
   tanzu package repository get TAP-REPO-NAME --namespace tap-install
   ```

   Where `TAP-REPO-NAME` is the package repository name. It must match with either `NEW-TANZU-TAP-REPOSITORY` or `tanzu-tap-repository` in the previous step.

Perform the upgrade of Tanzu Application Platform

The following sections describe how to upgrade in different scenarios.

Upgrade instructions for Profile-based installation

The following changes affect the upgrade procedures:

- **Introduced Artifact Metadata Repository**

  In Tanzu Application Platform v1.7.0 and later, the Artifact Metadata Repository component is introduced into the Supply Chain Security Tools (SCST) - Store package. In a multicluster deployment, this component requires additional configuration during upgrade. For more information, see Upgrading from AMR Beta to AMR GA release.

- **Keyless support deactivated by default**

  In Tanzu Application Platform v1.5.0, keyless support is deactivated by default. For more information, see Install Supply Chain Security Tools - Policy Controller.

  To support the keyless authorities in `ClusterImagePolicy`, Policy Controller no longer initializes TUF by default. To continue using keyless authorities, you must set the `policy.tuf_enabled` field to `true` in the `tap-values.yaml` file during the upgrade process.

  By default, the public official Sigstore “The Update Framework (TUF) server” is used. You can use an alternative Sigstore Stack by setting `policy.tuf_mirror` and `policy.tuf_root`.

- **Image Policy Webhook no longer in use**

  Tanzu Application Platform v1.5.0 removes Image Policy Webhook. If you use Image Policy Webhook in the previous version of Tanzu Application Platform, you must migrate the `ClusterImagePolicy` resource from Image Policy Webhook to Policy Controller.

- **CVE results require a read-write service account**

  Tanzu Application Platform v1.3.0 uses a read-only service account. In Tanzu Application Platform v1.4.0 and later, enabling CVE results for the Supply Chain Choreographer and Security Analysis GUI plug-ins requires a read-write service account. For more information, see Enable CVE scan results.

If you installed Tanzu Application Platform by using a profile, you can perform the upgrade by running the following command in the directory where the `tap-values.yaml` file resides:

```
tanzu package installed update tap -p tap.tanzu.vmware.com -v ${TAP_VERSION}  --values
-file tap-values.yaml -n tap-install
```

When upgrading to Tanzu Application Platform v1.5, you might encounter a temporary resource reconciliation failure. This error does not persist and the packages will reconcile subsequently. To facilitate the reconciliation of packages, you can execute the `tanzu package installed kick -n tap-install tap -y` command repeatedly.

Upgrade the full dependencies package

If you installed the full dependencies package, you can upgrade the package by following these steps:

1. (Optional) If you have an existing installation of the full dependencies from a version earlier than TAP v1.6.1, you must uninstall the full dependencies package and remove the package repository. Subsequent upgrades will not require a removal:

   Uninstall the package

   ```
   tanzu package installed delete full-tbs-deps -n tap-install
   ```

   Remove the package repository

   ```
   tanzu package repository delete tbs-full-deps-repository -n tap-install
   ```

2. After upgrading Tanzu Application Platform, retrieve the latest version of the Tanzu Application Platform package by running:

   ```
   tanzu package available list tap.tanzu.vmware.com --namespace tap-install
   ```

3. Relocate the Tanzu Build Service `full` dependencies package repository by running:

   ```
   imgpkg copy -b registry.tanzu.vmware.com/tanzu-application-platform/full-deps-p
   ackage-repo:VERSION \
   --to-repo ${INSTALL_REGISTRY_HOSTNAME}/${INSTALL_REPO}/full-deps-package-repo
   ```

   Where `VERSION` is the version of the Tanzu Application Platform package you retrieved in the previous step.

4. Update the Tanzu Build Service `full` dependencies package repository by running:

   ```
   tanzu package repository add full-deps-package-repo \
     --url ${INSTALL_REGISTRY_HOSTNAME}/${INSTALL_REPO}/full-deps-package-repo:VER
   SION \
     --namespace tap-install
   ```

5. Update the `full` dependencies package by running:

   ```
   tanzu package install full-deps -p full-deps.buildservice.tanzu.vmware.com -v
   "> 0.0.0" -n tap-install --values-file PATH-TO-TAP-VALUES-FILE
   ```

   Important

   The values file is only required for this command if you install this package for the first time or if the values have changed.

Multicluster upgrade order

Upgrading a multicluster deployment requires updating multiple clusters with different profiles. If upgrades are not performed at the exact same time, different clusters have different versions of profiles installed temporarily. This might cause a temporary API mismatch that leads to errors. Those errors eventually disappear when the versions are consistent across all clusters.

To reduce the likelihood of temporary failures, follow these steps to upgrade your multicluster deployment:

1. Upgrade the view-profile cluster.
2. Upgrade the remaining clusters in any order.

Upgrade instructions for component-specific installation

You can upgrade the following components outside of a Tanzu Application Platform profile upgrade:

- Tanzu Developer Portal: Upgrade Tanzu Developer Portal.
- Supply Chain Security Tools - Scan: Upgrade Supply Chain Security Tools - Scan.
- Supply Chain Security Tools - Store: Upgrading Supply Chain Security Tools - Store.

Verify the upgrade

Verify the versions of packages after the upgrade by running:

```
tanzu package installed list --namespace tap-install
```

Your output is similar, but probably not identical, to the following example output:

```
- Retrieving installed packages...
  NAME                                PACKAGE-NAME
PACKAGE-VERSION  STATUS
  accelerator                         accelerator.apps.tanzu.vmware.com

Upgrade your Tanzu Application Platform by using GitOps

This document tells you how to upgrade your Tanzu Application Platform (commonly known as TAP) by using GitOps.

Caution

Tanzu Application Platform (GitOps) is currently in beta and is intended for evaluation and test purposes only. Do not use in a production environment.

You can perform a fresh install of Tanzu Application Platform by following the instructions in Installing Tanzu Application Platform.

Prerequisites

Before you upgrade your Tanzu Application Platform:

- Verify that you meet all the prerequisites of the target Tanzu Application Platform version. If the target Tanzu Application Platform version does not support your existing Kubernetes version, VMware recommends upgrading to a supported version before proceeding with the upgrade.
- For information about installing your Tanzu Application Platform, see Install Tanzu Application Platform through Gitops with Secrets OPerationS (SOPS) or Install Tanzu Application Platform through GitOps with External Secrets Operator (ESO).
- For information about Tanzu Developer Portal considerations, see Tanzu Developer Portal Considerations.
- Verify all packages are reconciled by running `kubectl get packageinstall --namespace tap-install`.
- The previously deprecated field `scanning.metadataStore.url` is removed from the values for installing or upgrading Tanzu Application Platform v1.7 and later. This field must not present in the `tap-non-sensitive-values.yaml` file when performing the upgrade.

Relocate Tanzu Application Platform images to a registry

VMware recommends relocating the images from VMware Tanzu Network registry to your own container image registry before attempting installation. If you don't relocate the images, Tanzu Application Platform depends on VMware Tanzu Network for continued operation, and VMware Tanzu Network offers no uptime guarantees. The option to skip relocation is documented for evaluation and proof-of-concept only.

The supported registries are Harbor, Azure Container Registry, Google Container Registry, and Quay.io. See the following the documentation for instructions on setting up a registry:

- Harbor documentation
- Google Container Registry documentation
- Quay.io documentation

To relocate images from the VMware Tanzu Network registry to your registry:

1. Set up environment variables for installation use by running:

   ```
   export IMGPKG_REGISTRY_HOSTNAME_0=registry.tanzu.vmware.com
   export IMGPKG_REGISTRY_USERNAME_0=MY-TANZUNET-USERNAME
   export IMGPKG_REGISTRY_PASSWORD_0=MY-TANZUNET-PASSWORD
   export IMGPKG_REGISTRY_HOSTNAME_1=MY-REGISTRY
   export IMGPKG_REGISTRY_USERNAME_1=MY-REGISTRY-USER
   export IMGPKG_REGISTRY_PASSWORD_1=MY-REGISTRY-PASSWORD
   export INSTALL_REGISTRY_USERNAME=MY-REGISTRY-USER
   export INSTALL_REGISTRY_PASSWORD=MY-REGISTRY-PASSWORD
   export INSTALL_REGISTRY_HOSTNAME=MY-REGISTRY
   export TAP_VERSION=VERSION-NUMBER
   export INSTALL_REPO=TARGET-REPOSITORY
   ```

   Where:

   - `MY-REGISTRY-USER` is the user with write access to `MY-REGISTRY`.
   - `MY-REGISTRY-PASSWORD` is the password for `MY-REGISTRY-USER`.
   - `MY-REGISTRY` is your own container registry.
   - `MY-TANZUNET-USERNAME` is the user with access to the images in the VMware Tanzu Network registry `registry.tanzu.vmware.com`.
   - `MY-TANZUNET-PASSWORD` is the password for `MY-TANZUNET-USERNAME`.
   - `VERSION-NUMBER` is your Tanzu Application Platform version. For example, `1.9.1`.
   - `TARGET-REPOSITORY` is your target repository, a folder or repository on `MY-REGISTRY` that serves as the location for the installation files of Tanzu Application Platform.

   VMware recommends using a JSON key file to authenticate with Google Container Registry. In this case, the value of `INSTALL_REGISTRY_USERNAME` is `_json_key` and the value of `INSTALL_REGISTRY_PASSWORD` is the content of the JSON key file. For more information about how to generate the JSON key file, see Google Container Registry documentation.

2. Install the Carvel tool `imgpkg` CLI.

   To query for the available versions of Tanzu Application Platform on VMWare Tanzu Network Registry, run:

   ```
   imgpkg tag list -i registry.tanzu.vmware.com/tanzu-application-platform/tap-pac
   kages | sort -V
   ```

3. Relocate the images with the `imgpkg` CLI by running:

   ```
   imgpkg copy -b registry.tanzu.vmware.com/tanzu-application-platform/tap-package
   s:${TAP_VERSION} --to-repo ${INSTALL_REGISTRY_HOSTNAME}/${INSTALL_REPO}/tap-pac
   ```

```
kages
```

Upgrade to a patch version

Caution

Tanzu Application Platform (GitOps) does not provide a separate artifact for each patch version within a minor line. For example, Tanzu Application Platform v1.6.x only contains the v1.6.1 GitOps artifact.

Follow these steps to upgrade to the latest patch:

1. Download and unpack the latest version of Tanzu GitOps RI.
2. Update the Tanzu Application Platform version in `GIT-REPO-ROOT/clusters/CLUSTER-NAME/cluster-config/values/tap-install-values.yaml`:

   ```
   tap_install:
       ...
       version:
           package_repo_bundle_tag: "1.9.1"
           package_version: "1.9.1"
   ```

   Where:

   - `package_repo_bundle_tag` is the version of Tanzu Application Platform you want to upgrade to.
   - `package_version` is the version of Tanzu Application Platform you want to upgrade to. This version must match `package_repo_bundle_tag`.
3. Commit the upgrade configurations:

   ```
   git add . && git commit -m "Upgrade TAP to 1.9.1"
   git push
   ```

Upgrade the existing SOPs based installation

In previous versions of Tanzu GitOps RI, sensitive values were provided to Tanzu Sync by using the command line and environment variables. This is replaced by a SOPs encrypted file that is committed to the repository.

Follow these steps to upgrade the existing SOPs based installation:

1. Download and unpack the new version of Tanzu GitOps RI.
2. Overwrite the configuration for TAP installation and Tanzu Sync from the catalog:

   ```
   cd $HOME/tap-gitops

   ./setup-repo.sh CLUSTER-NAME sops
   ```

   Where:

   - `CLUSTER-NAME` the name of your cluster you want to upgrade.
   - `sops` selects the Secrets OPerationS-based secrets management variant. Changing between SOPs and any other secret management variant is not supported!

   Example:

```
cd $HOME/tap-gitops

./setup-repo.sh full-tap-cluster sops
Created cluster configuration in ./clusters/full-tap-cluster.
...
```

3. Prepare sensitive Tanzu Sync values.

Upgrade the existing ESO based installation

Follow these steps to upgrade the existing ESO based installation with secrets managed externally in AWS Secrets Manager:

1. Download and unpack the new version of Tanzu GitOps RI.
2. Overwrite the configuration for Tanzu Application Platform installation and Tanzu Sync from the catalog:

   ```
   cd $HOME/tap-gitops

   ./setup-repo.sh CLUSTER-NAME aws-secrets-manager
   ```

   Where:

   - `CLUSTER-NAME` the name of your cluster you want to upgrade.
   - `aws-secrets-manager` selects the AWS Secrets Manager external Secret Store.

   Example:

   ```
   cd $HOME/tap-gitops

   ./setup-repo.sh full-tap-cluster aws-secrets-manager
   Created cluster configuration in ./clusters/full-tap-cluster.
   ...
   ```

3. Generate the default configuration.

Verify the upgrade

Verify the versions of packages after the upgrade by running:

```
kubectl get packageinstall --namespace tap-install
```

Your output is similar, but probably not identical, to the following example output:

```
- Retrieving installed packages...
  NAME                                PACKAGE-NAME
PACKAGE-VERSION  DESCRIPTION
  accelerator                         accelerator.apps.tanzu.vmware.com

Opt out of telemetry collection

This topic tells you how to opt out of the VMware Customer Experience Improvement Program (CEIP) and out of Pendo telemetry on an organizational level.

There are two components for telemetry collection in Tanzu Application Platform (commonly known as TAP) under the VMware Customer Experience Improvement Program (CEIP):

1. The standard CEIP telemetry collection
2. Pendo telemetry from Tanzu Developer Portal

Each telemetry component has its own opt-in and opt-out process. The CEIP telemetry opt-out decision can be made at an organizational level, whereas the decision regarding the Pendo telemetry is available both on an organizational level and at an individual user level.

When you install Tanzu Application Platform, both standard CEIP and Pendo telemetry are turned on by default. If you opt out of standard CEIP telemetry collection, VMware cannot offer you proactive support and the other benefits that accompany participation in the CEIP.

Turn off standard CEIP telemetry collection

To deactivate Pendo telemetry collection, see Enable or deactivate the Pendo telemetry for the organization later in the topic.

Note

If you decide to opt in to Pendo telemetry collection, each user is given the option to opt in or opt out. For more information, see Opt in or opt out of Pendo telemetry for Tanzu Developer Portal.

To turn off CEIP telemetry collection, follow these instructions:

kubectl

To turn off telemetry collection on Tanzu Application Platform by using kubectl:

1. Ensure that your Kubernetes context is pointing to the cluster where Tanzu Application Platform is installed.
2. Run:

```
kubectl apply -f - <<EOF
apiVersion: v1
kind: Namespace
metadata:
  name: vmware-system-telemetry
---
apiVersion: v1
kind: ConfigMap
metadata:
  namespace: vmware-system-telemetry
  name: vmware-telemetry-cluster-ceip
data:
  level: disabled
EOF
```

3. If you already have Tanzu Application Platform installed, restart the telemetry collector to apply the change:

```
kubectl delete pods --namespace tap-telemetry --all
```

Your Tanzu Application Platform deployment now no longer emits telemetry, and you have opted out of the CEIP.

Tanzu CLI

The Tanzu CLI provides a telemetry plug-in enabled by the Tanzu Framework v0.25.0, which is included in Tanzu Application Platform v1.3 and later.

To turn off telemetry collection on your Tanzu Application Platform by using the Tanzu CLI, run:

```
tanzu telemetry update --CEIP-opt-out
```

To learn more about how to update the telemetry settings, run:

```
tanzu telemetry update --help
```

Your Tanzu Application Platform deployment now no longer emits telemetry, and you have opted out of the CEIP.

Turn off Pendo telemetry collection

To deactivate the program for the entire organization, add the following parameters to your `tap-values.yaml` file:

```
tap_gui:
  app_config:
    pendoAnalytics:
      enabled: false
```

To enable Pendo telemetry for the organization, add the following parameters to your `tap-values.yaml` file:

```
tap_gui:
  app_config:
    pendoAnalytics:
      enabled: true
```

Opt in or opt out of Pendo telemetry for Tanzu Developer Portal

Tanzu Developer Portal uses Pendo.io to better understand the way users interact with it to provide a better user experience for VMware customers and to improve VMware products and services.

Pendo.io collects data based on your interaction with the software, such as clickstream data and page loads, hashed user ID, and limited browser and device information.

By default, each instance of Tanzu Developer Portal is assigned to a random organization ID to ensure that your sensitive information is not revealed.

However, you can choose to customize your organization ID and self-identify. Doing so allows VMware to observe account-level telemetry, such as frequency of portal use, most popular function, and so on. All personally identifiable information remains anonymized in any case. The organization name is hashed to prevent VMware from identifying you by the value.

To customize your organization ID, see Customize the Tanzu Developer Portal telemetry collection.

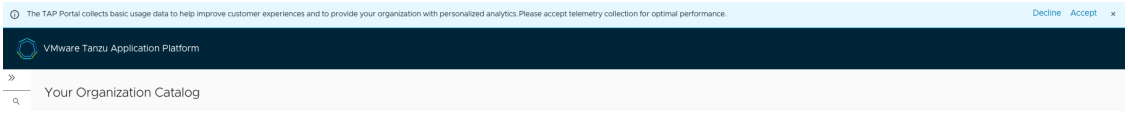
To enable or deactivate Pendo telemetry for the organization, see Enable or deactivate the Pendo telemetry for the organization.

Note

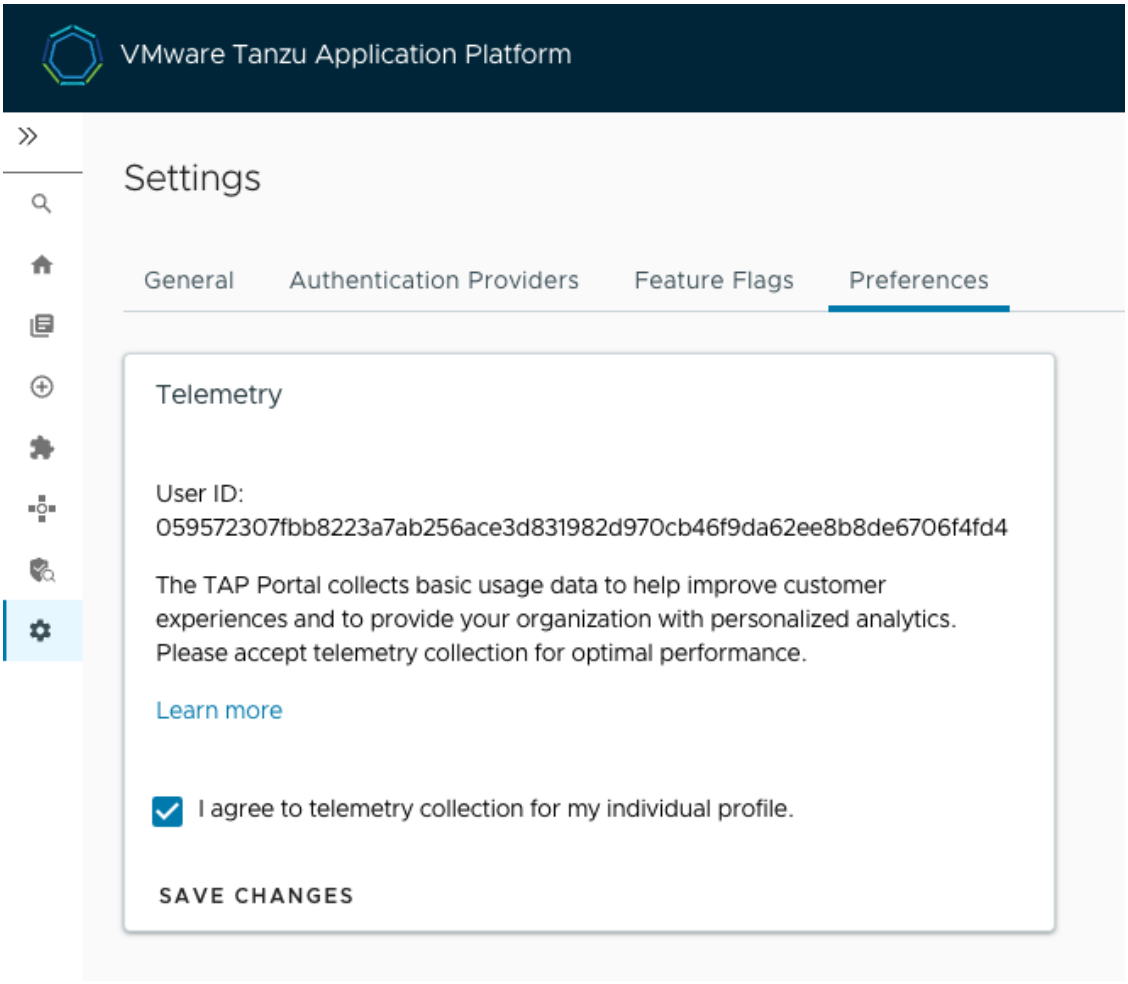
Pendo telemetry is separate from the VMware CEIP telemetry. There is a separate process for opting in or out of the VMware CEIP. For more information, see Opt out of telemetry collection.

Opt in or opt out of Pendo telemetry from Tanzu Developer Portal

After the Pendo telemetry is enabled for the organization, in accordance with VMware policy each user is prompted to agree to participate in the program or decline.



Each individual's preference is stored in Tanzu Developer Portal and can be modified at any time. To change your preferences, go to **Settings** > **Preferences**.



Request to delete your anonymized data

If you no longer want to participate in the program and you want VMware to delete all your anonymized data, please send an email requesting deletion, with your hashed User ID, to tap-pendo@groups.vmware.com.

This enables VMware to identify your anonymized data and delete it in accordance with the applicable regulations.

To find your hashed User ID, go to **Settings** > **Preferences** in Tanzu Developer Portal.

Access an experimental sandbox environment

This topic describes how you can access a hosted experimental Tanzu Application Platform (formerly known as TAP) environment.

VMware provides an experimental developer sandbox that you can use for 8 hours. Your sandbox session takes 2 minutes to start, though it can take up to 25 minutes. The sandbox environment includes the following services:

- Spring Cloud Services: Application Config Service, Spring Cloud Gateway and AppSSO
- Data Services: PostgreSQL, MySQL, RabbitMQ, Kafka and MongoDB

Procedure

1. Create a VMware Customer Connect account and log in to Tanzu Academy.
2. Get started with your developer sandbox in Tanzu Academy.

Note

This is an evaluation environment only, do not use it for production applications or to store sensitive data.

Scale workloads

This topic describes the best practices required to build and deploy workloads at scale.

Sample application reference

The following sections describe the configuration of the different-size applications used to derive scalability best practices.

Small

This is the simplest configuration and consists of the following services and workloads:

- API Gateway workload
- Search workload with in-memory database
- Search processor workload
- Availability workload with in-memory database
- UI workload
- 3 Node RabbitMQ cluster

Medium

This includes all of the services of the small-size application and the following services and workloads:

- Notify workload
- Persistent Database, MySQL or Postgres

Large

This includes all of the services of the medium size application and the following services and workloads:

- Crawler Service
- Redis

Application Configuration

The following section describes the application configuration used to derive the scalability best practices.

Supply chains used:

- Out of the Box Supply Chain with Testing and Scanning (Build+Run)
- Out of the Box Supply Chain Basic + Out of the Box Supply Chain with Testing (Iterate)

Workload type: `web`, `server` + `worker`

Kubernetes Distribution: Azure Kubernetes Service

Number of applications deployed concurrently: 50–55

	CPU	Memory Range	Workload CRs in Iterate	Workload CRs in Build+Run	Workload Transactions per second
Small	500m - 700m	3-5 GB	4	5	4
Medium	700m - 1000m	4-6 GB	NA	6	4
Large	1000m - 1500m	6-8 GB	NA	7	4

Scale configuration for workload deployments

This section describes cluster sizes for deploying a 1K workload.

Node configuration: 4 vCPUs, 16 GB RAM, 120 GB Disk size

Cluster Type / Workload Details	Shared Iterate Cluster	Build Cluster	Run Cluster 1	Run Cluster 2	Run Cluster 3
No. of Namespaces	300	333	333	333	333
Small	300	233	233	233	233
Medium		83	83	83	83
Large		17	17	17	17
No. of Nodes	90	60	135	135	135

Best Practices

The following table describes the resource limit changes that are required for components to support the scale configuration described in the previous table.

Controller/Pod	CPU Requests/Limits	Memory Requests/Limits	Other changes	Build	Run	Iterate	Changes made in
AMR Observer	200 m/1000 m	2 Gi/**3 Gi**	n/a	Yes	Yes	No	`tap-values.yaml`
Build Service/kpack controller	20 m/100 m	**1 Gi/2 Gi**	n/a	Yes	No	Yes	`tap-values.yaml`
Scanning/scan-link	200 m/500 m	**1 Gi/3 Gi**	“SCAN_JOB_TTL_SECONDS_AFTER_FINISHED” - 10800*	Yes	No	No	`tap-values.yaml`
Cartographer	**3000 m/4000 m**	**10 Gi/10 Gi**	In `tap-values.yaml`, change `concurrency` to 25.	Yes	Partial (only CPU)	Yes	`tap-values.yaml`
Cartographer conventions	100 m/100 m	20 Mi/**1.8 Gi**	n/a	Yes	Yes	Yes	`tap-values.yaml`

Controller/Pod	CPU Requests/Limits	Memory Requests/Limits	Other changes	Build	Run	Iterate	Changes made in
Namespace Provisioner	100 m/500 m	**500 Mi/2 Gi**	n/a	Yes	Yes	Yes	`tap-values.yaml`
Cnrs/knative-controller	100 m/1000 m	**1 Gi/3 Gi**	n/a	No	Yes	Yes	`tap-values.yaml`
Cnrs/net-contour	40 m/400 m	**512 Mi/2 Gi**	In `tap-values.yaml`, change Contour envoy workload type from `Daemonset` to `Deployment`.	No	Yes	Yes	`tap-values.yaml`
Cnrs/activator	300 m/1000 m	**5 Gi/5 Gi**	n/a	No	Yes	No	`tap-values.yaml`
Cnrs/autoscaler	100 m/1000 m	**2 Gi/2 Gi**	n/a	No	Yes	No	`tap-values.yaml`
Services Toolkit Controller	100 m/200 m	**750 Mi/1.5 Gi**	n/a	No	Yes	Yes	overlay
tap-telemetry/tap-telemetry-informer	100 m/1000 m	100 Mi/**2 Gi**	n/a	Yes	No	Yes	`tap-values.yaml`
App SSO/App SSO Controller	20 m/500 m	**512 Mi/2 Gi**	n/a	No	Yes	Yes	`tap-values.yaml`
Tekton	n/a	n/a	Update default timeout for Tekton pipeline	Yes	No	Yes	`tap-values.yaml`
App Scanning	n/a	n/a	Update `maxConcurrentScan` to 100	Yes	No	No	`tap-values.yaml`
SpringBoot Conventions	n/a	n/a	Update `livenessProbe`	No	Yes	Yes	`tap-values.yaml`

- CPU is measured in millicores. m = millicore. 1000 millicores = 1 vCPU.
- Memory is measured in Mebibyte and Gibibyte. Mi = Mebibyte. Gi = Gibibyte
- In the CPU Requests/Limits column and the Memory Requests/Limits, the changed values are bolded. Non-bolded values are the default ones set during a Tanzu Application Platform installation.
- In the CPU Requests/Limits column, some of the request and limits values are set equally so that the pod is allocated in a node where the requested limit is available.

* Only when there is an issue with scan pods getting deleted before Cartographer can process it

Example resource limit changes

The following section provides examples of the changes required to the default limits to achieve scalability:

Cartographer

The default Cartographer concurrency limits are:

```
cartographer:
  cartographer:
    concurrency:
      max_workloads: 2
      max_deliveries: 2
      max_runnables: 2
```

Edit `values.yaml` to scale Cartographer concurrency limits. Configure the node with 4 vCPUs, 16 GB RAM, and 120 GB disk size:

```
cartographer:
  cartographer:
    concurrency:
      max_workloads: 25
      max_deliveries: 25
      max_runnables: 25
```

The default resource limits are:

```
resources:
  limits:
    cpu: 1
    memory: 1Gi
  requests:
    cpu: 500m
    memory: 512Mi
```

Edit `values.yaml` to scale resource limit:

```
# build-cluster
cartographer:
  cartographer:
    resources:
      limits:
        cpu: 4
        memory: 10Gi
      requests:
        cpu: 3
        memory: 10Gi

# run-cluster
cartographer:
  cartographer:
    resources:
      limits:
        cpu: 4
        memory: 2Gi
      requests:
        cpu: 3
        memory: 1G
```

Cartographer Conventions

The default resource limits are:

```
resources:
  limits:
    cpu: 100m
    memory: 256Mi
  requests:
    cpu: 100m
    memory: 20Mi
```

Edit `values.yaml` to scale resource limit:

```
cartographer_conventions:
  resources:
    limits:
      memory: 1.8Gi
```

Scan-link-controller

The default resource limits are:

```
resources:
  limits:
    cpu: 250m
    memory: 256Mi
  requests:
    cpu: 100m
    memory: 128Mi
```

Edit `values.yaml` to scale resource limit:

```
scanning:
  resources:
    limits:
      cpu: 500m
      memory: 3Gi
    requests:
      cpu: 200m
      memory: 1Gi
```

AMR Observer

The default resource limits are:

```
resources:
  limits:
    cpu: 500m
    memory: 512Mi
  requests:
    cpu: 100m
    memory: 256Mi
```

Edit `values.yaml` to scale resource limits:

```
amr:
  observer:
    app_limit_cpu: 1000m
    app_limit_memory: 3Gi
    app_req_cpu: 200m
    app_req_memory: 2Gi
```

kpack-controller in Tanzu Build Service

The default resource limits are:

```
resources:
  limits:
    memory: 1Gi
  requests:
    cpu: 20m
    memory: 1Gi
```

Edit `values.yaml` to scale resource limits:

```
buildservice:
  controller:
    resources:
      limits:
        memory: 2Gi
        cpu: 100m
      requests:
        memory: 1Gi
        cpu: 20m
```

Namespace Provisioner

The default resource limits are:

```
resources:
  limits:
    cpu: 500m
    memory: 100Mi
  requests:
    cpu: 100m
    memory: 20Mi
```

Edit `values.yaml` to scale resource limits:

```
namespace_provisioner:
  controller_resources:
    resources:
      limits:
        cpu: 500m
        memory: 2Gi
      requests:
        cpu: 100m
        memory: 500Mi
```

Cloud Native Runtimes Knative Serving

The default resource limits are:

```
resources:
  limits:
    cpu: 1
    memory: 1000Mi
  requests:
    cpu: 100m
    memory: 100Mi
```

Edit `values.yaml` to scale resource limits:

```
cnrs:
  resource_management:
  - name: "controller"
```

```
    limits:
      cpu: 1000m
      memory: 3Gi
    requests:
      cpu: 100m
      memory: 1Gi
```

net-contour controller

Change deployment type from Daemonset to Deployment.

```
contour:
  envoy:
    workload:
      type: Deployment
      replicas: 3
```

The default resource limits are:

```
resources:
  limits:
    cpu: 400m
    memory: 400Mi
  requests:
    cpu: 40m
    memory: 40Mi
```

Edit `values.yaml` to scale resource limits:

```
cnrs:
  resource_management:
  - name: "net-contour-controller"
    limits:
      cpu: 400m
      memory: 2Gi
    requests:
      cpu: 40m
      memory: 512Mi
```

Autoscaler

The default resource limits are:

```
resources:
  limits:
    cpu: 1
    memory: 1000Mi
  requests:
    cpu: 100m
    memory: 100Mi
```

Edit `values.yaml` to scale resource limits:

```
cnrs:
  resource_management:
  - name: "autoscaler"
    limits:
      cpu: 1000m
      memory: 2Gi
    requests:
      cpu: 100m
      memory: 2Gi
```

Activator

The default resource limits are:

```
resources:
  limits:
    cpu: 1
    memory: 600Mi
  requests:
    cpu: 300m
    memory: 60Mi
```

Edit `values.yaml` to scale resource limits:

```
cnrs:
  resource_management:
  - name: "activator"
    limits:
      cpu: 1000m
      memory: 5Gi
    requests:
      cpu: 300m
      memory: 5Gi
```

Tanzu Application Platform Telemetry

The default resource limits are:

```
resources:
  limits:
    cpu: 1
    memory: 1000Mi
  requests:
    cpu: 100m
    memory: 100Mi
```

Edit `values.yaml` to scale resource limits:

```
tap_telemetry:
  limit_memory: 2Gi
```

Application Single Sign-On

The default resource limits are:

```
resources:
  limits:
    cpu: 500m
    memory: 5000Mi
  requests:
    cpu: 20m
    memory: 100Mi
```

Edit `values.yaml` to scale resource limits:

```
appsso:
  resources:
    limits:
      memory: 1Gi
    requests:
      memory: 512Mi
```

Services Toolkit Controller

The default resource limits are:

```
resources:
  limits:
    cpu: 200m
    memory: 500Mi
  requests:
    cpu: 100m
    memory: 100Mi
```

Edit `values.yaml` to scale resource limits:

```
services_toolkit:
  controller:
    resources:
      requests:
        cpu: "200m"
        memory: "750Mi"
      limits:
        cpu: "200m"
        memory: "1.5Gi"
```

Services Toolkit Resource Claims API Server

The default resource limits are:

```
resources:
  limits:
    cpu: 120m
    memory: 500Mi
  requests:
    cpu: 100m
    memory: 100Mi
```

Edit `values.yaml` to scale resource limits:

```
services_toolkit:
  resource_claims_apiserver:
    resources:
      requests:
        cpu: "200m"
        memory: "750Mi"
      limits:
        cpu: "200m"
        memory: "1.5Gi"
```

FluxCD Source Controller

The default resource limits are:

```
resources:
  limits:
    cpu: 1000m
    memory: 1Gi
  requests:
    cpu: 50m
    memory: 64Mi
```

To change the resource limits for FluxCD Source controller, follow the procedure in Configure resource Limits.

Tekton Pipeline default timeout

The default resource limits are:

```
tekton_pipelines:
  defaults:
    timeout_minutes: "60"
```

Edit `values.yaml` to scale resource limits:

```
tekton_pipelines:
  defaults:
    timeout_minutes: "120"
```

App Scanning maximum concurrent scan (Scan 2.0)

The default resource limits are:

```
app_scanning:
  scans:
    maxConcurrentScans: 10
```

Edit `values.yaml` to scale resource limits:

```
app_scanning:
  scans:
    maxConcurrentScans: 100
```

For more information, see Supply Chain Security Tools - Scan 2.0.

Spring Boot Conventions

The default resource limits are:

```
springboot_conventions:
  livenessProbe:
    initialDelaySeconds: 0
```

Edit `values.yaml` to scale resource limits:

```
springboot_conventions:
  livenessProbe:
    initialDelaySeconds: 45
```

kube-dns resource limit changes for GKE clusters

The default memory limit for kube-dns pods is set to 210 Mi. VMware recommends that you set it to 1 Gi. For instructions, see the GKE documentation.

Overview of security and compliance in Tanzu Application Platform

Security is a primary focus for Tanzu Application Platform (commonly known as TAP).

This section describes how to:

Secure exposed ingress endpoints in Tanzu Application Platform

Plan ingress certificates inventory in Tanzu Application Platform

Use custom CA certificates in Tanzu Application Platform

Assess Tanzu Application Platform against the NIST 800-53 Moderate Assessment

Harden Tanzu Application Platform

See also:

External Secrets Operator

Secure exposed ingress endpoints in Tanzu Application Platform

This topic tells you how to secure exposed ingress endpoints with TLS in Tanzu Application Platform (commonly known as TAP).

Tanzu Application Platform exposes ingress endpoints so that:

- Platform operators and application developers can interact with the platform.
- End users can interact with applications running on the platform.

There are two ways of configuring ingress certificates to secure endpoints with TLS, such as `https://`:

- Shared ingress issuer
- Component-level configuration

Shared ingress issuer

Ingress communication uses TLS by default. VMware recommends a shared ingress issuer for issuing ingress certificates on Tanzu Application Platform.

The shared ingress issuer is an on-platform representation of a certificate authority. It provides a method to set up TLS for the entire platform. The shared ingress issuer issues ingress certificates for all participating components.

Default self-signed ingress issuer

By default, Tanzu Application Platform installs and uses a self-signed CA ingress issuer for all components. The default ingress issuer is a self-signed `cert-manager.io/v1/ClusterIssuer` provided by the cert-manager package.

The ingress issuer is designated by the Tanzu Application Platform configuration value `shared.ingress_issuer`. It defaults to `tap-ingress-selfsigned`.

Caution

The default ingress issuer is appropriate for testing and evaluation. VMware recommends that you replace the default self-signed issuer with your own issuer.

Default self-signed issuer limitations

The default ingress issuer represents a self-signed certificate authority. This is not problematic as far as security is concerned, however, it is not included in any trust chain configured. As a result, nothing trusts the default ingress issuer implicitly, not even Tanzu Application Platform components. While the issued certificates are valid in principle, they are rejected, for example, by your browser. Furthermore, some interactions between components are not functional by default.

Default self-signed issuer prerequisites

To use the Tanzu Application Platform ingress issuer, your certificate authority must be representable by a cert-manager `ClusterIssuer`. You need one of the following:

- Your own CA certificate
- Your CA is an ACME, Venafi, or Vault-based issuer, for example, LetsEncrypt
- Your CA can be represented by an external cert-manager `ClusterIssuer`.

Without one of the above, you cannot use the ingress issuer, but you can still configure TLS for components. For more information, see Ingress certificates inventory.

Important

If `cert-manager.tanzu.vmware.com` is excluded from the installation, then `tap-ingress-selfsigned` is not installed either. In this case, bring your own ingress issuer.

Trust the default, self-signed issuer

You can trust the default ingress issuer by including `tap-ingress-selfsigned`'s certificate in the Tanzu Application Platform trusted CA certificates and your device's certificate chain.

Caution

This approach is discouraged. Instead, replace the default ingress issuer.

1. Obtain `tap-ingress-selfsigned`'s PEM-encoded certificate

   ```
   kubectl get secret \
     tap-ingress-selfsigned-root-ca \
     --namespace cert-manager \
     --output go-template='{{ index .data "tls.crt" | base64decode }}'
   ```

2. Add the certificate to custom CA certificates by appending it to `shared.ca_cert_data` and applying Tanzu Application Platform's installation values.

3. Add the certificate to your device's trust chain. The trust chain will vary depending on your operating system and privileges.

Replace the default ingress issuer

Tanzu Application Platform's default ingress issuer can be replaced by any other cert-manager-compliant ClusterIssuer.

To replace the default ingress issuer:

Custom CA
Complete the following steps:

Prerequisites

You need your own CA certificates and private key for this.

1. Create your `ClusterIssuer`

   Create a `Secret` and `ClusterIssuer` which represent your CA on the platform:

   ```
   ---
   apiVersion: v1
   kind: Secret
   type: kubernetes.io/tls
   metadata:
     name: my-company-ca
     namespace: cert-manager
   stringData:
     tls.crt: #! your CA's PEM-encoded certificate
     tls.key: #! your CA's PEM-encoded private key

   ---
   apiVersion: cert-manager.io/v1
   kind: ClusterIssuer
   metadata:
     name: my-company
   spec:
     ca:
       secretName: my-company-ca
   ```

2. Set `shared.ingress_issuer` to the name of your issuer:

   ```
   #! my-tap-values.yaml
   #! ...
   shared:
     ingress_issuer: my-company-ca
   #! ...
   ```

3. Apply the Tanzu Application Platform installation values file.

   When the configuration is applied, components obtain certificates from the new issuer and serve them.

LetsEncrypt production
Complete the following steps

Prerequisites

- Public CAs, like LetsEncrypt, record signed certificates in publicly-available certificate logs for the purpose of certificate transparency. Ensure that you are OK with this before using LetsEncrypt.
- LetsEncrypt's production API has rate limits.

- LetsEncrypt requires your `shared.ingress_domain` to be accessible from the Internet.
- Depending on your setup, you might need to adjust .spec.acme.solvers
- Replace `.spec.acme.email` with the email that should receive notices for certificates from LetsEncrypt.

Caution

ACME HTTP01 challenges can fail under certain conditions. For more information, see ACME challenges.

1. Create a `ClusterIssuer` for Let's Encrypts production API:

```
---
apiVersion: cert-manager.io/v1
kind: ClusterIssuer
metadata:
  name: letsencrypt-production
spec:
  acme:
    email: certificate-notices@my-company.com
    privateKeySecretRef:
      name: letsencrypt-production
    server: https://acme-v02.api.letsencrypt.org/directory
    solvers:
      - http01:
          ingress:
            class: contour
```

2. Set `shared.ingress_issuer` to the name of your issuer

```
#! my-tap-values.yaml
#! ...
shared:
  ingress_issuer: letsencrypt-production
#! ...
```

3. Apply Tanzu Application Platform installation values

   When the configuration is applied, components obtain certificates from the new issuer and serve them.

LetsEncrypt staging

Complete the following steps

Prerequisites

- Public CAs - like LetsEncrypt - record signed certificates in publicly-available certificate logs for the purpose of certificate transparency. Ensure that you are OK with this before using LetsEncrypt.
- LetsEncrypt's staging API is not a publicly-trusted CA. You have to add its certificate to your devices trust chain and Tanzu Application Platform's custom CA certificates.
- LetsEncrypt requires your `shared.ingress_domain` to be accessible from the Internet.
- Depending on your setup you might need to adjust .spec.acme.solvers.
- Replace `.spec.acme.email` with the email that should receive notices for certificates from LetsEncrypt.

Caution

ACME HTTP01 challenges can fail under certain conditions. For more information, see ACME challenges.

1. Create a `ClusterIssuer` for Let's Encrypts staging API:

```
---
apiVersion: cert-manager.io/v1
kind: ClusterIssuer
metadata:
  name: letsencrypt-staging
spec:
  acme:
    email: certificate-notices@my-company.com
    privateKeySecretRef:
      name: letsencrypt-production
    server: https://acme-staging-v02.api.letsencrypt.org/directory
    solvers:
      - http01:
          ingress:
            class: contour
```

2. Set `shared.ingress_issuer` to the name of your issuer

```
#! my-tap-values.yaml
#! ...
shared:
  ingress_issuer: letsencrypt-staging
#! ...
```

3. Apply Tanzu Application Platform installation values

   After the configuration is applied, components obtain certificates from the new issuer and serve them.

Other

Complete the following steps

You can use any other cert-manager-supported `ClusterIssuer` as an ingress issuer for Tanzu Application Platform.

cert-manager supports a host of in-tree and out-of-tree issuers. See cert-manager's documentation of issuers.

1. Set `shared.ingress_issuer` to the name of your issuer

```
#! my-tap-values.yaml
#! ...
shared:
  ingress_issuer: my-company-ca
#! ...
```

2. Apply Tanzu Application Platform's installation values

   After the configuration is applied, components obtain certificates from the new issuer and serve them.

There are many ways and tools to assert that new certificates are issued and served. It is best to connect to one of the ingress endpoints and inspect the certificate it serves.

The `openssl` command-line utility is available on most operating systems. The following command retrieves the certificate from an ingress endpoint and shows its text representation:

```
# replace tap.example.com with your Tanzu Application Platform installation's ingress
domain
openssl s_client -showcerts -servername tap-gui.tap.example.com -connect tap-gui.tap.e
xample.com:443 <<< Q | openssl x509 -text -noout
```

Alternatively, use a browser to navigate to the ingress endpoint and click the lock icon in the navigation bar to inspect the certificate.

Component-level configuration

In some situations, depending on prerequisites, the shared ingress issuer is not the right choice. You can override configuration of TLS and certificates per component. A component's ingress and TLS configuration take precedence over the shared ingress issuer.

For a list of components with ingress and how to customize them, see Plan Ingress certificates inventory in Tanzu Application Platform.

Tanzu Application Platform also has limited support for wildcard certificates. For more information, see Wildcards.

Deactivate TLS for ingress

While VMware does not recommend it, you can deactivate the ingress issuer by setting `shared.ingress_issuer: ""`.

Plan ingress certificates inventory in Tanzu Application Platform

This topic tells you how to plan for TLS certificates in Tanzu Application Platform (commonly known as TAP).

The effective number of ingress endpoints can vary widely, depending on the installation profile, excluded packages, and end-user-facing resources such as `Workload`, and `AuthServer`. As a result, the number of TLS certificates is not fixed but is a function of the platform's configuration and tenancy.

Ingress refers to any resource that facilitates ingress, for example, core `Ingress` and Contour's `HTTPProxy`.

Wildcards

You can use wildcard certificates but Tanzu Application Platform does not offer support. Wildcard certificates require component-level configuration.

You can use a mixed approach for configuring TLS for components. For example, use a shared ingress issuer, but override TLS configuration for select components while using wildcard certificates for some.

When using wildcard certificates the approach differs between components that have a fixed set of ingress endpoints and those that have a variable set of ingress endpoints:

Components with ingress endpoints can have a fixed or variable number of ingress endpoints:

- Components with a fixed set of ingress endpoints can receive a reference to the wildcard certificate's `Secret` and an ingress domain, for example, Tanzu Developer Portal.
- Components with a variable set of ingress endpoints usually offer Kubernetes APIs that create ingress resources. These components allow configuration of domain templating so that wildcard certificates can be used, for example, Cloud Native Runtimes and Application Single Sign-On.

Ingress support for components

Use the following table to help with the planning and accounting of TLS certificates. For a full list of components and the profiles supported for each component, see About Tanzu Application Platform components and profiles.

Package name	Ingress purpose	Supports ingress issuer	Supports wildcards	Number of ingress	SANs*
api-portal.tanzu.vmware.com	Serves the API portal	No	Yes	`1`	`api-portal.INGRESS-DOMAIN`
cnrs.tanzu.vmware.com	Instances of Knative's `Service` have ingress	Yes	Yes	`Number of Services`	SANs depend on the component's `domain_template`
metadata-store.apps.tanzu.vmware.com	Serves the Supply Chain Security Tools store	Yes	Yes	`1`	`metadata-store.INGRESS-DOMAIN`
spring-cloud-gateway.tanzu.vmware.com	Instances of SpringCloudGateway have ingress	No	Yes	`Number of SpringCloudGateways`	See Using an Ingress Resource in the Spring Cloud Gateway documentation
sso.apps.tanzu.vmware.com	Instances of AuthServer have ingress	Yes	Yes	`Number of AuthServers`	Depends on the component's `domain_template`
tap-gui.tanzu.vmware.com	Serves the platform-internal developer and service portal	Yes	Yes	`1`	`tap-gui.INGRESS-DOMAIN`

*The SANs is configurable for components in the following two ways:

- Components that install a single ingress resource in the form of `COMPONENT.DOMAIN-NAME`, such as Tanzu Developer Portal
- Components that install an ingress resource per API instance that gets templated from a `domain_template` feeding `DOMAIN-NAME`, such as `cnrs.tanzu.vmware.com` and `sso.apps.tanzu.vmware.com`

Use custom CA certificates in Tanzu Application Platform

This topic tells you about configuring custom CA certificates in Tanzu Application Platform (commonly known as TAP).

For egress communication, you can establish trust for custom CA certificates. This is helpful if any Tanzu Application Platforms components are connecting to services that serve certificates issued by private certificate authorities.

The `shared.ca_cert_data` installation value can contain a PEM-encoded CA bundle. Each component then trusts the CAs contained in the bundle.

You can also configure trust per component by providing a CA bundle in the component's installation values. The component then trusts those CAs and the CAs configured in `shared.ca_cert_data`. For more information, see components.

For example:

```
#! my-tap-values.yaml

shared:
  ca_cert_data: |
    Corporate CA 1
    -----BEGIN CERTIFICATE-----
    MIIFmDCCA4....
    -----END CERTIFICATE-----
    Corporate CA 2
    -----BEGIN CERTIFICATE-----
    MIIFkzCCA3....
    -----END CERTIFICATE-----
```

Some Tanzu Application Platform components do not support the `shared.ca_cert_data` feature, such as Flux CD, Tekton, and the External Secrets operator. Any custom CA certificates must be configured directly by those components.

For information about using Git with a custom CA in supply chains and configuring the `caFile` parameter, see Git Authentication.

Assess Tanzu Application Platform against the NIST 800-53 Moderate Assessment

This topic provides you with an assessment of Tanzu Application Platform (commonly known as TAP) against the NIST SP 800-53 Revision 4 Moderate baseline controls. This translates to FISMA Moderate and CNSSI 1253 Mod/Mod/Mod for use in US Federal systems accreditation.

The Moderate baseline applies to only technical controls. Organizational policy controls, physical security, media policies, and similar are excluded as they are not applicable to Tanzu Application Platform. These excluded controls are still relevant to the system at large and must be inherited from existing accreditations or otherwise addressed.

The initial iteration of this assessment delineates responsible parties. Incremental updates will add more details about implementation and updates to 800-53 Revision 5.

Name	Title	Responsible Party	Notes
AC-2(1)	Automated System Account Management	Customer	Implemented on customer identity store. The customer must employ automated mechanisms to support the management of information system accounts used to access their Tanzu Application Platform installation.
AC-2(2)	Removal of Temporary / Emergency Accounts	Customer	Implemented on customer identity store. If the customer chooses to use temporary or emergency accounts, they must ensure that the system automatically deactivates or removes the account following an organization-defined time period.
AC-2(3)	Deactivate Inactive Accounts	Customer	Implemented on customer identity store. The customer must automatically deactivate inactive accounts used to access their Tanzu Application Platform installation following an organization-defined time period of inactivity.

Name	Title	Responsible Party	Notes
AC-2(4)	Automated Audit Actions	Customer	Implemented on customer identity store. The customer must automatically audit account creation, modification, enabling, deactivating, and removal actions associated with accounts used to access their Tanzu Application Platform installation and must notify an organization-defined personnel or role.
AC-3	Access Enforcement	Customer	The customer must federate their IdP with Tanzu Application Platform to enforce approved access authorizations to their Tanzu Application Platform installation.
AC-4	Information Flow Enforcement	Customer	The customer is responsible for enforcing approved authorizations for controlling the flow of information between Tanzu Application Platform and interconnected systems, based on organization-defined information flow control policies, for example, a SIEM. Tanzu Application Platform does not restrict intra-service or inter-system communication. Future versions of Tanzu Application Platform will include this feature using service mesh architecture or similar methods.
AC-6	Least Privilege	Shared	The customer is responsible for enforcing least privilege by ensuring Tanzu Application Platform users have the minimum permissions necessary to perform their job function. Tanzu Application Platform is responsible for providing RBAC functionality to enforce least privilege.
AC-6(1)	Authorize Access to Security Functions	Shared	The customer is responsible for explicitly authorizing access to organization-defined security functions and security-relevant information as it relates to their Tanzu Application Platform installation. Tanzu Application Platform is responsible for providing the RBAC functionality necessary to restrict which users can access security functions and security-related information.
AC-6(5)	Privileged Accounts	Shared	The customer must restrict privileged Tanzu Application Platform accounts to organization-defined personnel or roles. Tanzu Application Platform is responsible for providing the RBAC functionality for customers to restrict privileged Tanzu Application Platform accounts to organization-defined personnel or roles.
AC-6(9)	Auditing Use of Privileged Functions	Shared	The customer is responsible for configuring Tanzu Application Platform and underlying Kubernetes to send log streams to their SIEM tool for log analysis to be capable of auditing the execution of privileged functions. Tanzu Application Platform is responsible for generating logs pertaining to the execution of privileged functions that can be ingested by the customer SIEM tool for analysis.
AC-6(10)	Prohibit Non-Privileged Users from Executing Privileged Functions	Tanzu Application Platform	This functionality is inherent to Tanzu Application Platform/Kubernetes RBAC and can't be configured otherwise.
AC-7 AC-7a AC-7b	Unsuccessful Logon Attempts	Customer	Implemented on customer identity provider. The customer is responsible for configuring their IdP to enforce a limit of consecutive invalid logon attempts by a user during an organization-defined time period which locks the user's account for an organization-defined time period, or until released by an administrator.

Name	Title	Responsible Party	Notes
AC-8 AC-8a AC-8a.1 AC-8a.2 AC-8a.3 AC-8a.4 AC-8b AC-8c AC-8c.1 AC-8c.2 AC-8c.3	System Use Notification	Customer	Implemented on customer identity provider. Customer must configure their IdP to display the system use notification banner before login.
AC-11 AC-11a AC-11b	Session Lock	Customer	The customer must configure sessions locks on user workstations used to access their Tanzu Application Platform installation. Tanzu Application Platform does not have a concept of session locks and relies on sessions locks applied by the user's workstation. Tanzu Application Platform provides logout functionality in place of session locking.
AC-11(1)	Pattern-Hiding Displays	Customer	The customer must configure sessions locks on user workstations used to access their Tanzu Application Platform installation. This includes hiding the user's private session with a publicly available image. Tanzu Application Platform does not have a concept of session locks and relies on sessions locks applied by the user's workstation. Tanzu Application Platform provides logout functionality in place of session locking.
AC-12	Session Termination	Shared	Implemented on customer identity provider. The customer is responsible for configuring IdP token TTL and refresh policies that apply to Tanzu Application Platform sessions. Tanzu Application Platform enforces token policies and cannot be configured otherwise.
AC-14 AC-14a	Permitted Actions Without Identification or Authentication	Shared	The customer is responsible for identifying organization-defined user actions that can be performed on the information system without identification or authentication consistent with organizational missions/business functions. For production installations, Tanzu Developer Portal must be configured with OIDC authentication and guest access deactivated.
AC-17(1)	Automated Monitoring / Control	Customer	"Remote Access" is defined as outside-the-org endpoints like remote workers over VPN. This is outside the scope of Tanzu Application Platform. The customer is responsible for all aspects regarding "remote access" to Tanzu Application Platform.
AC-17(2)	Protection of Confidentiality / Integrity Using Encryption	Customer	"Remote Access" is defined as outside-the-org endpoints like remote workers over VPN. This is outside the scope of Tanzu Application Platform. The customer is responsible for implementing cryptographic mechanisms to protect the confidentiality and integrity of "remote access" sessions to Tanzu Application Platform.
AC-17(3)	Managed Access Control Points	Customer	"Remote Access" is defined as outside-the-org endpoints like remote workers over VPN. This is outside the scope of Tanzu Application Platform. The customer is responsible for routing all "remote accesses" to Tanzu Application Platform through an organization-defined number of managed network access control points.
AC-19 AC-19 AC-19b	Access Control for Mobile Devices	Customer	The customer is responsible for all aspects regarding mobile devices which grant access to Tanzu Application Platform.
AU-3	Content of Audit Records	Tanzu Application Platform	The Tanzu Application Platform application must be capable of generating audit logs that contain the minimum content required by the customer consuming the application.

Name	Title	Responsible Party	Notes
AU-3(1)	Additional Audit Information	Customer	Implemented on customer SIEM. The customer is responsible for parsing Tanzu Application Platform logs on their SIEM to extract organization-defined extra information.
AU-4	Audit Storage Capacity	Customer	Implemented on customer Kubernetes. Tanzu Application Platform logs are all captured by Kubernetes logging. The customer is responsible for configuring their Kubernetes hosts with record storage capacity to ensure that there is adequate storage of logs generated by Tanzu Application Platform clusters.
AU-5 AU-5a AU-5b	Response to Audit Processing Failures	Customer	Implemented on customer Kubernetes. Tanzu Application Platform audit records are collected and managed by Kubernetes and are out of Tanzu Application Platform scope. The customer is responsible for configuring their Kubernetes hosts to account for audit processing failures and to alert the appropriate personnel responsible to take appropriate action.
AU-7 AU-7a AU-7b	Audit Reduction and Report Generation	Customer	Implemented on customer Kubernetes and SIEM Tanzu Application Platform audit records are collected and managed by Kubernetes. The customer is responsible for ensuring that Kubernetes ships Tanzu Application Platform audit records to a central SIEM for review and analysis.
AU-7(1)	Automatic Processing	Customer	Implemented on customer Kubernetes and SIEM Tanzu Application Platform audit records are collected and managed by Kubernetes. The customer is responsible for ensuring that Kubernetes ships Tanzu Application Platform audit records to a central SIEM for review and analysis.
AU-8 AU-8a AU-8b	Time Stamps	Tanzu Application Platform	Tanzu Application Platform components pull their system time from the container OS and the Kubernetes host and cannot be configured otherwise. Tanzu Application Platform components log statements include UTC timestamps and cannot be configured otherwise.
AU-8(1) AU-8(1)(a) AU-8(1)(b)	Synchronization With Authoritative Time Source	Customer	The customer is responsible for configuring authoritative time sources on K8 clusters.
AU-9	Protection of Audit Information	Customer	Tanzu Application Platform audit records are collected and managed by Kubernetes. The customer is responsible for protecting Kubernetes and Kubernetes logging configurations from unauthorized access, modification, and deletion.
AU-12 AU-12a AU-12b AU-12c	Audit Generation	Shared	Tanzu Application Platform audit records are collected and managed by Kubernetes. The customer is responsible for ensuring that Kubernetes ships Tanzu Application Platform audit records to a central SIEM for review and analysis. Tanzu Application Platform cannot be configured to audit specific information. Tanzu Application Platform logs verbosely and lets the customer filter out what is relevant to them using their SIEM. Tanzu Application Platform logging cannot be deactivated.
CM-7 CM-7a CM-7b	Least Functionality	Shared	The customer is responsible for configuring Tanzu Application Platform to provide only essential capabilities. Tanzu Application Platform is responsible for providing customers with the capability to deactivate non-essential features not required by the customer. The customer must restrict the use of functions, ports, protocols, and services for the Tanzu Application Platform installation. Tanzu Application Platform is responsible for ensuring that functions, ports, protocols, and services are limited to those explicitly required for the application to operate.

Name	Title	Responsible Party	Notes
CM-7(2)	Prevent Program Execution	Tanzu Application Platform	As an extension of CM-7, Least Functionality, this control is a responsibility of Tanzu Application Platform. Tanzu Application Platform only consists of containers with purposeful services with no extra programs running or bloat. This cannot be configured by the customer.
CM-7(4) (b)	Unauthorized Software/Denylisting	Tanzu Application Platform	Tanzu Application Platform service containers do not implement a deny-by-exception policy to prohibit the execution of unauthorized software programs. Tanzu Application Platform service containers are built to provide stripped-down services and do not include extra programs or bloat. Tanzu Application Platform can provide a SBOM to compare against customer organization policies on disallowed software.
IA-2	Identification and Authentication (Organizational Users)	Shared	The customer is responsible for configuring Tanzu Application Platform to use their IdP which is capable of uniquely identifying and authenticating organizational users. Tanzu Application Platform is responsible for providing customers with the capability to integrate their IdP to allow Tanzu Application Platform to uniquely identify organizational users.
IA-2(1)	Network Access to Privileged Accounts	Customer	Implemented on customer identity provider. The customer is responsible for implementing multifactor authentication on their IdP for network access to privileged accounts.
IA-2(2)	Network Access to Non-Privileged Accounts	Customer	Implemented on customer identity provider. The customer is responsible for implementing multifactor authentication on their IdP for network access to non-privileged accounts.
IA-2(3)	Local Access to Privileged Accounts	N/A	Tanzu Application Platform does not use local accounts. All access occurs over a network connection.
IA-2(8)	Network Access to Privileged Accounts - Replay Resistant	Tanzu Application Platform	Tanzu Application Platform is responsible for ensuring that all connections to the customer IdP are over TLS 1.2+.
IA-2(11)	Remote Access - Separate Device	Customer	The customer is responsible for all aspects of MFA and MFA devices used to authenticate to their Tanzu Application Platform installation, including using remote access.
IA-2(12)	Acceptance of Piv Credentials	Customer	Implemented on customer identity provider. The customer is responsible for implementing CAC/PIV credentials with their IdP.
IA-3	Device Identification and Authentication	Customer	The customer is responsible for uniquely identifying and authenticating organization-defined specific and/or types of devices before establishing a local, remote, or network connection.
IA-4e	Identifier Management	Customer	Implemented on customer identity provider. The customer is responsible for configuring IdP token TTL and refresh policies that apply to Tanzu Application Platform sessions. Tanzu Application Platform enforces token policies and cannot be configured otherwise.

Name	Title	Responsible Party	Notes
IA-5(1) IA-5(1)(a) IA-5(1)(b) IA-5(1)(c) IA-5(1)(d) IA-5(1)(e) IA-5(1)(f)	Password-Based Authentication	Customer	Implemented on customer identity store. The customer is responsible for all aspects of password-based authentication to their IdP, using their identity store. Tanzu Application Platform does not employ password-based authentication itself.
IA-5(2) IA-5(2)(a) IA-5(2)(b) IA-5(2)(c) IA-5(2)(d)	PKI-Based Authentication	Customer	Implemented on customer identity provider. The customer is responsible for all aspects of PKI-based authentication on the IdP used to access their Tanzu Application Platform installation.
IA-5(11)	Hardware Token-Based Authentication	Customer	The customer is responsible for ensuring hardware token-based authentication employs mechanisms that satisfy organization-defined token quality requirements.
IA-6	Authenticator Feedback	Customer	Implemented on customer identity provider. The customer is responsible for ensuring their IdP obscures feedback of authentication information during the authentication process.
IA-7	Cryptographic Module Authentication	Customer	Implemented on customer identity provider. The customer is responsible for ensuring their IdP implements FIPS 140-2 validated cryptographic modules.
IA-8	Identification and Authentication(Non-Organizational Users)	Customer	Implemented on customer identity provider. The customer is responsible for ensuring that their IdP uniquely identifies and authenticates non-organizational Tanzu Application Platform users, or processes acting on behalf of non-organizational users.
IA-8(1)	Acceptance of Piv Credentials from Other Agencies	Customer	Implemented on customer identity provider. The customer is responsible for configuring their IdP to accept and electronically verify Personal Identity Verification(PIV) credentials from other federal agencies.
IA-8(2)	Acceptance of Third-Party Credentials	Customer	Implemented on customer identity provider. The customer is responsible for configuring their IdP to accept only FICAM-approved third-party credentials.
IA-8(3)	Use of FICAM-Approved Products	Customer	Implemented on customer identity provider. The customer is responsible for employing only FICAM-approved information system components on their IdP to accept third-party credentials.
IA-8(4)	Use of FICAM-Issued Profiles	Customer	Implemented on customer identity provider. The customer is responsible for ensuring their IdP conforms to FICAM-issued profiles.
SC-2	Application Partitioning	Tanzu Application Platform	Tanzu Application Platform does not isolate user and management functionality on separate network interfaces, instances, CPUs, or similar. Tanzu Application Platform relies on different roles and Kubernetes RBAC to keep user and management functionality distinct.
SC-4	Information in Shared Resources	Tanzu Application Platform	Tanzu Application Platform creates dedicated Kubernetes namespaces upon deployment. Kubernetes namespaces prevent unauthorized and unintended information transfer using shared system resources.

Name	Title	Responsible Party	Notes
SC-5	Denial of Service Protection	Customer	The customer is responsible for ensuring that organizational DoS protections at the network layer include the Tanzu Application Platform installation.
SC-7 SC-7a SC-7b SC-7c	Boundary Protection	Customer	The customer is responsible for the configuration and management of boundary protection devices.
SC-7(4)(c)	External Telecommunications Services	Customer	The customer is responsible for external telecommunication services used to establish connections to their Tanzu Application Platform installation.
SC-7(5)	Deny by Default / Allow by Exception	Shared	Tanzu Application Platform does not implement “deny by default” network policies. This might be mitigated by network-level access controls configured by the customer.
SC-7(7)	Prevent Split Tunneling for Remote Devices	Customer	The customer is responsible for all configuration of remote devices used to access Tanzu Application Platform.
SC-8	Transmission Confidentiality and Integrity	Tanzu Application Platform	Tanzu Application Platform is responsible for ensuring all communications occur over TLS 1.2+.
SC-8(1)	Cryptographic or Alternate Physical Protection	Tanzu Application Platform	Tanzu Application Platform is responsible for ensuring all communications occur over TLS 1.2+.
SC-10	Network Disconnect	Tanzu Application Platform	Tanzu Application Platform tears down TCP connections and deallocates system resources following the expiration of a session token and cannot be configured otherwise.
SC-12	Cryptographic Key Establishment and Management	Tanzu Application Platform	Tanzu Application Platform is responsible for providing customers with the ability to manage trust stores.
SC-13	Cryptographic Protection	Tanzu Application Platform	Tanzu Application Platform is responsible for implementing FIPS 140 validated cryptographic modules and providing the customer with a means to enable “FIPS Mode”.
SC-21	Secure Name / Address Resolution Service (Recursive or Caching Resolver)	Customer	Tanzu Application Platform inherits the DNSSEC capabilities of the organization resolvers it is configured to use. The customer is responsible for configuring the Tanzu Application Platform and Kubernetes infrastructure to use DNSSEC-capable resolvers.
SC-23	Session Authenticity	Tanzu Application Platform	Tanzu Application Platform is responsible for ensuring all communications occur over TLS 1.2+.

Name	Title	Responsible Party	Notes
SC-28	Protection of Information at Rest	Customer	Tanzu Application Platform does not natively provide encryption for data at rest, but instead relies on the underlying Kubernetes persistent volumes for appropriate cryptographic protections. The customer is responsible for deploying Tanzu Application Platform to Kubernetes with persistent volumes for appropriate cryptographic protections.
SC-39	Process Isolation	Tanzu Application Platform	Tanzu Application Platform container OS enforces the use of separate execution domains for each executing process and cannot be configured otherwise. The underlying Kubernetes host isolates each container from the other.
SI-2c	Flaw Remediation	Tanzu Application Platform	The customer is responsible for keeping the Tanzu Application Platform installation up to date, to within org-defined standards. Tanzu Application Platform does not automatically update itself.
SI-3(2)	Automatic Updates	N/A	Tanzu Application Platform does not include malicious code protection mechanisms therefore automatic update to such mechanisms does not apply.
SI-7(1)	Integrity Checks	Tanzu Application Platform	Tanzu Application Platform performs a hash check when images are downloaded, and a cryptographic signature validation at runtime. This cannot be configured otherwise.
SI-10	Information Input Validation	Tanzu Application Platform	Tanzu Application Platform is responsible for performing input validation of user-supplied input to Tanzu Application Platform.
SI-11 SI-11a SI-11b	Error Handling	Tanzu Application Platform	Tanzu Application Platform limits error message verbosity but does display errors to users. Given the development/coding nature of Tanzu Application Platform, deployment errors and similar must be raised to the user so they can be corrected.
SI-16	Memory Protection	Tanzu Application Platform	Tanzu Application Platform container OS protects its memory from unauthorized code execution and cannot be configured otherwise. The underlying Kubernetes host also isolates container memory pages.

Harden Tanzu Application Platform

This topic provides you with VMware recommendations on how to install and configure Tanzu Application Platform (commonly known as TAP) so that it to complies with NIST Publication 800-53.

Configuring your Tanzu Application Platform installation to this standard does not ensure approval as there are multiple organizational requirements and deviations that a platform team can make during installation and configuration.

Tanzu Application Platform is deployed on Kubernetes and relies on the Kubernetes platform being hardened in a shared responsibility model. For information about hardening Kubernetes, see:

- NSA/CISA Cybersecurity Technical Report
- NIST Kubernetes STIG Checklist
- CIS Kubernetes Benchmark

Identity and access management

To provide an audit trail of what a user does in a system, it is important to configure Tanzu Application Platform so that the identity of a user is known. When installing and configuring Tanzu Application Platform, there are several areas where user identity configuration must be considered. Tanzu Application Platform has three different areas where users have identities.

1. Tanzu Developer Portal
2. Tanzu Developer Portal authentication to remote clusters
3. The Kubernetes cluster where Tanzu Application Platform components are installed

VMware recommends using the same identity provider for each of these so that a common identity is shared across Tanzu Application Platform. To facilitate this, components can use common OIDC providers.

Tanzu Developer Portal

Tanzu Developer Portal is based on the Backstage open source project and has a variety of OIDC providers that you can configure as an identity provider.

To configure authentication for the Tanzu Developer Portal, VMware recommends the following:

1. Enable user authentication using one of the supported providers. For more information, see Set up authentication for Tanzu Developer Portal.

   Note

   Due to the limitations of the Backstage authentication implementation, enabling authentication does not ensure full end-to-end security as Backstage doesn't currently support per-API authentication. VMware recommends implementing additional security either using an inbound proxy or by leveraging networking using a firewall or VPN. For more information, see Authentication in Backstage.

2. Disable guest access in the `tap_gui` section in the `tap-values.yaml` file:

   ```
   tap_gui:
    app_config:
      auth:
        allowGuestAccess: false
   ```

Tanzu Developer Portal authentication to remote clusters

Several plug-ins within the Tanzu Developer Portal, such as the Runtime Resource Viewer, Supply Chain Visualization, and Security Analysis GUI require authentication to remote Kubernetes clusters to query Kubernetes resources.

To do so, the plug-ins must authenticate to the Kubernetes API on remote clusters. Configure authentication in two ways: a shared Kubernetes service account that all users use to authenticate to remote clusters, and by setting up an authentication provider for the remote cluster. As best security practice, VMware recommends setting up a remote authentication provider for the Kubernetes cluster.

For more information, see Update Tanzu Developer Portal to view resources on multiple clusters.

As best practice, the users on the Kubernetes clusters that are used for remote authentication must be assigned to Kubernetes roles that limit access in a least privilege model.

The Kubernetes cluster

VMware recommends enabling authentication to the Kubernetes clusters where the Tanzu Application Platform components are installed, using the same identity provider that other components are using.

While there are many options on how to enable OIDC providers for authentication with the Kubernetes API, VMware supports the Pinniped project. For information on using Pinniped in Tanzu Application Platform, see Set up authentication for your Tanzu Application Platform deployment and Install Pinniped on Tanzu Application Platform.

By configuring this to use the same identify provider as the Tanzu Developer Portal, users can have a common identity across the Kubernetes clusters and the Tanzu Developer Portal. Because the Tanzu CLI is making Kubernetes API calls, this configuration is also enabled for the Tanzu CLI.

Using Pinniped provides authentication for Kubernetes clusters but still requires the users to be bound to Kubernetes roles. To provide a starting point, the Tanzu Application Platform provides six Kubernetes Roles as part of the installation that users can be bound to. For more information about the roles used for authorization, see Default roles for Tanzu Application Platform.

Artifact Metadata Repository (AMR) Observer, CloudEvent Handler, and GraphQL

AMR Observer deploys on Full, Build and Run Tanzu Application Platform profiles.

AMR CloudEvent Handler and GraphQL deploy on Full and View Tanzu Application Platform profiles.

AMR Observer, AMR CloudEvent Handler, and GraphQL create Kubernetes service accounts, cluster roles, cluster role bindings, and secrets required for communication between these components internally and externally between Kubernetes clusters. For more information, see Kubernetes service account automatic configuration.

Deactivate the automatic configuration for each of these components for the respective profiles and manually create them as known resources.

To deactivate AMR Observer automatic configuration, update the `tap-values.yaml` as follows:

```
amr:
  observer:
    auth:
      kubernetes_service_accounts:
        autoconfigure: false
```

To deactivate AMR CloudEvent Handler and GraphQL automatic configuration, update the `tap-values.yaml` as follows:

```
amr:
  cloudevent_handler:
    auth:
      kubernetes_service_accounts:
        autoconfigure: false

  graphql:
    auth:
      kubernetes_service_accounts:
        autoconfigure: false
```

For best practice, users on the Kubernetes clusters must create resources with Kubernetes roles that limit access in a least privilege model. For more information, see User-defined Kubernetes Service Account Configuration.

Encryption

Encryption of data prevents unauthorized access to data. In Tanzu Application Platform, there are two states where data should be encrypted:

1. Encryption of data in transit

2. Encryption of data at rest

Encryption of data in transit

This section describes how to encryption of internal communication between services that originate within the cluster and data at rest, and how to secure exposed ingress endpoints.

Internal Communication of data in transit configuration

Communication between services that originate and terminate within the cluster is referred to as internal communication. Tanzu Application Platform is in the process of enabling TLS on internal communication for components.

If you require encrypted internal communication, there are three remediating options:

1. Enable Tanzu Service Mesh, which provides mutual TLS between components. For more information, see Set up Tanzu Service Mesh.
2. Configure Kubernetes to encrypt all communication with a Container Networking Interface (CNI) that supports traffic encryption, for example, Antrea.
3. Use the underlying network infrastructure running Kubernetes which has encryption on all network traffic.

External communication of data in transit configuration

TLS enables encryption of communication from end-users to the cluster. Because Contour is the edge gateway for all the traffic ingressing into the cluster, it is suitable to set up TLS and ensure that all communications between users and the cluster are encrypted.

It also allows cluster owners to satisfy compliance requirements such as NIST 800-53 ControlSC-8 to protect the confidentiality of transmitted information.

It might be required that certain cipher suites or TLS versions are used when encrypting communications. NIST 800-53 requires that all government-only applications use TLS v1.2 and they also must be configured to use TLS v1.3.

Configuring TLS for Contour

To configure Contour to use TLS, create a new section in `tap-values.yaml`:

```
...
contour:
  * existing stuff, probably already there if you're following tap docs
  envoy:
    service:
      type: LoadBalancer # This is set by default, but can be overridden by setting a
different value.
  * new stuff
  contour:
    configFileContents:
      tls:
        minimum-protocol-version: "1.2"
        cipher-suites:
        - '[ECDHE-ECDSA-AES128-GCM-SHA256|ECDHE-ECDSA-CHACHA20-POLY1305]'
        - '[ECDHE-RSA-AES128-GCM-SHA256|ECDHE-RSA-CHACHA20-POLY1305]'
        - 'ECDHE-ECDSA-AES256-GCM-SHA384'
        - 'ECDHE-RSA-AES256-GCM-SHA384'
```

After adding this section, apply the `tap-values.yaml` file that will change the configuration of TLS to match the requirements.

For more information, see TLS Configuration in the Contour documentation.

Ingress Certificates

For information about how to configure TLS for a Tanzu Application Platform installation's ingress endpoints, see Secure exposed ingress endpoints in Tanzu Application Platform.

Encryption of Data At Rest

All data must be encrypted at rest. The Tanzu Application Platform runs on Kubernetes and verifies the default storage class configured on the Kubernetes cluster. If you require Encryption of Data at Rest (DARE), you must provide a PersistentVolume Provisioner that supports encryption to the Kubernetes infrastructure.

Ports and protocols

Ports are used in TCP and UDP protocols for identification of applications. While some applications use common port numbers, such as 80 for HTTP, or 443 for HTTPS, some applications use dynamic ports. An open port refers to a port on which a system is accepting communication. An open port does not always mean that there is a security issue, but it can provide a pathway for attackers listening on that port. To help understand the traffic flows in Tanzu Application Platform, VMware provides a list of Tanzu Application Platform ports and protocols on request. For more information, see the TAP Architecture Overview.

Networking

Ensure that workloads only expose internal-only routes.

All traffic must go through Contour and LoadBalancer without using NodePort services.

Tanzu Application Platform is supported by Tanzu Service Mesh.

You must configure proper affinity rules on Knative deployed services. For more information, see Install Tanzu Application Platform in an air-gapped environment.

Key management

Key management is the foundation of all data security. Data is encrypted and decrypted with encryption keys or secrets that must be safely stored to prevent the loss or compromise of infrastructure, systems, and applications. Tanzu Application Platform values are secrets and must be protected to ensure that the security and integrity of the platform is maintained.

Tanzu Application Platform stores all sensitive values as Kubernetes Secrets.

Encryption of secrets at rest are Kubernetes distribution dependent.

Use External Secrets Operator (beta) to automate the lifecycle management of Secrets stored in a Secret management service, such as, Hashicorp Vault, Google Secrets Manager, Amazon Secrets Manager, or Microsoft Azure Key Vault use.

For more information related to safeguarding sensitive information from exploitation, such as, Tanzu Application Platform values, see the AC-23 section in the SP 800-53 publication.

Logging

Log files provide an audit trail to monitor activity within infrastructure. Use log files to identify policy violations, unusual activity, and security incidents. It is important that logs are captured and retained according to the policies set forth by your organization's security team or governing body.

Tanzu Application Platform components run as pods on the Kubernetes infrastructure and all components output is captured as part of the pod logs.

All Tanzu Application Platform components follow Kubernetes logging best practices. Log aggregation must be implemented following the best practices of the organization log retention process. For more information, see the AU-4 Audit Log Storage Capacity section in the SP 800-53 publication.

Deployment architecture

Tanzu Application Platform provides a reference architecture that depicts separate components based on function. VMware recommends multiple Kubernetes clusters for the iterate, build, view, and run functions. This separation enables Kubernetes administrators to manage each function independently and therefore, protect the availability and performance of the platform during high usage periods, for example, building or scanning.

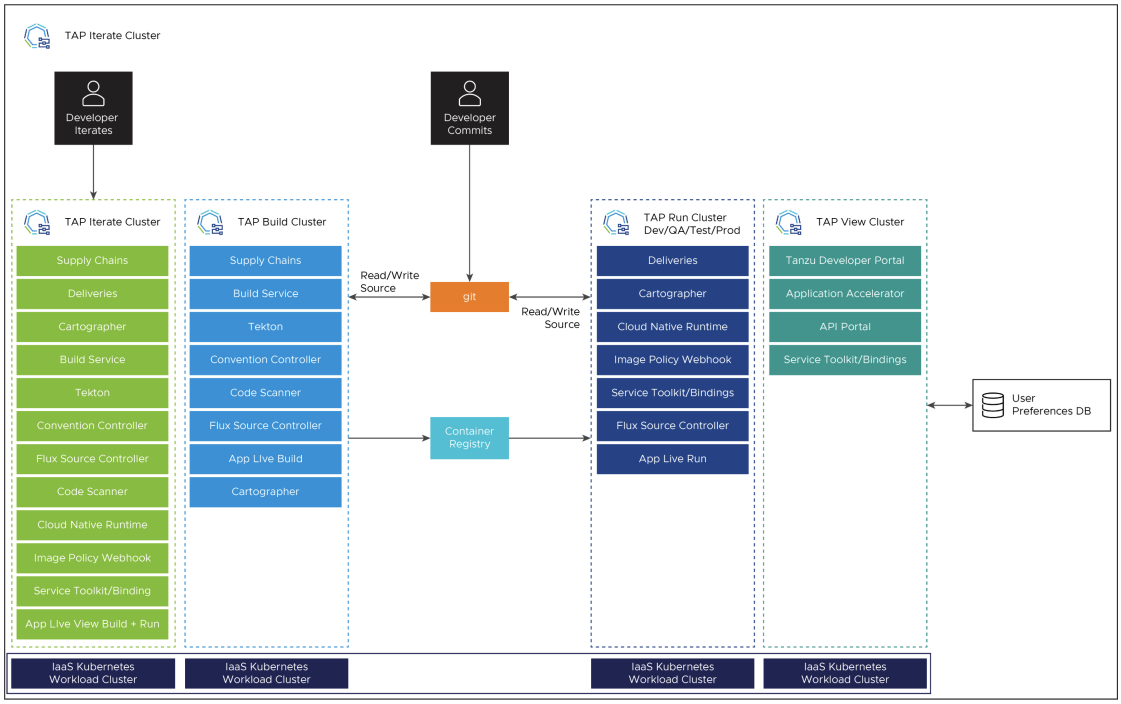
Overview of multicluster Tanzu Application Platform

You can install Tanzu Application Platform (commonly known as TAP) in various topologies to reflect your existing landscape. VMware has tested and recommends a multicluster topology for production use. Because flexibility and choice are core to Tanzu Application Platform's design, none of the implementation recommendations are set in stone.

The multicluster topology uses Tanzu Application Platform profiles. Each cluster adopts one of following multicluster-aligned profiles:

- **Iterate:** Intended for inner-loop iterative application development.
- **Build:** Transforms source revisions to workload revisions; specifically, hosting workloads and supply chains.
- **Run:** Transforms workload revisions to running pods; specifically, hosting deliveries and deliverables.
- **View:** For applications related to centralized developer experiences; specifically, Tanzu Developer Portal and metadata store.

The following diagram illustrates this topology.



Next steps

To get started with installing a multicluster topology, see Install multicluster Tanzu Application Platform profiles.

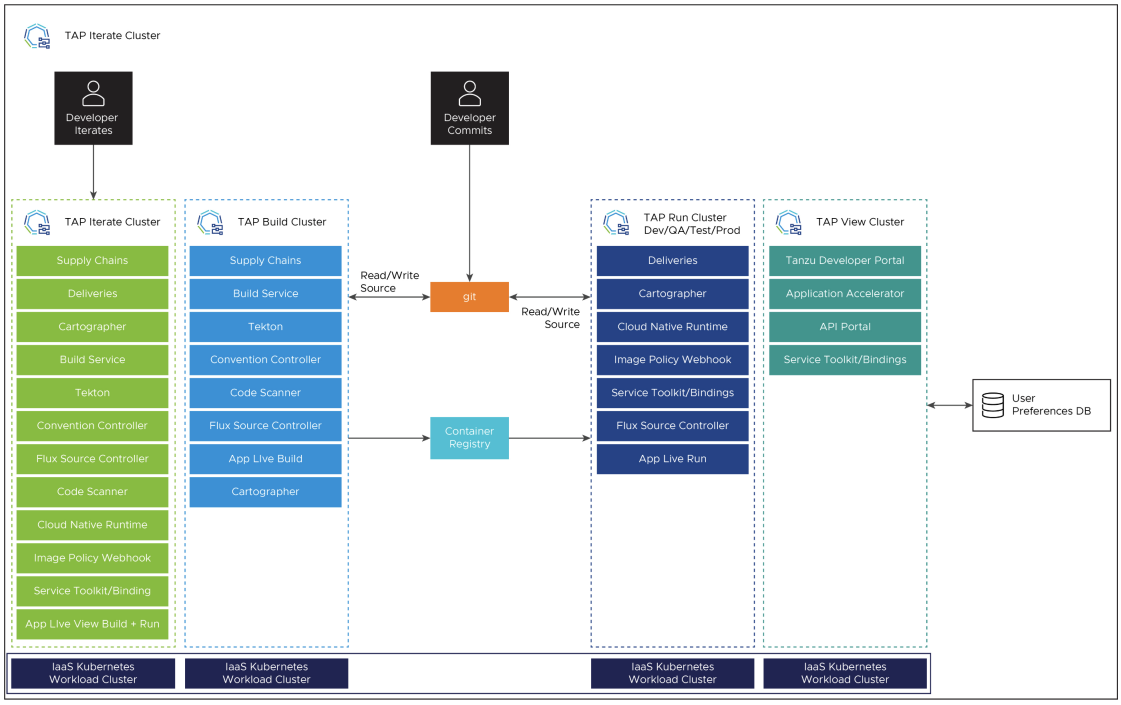
Overview of multicluster Tanzu Application Platform

You can install Tanzu Application Platform (commonly known as TAP) in various topologies to reflect your existing landscape. VMware has tested and recommends a multicluster topology for production use. Because flexibility and choice are core to Tanzu Application Platform's design, none of the implementation recommendations are set in stone.

The multicluster topology uses Tanzu Application Platform profiles. Each cluster adopts one of following multicluster-aligned profiles:

- **Iterate:** Intended for inner-loop iterative application development.
- **Build:** Transforms source revisions to workload revisions; specifically, hosting workloads and supply chains.
- **Run:** Transforms workload revisions to running pods; specifically, hosting deliveries and deliverables.
- **View:** For applications related to centralized developer experiences; specifically, Tanzu Developer Portal and metadata store.

The following diagram illustrates this topology.



Next steps

To get started with installing a multicluster topology, see Install multicluster Tanzu Application Platform profiles.

Install multicluster Tanzu Application Platform profiles

This topic tells you how to install a multicluster topology for your Tanzu Application Platform (commonly known as TAP).

Prerequisites

Before installing multicluster Tanzu Application Platform profiles, you must meet the following prerequisites:

- All clusters must satisfy all the requirements to install Tanzu Application Platform. See Prerequisites.
- Accept Tanzu Application Platform EULA and install Tanzu CLI with any required plug-ins.
- Install Tanzu Cluster Essentials on all clusters. For more information, see Deploy Cluster Essentials.

Multicluster Installation Order of Operations

The installation order is flexible given the ability to update the installation with a modified values file using the `tanzu package installed update` command. The following is an example of the order of operations to be used:

1. Install View profile cluster.
2. Install Build profile cluster.
3. Install Run profile cluster.
4. Install Iterate profile cluster.
5. Add Build, Run and Iterate clusters to Tanzu Developer Portal.
6. Update the View cluster's installation values file with the previous information and run the following command to pass the updated config values to Tanzu Developer Portal:

   ```
   tanzu package installed update tap -p tap.tanzu.vmware.com -v TAP-VERSION --val
   ues-file tap-values.yaml -n tap-install
   ```

   Where `TAP-VERSION` is the Tanzu Application Platform version you've installed.

Install View cluster

Install the View profile cluster first, because some components must exist before installing the Run clusters. For example, the Application Live View back end must be present before installing the Run clusters. For more information about profiles, see About Tanzu Application Platform package profiles.

To install the View cluster:

1. Follow the steps described in Installing the Tanzu Application Platform package and profiles by using a reduced values file as shown in View profile.
2. Verify that you can access Tanzu Developer Portal by using the ingress that you set up. The address must follow this format: `https://tap-gui.INGRESS-DOMAIN`, where `INGRESS-DOMAIN` is the DNS domain you set in `shared.ingress_domain` which points to the shared Contour installation in the `tanzu-system-ingress` namespace with the service `envoy`.
3. Follow the steps to configure Supply Chain Security Tools - Store described in Set up multicluster Supply Chain Security Tools (SCST) - Store.

Install Build clusters

To install the Build profile cluster, follow the steps described in Installing the Tanzu Application Platform package and profiles by using a reduced values file as shown in Build profile.

Install Run clusters

To install the Run profile cluster:

1. Follow the steps described in Install the Tanzu Application Platform package and profiles by using a reduced values file as shown in Run profile.
2. To use Application Live View, set the `INGRESS-DOMAIN` for `appliveview_connector` to match the value you set on the View profile for the `appliveview` in the values file.

> **Note**
>
> The default configuration of `shared.ingress_domain` points to the local Run cluster, rather than the View cluster, as a result, `shared.ingress_domain` must be set explicitly.

Install Iterate clusters

To install the Iterate profile cluster, follow the steps described in Install the Tanzu Application Platform package and profiles by using a reduced values file as shown in Iterate profile.

Add Build, Run and Iterate clusters to Tanzu Developer Portal

After installing the Build, Run and Iterate clusters, follow the steps in View resources on multiple clusters in Tanzu Developer Portal to:

1. Create the `Service Accounts` that Tanzu Developer Portal uses to read objects from the clusters.
2. Add a remote cluster.

These steps create the necessary RBAC elements allowing you to pull the URL and token from the Build, Run and Iterate clusters that allows them come back and add to the View cluster's values file.

You must add the Build, Run and Iterate clusters to the View cluster for all plug-ins to function as expected.

Next steps

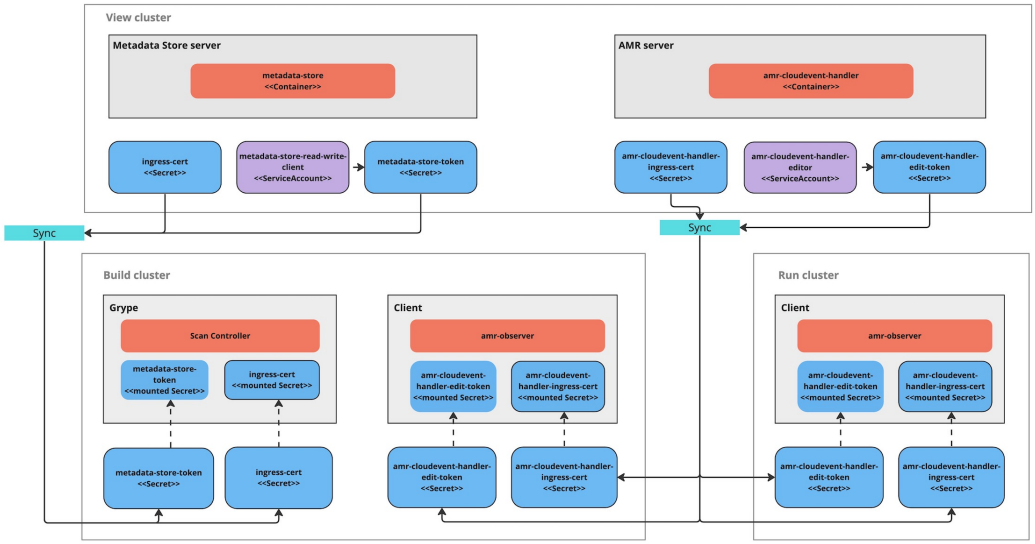
After setting up the four profiles, you're ready to run a workload by using the supply chain. See Get started with multicluster Tanzu Application Platform.

Multicluster setup for Supply Chain Security Tools - Store

This topic describes how you can deploy Supply Chain Security Tools (SCST) - Store in a multicluster setup, including installing multiple profiles such as, View, Build, Run, and Iterate.

Overview

After installing the View profile, but before installing the Build profile and Run profile, you must copy certain configurations from the View cluster to the Build and Run Kubernetes clusters. This topic explains how to add these configurations which allows components in the Build and Run clusters to communicate with SCST - Store in the View cluster.



Prerequisites

You must first install the View profile. See Install View profile. This installation automatically creates the CA certificates and tokens necessary to talk to the CloudEvent Handler.

Procedure summary

To deploy Supply Chain Security Tools (SCST) - Store in a multicluster setup:

1. Copy SCST - Store CA certificates from the View cluster.
    1. Copy the Metadata Store CA certificate from the View cluster.
    2. Copy the AMR CloudEvent Handler CA certificate from the View cluster.
2. Copy SCST - Store tokens from the View cluster.
    1. Copy the Metadata Store authentication token from the View cluster.
    2. Copy the AMR CloudEvent Handler edit token from the View cluster.
3. Apply the SCST - Store CA certificates and SCST - Store tokens to the Build and Run clusters.
    1. Apply the Metadata Store CA certificate and authentication token to the Build cluster.
    2. Apply the AMR CloudEvent Handler CA certificate and edit token for the Build and Run cluster.
4. Install the Build and Run profiles.

Copy SCST - Store CA certificates from the View cluster

To copy SCST - Store CA certificates from the View cluster, you must copy the Metadata Store CA certificate and the AMR CloudEvent Handler CA certificate from the View cluster.

Copy Metadata Store CA certificate from the View cluster

With your kubectl targeted at the View cluster, you can get Metadata Store's TLS CA certificate.

```
MDS_CA_CERT=$(kubectl get secret -n metadata-store ingress-cert -o json | jq -r ".dat
```

```
a.\"ca.crt\"" | base64 -d)
```

Copy AMR CloudEvent Handler CA certificate data from the View cluster

With your kubectl targeted at the View cluster, you can get AMR CloudEvent Handler's TLS CA certificate's data.

```
CEH_CA_CERT_DATA=$(kubectl get secret -n metadata-store amr-cloudevent-handler-ingress
-cert -o json | jq -r ".data.\"ca.crt\"" | base64 -d)
```

Copy SCST - Store authentication tokens from the View cluster

To copy SCST - Store tokens from the View cluster, you must copy the Metadata Store authentication token and the AMR CloudEvent Handler edit token from the View cluster.

Copy Metadata Store authentication token from the View cluster

Copy the Metadata Store authentication token into an environment variable:

```
MDS_AUTH_TOKEN=$(kubectl get secrets metadata-store-read-write-client -n metadata-stor
e -o jsonpath="{.data.token}" | base64 -d)
```

You use this environment variable in the next step.

Copy AMR CloudEvent Handler edit token from the View cluster

Copy the AMR CloudEvent Handler token into an environment variable:

```
CEH_EDIT_TOKEN=$(kubectl get secrets amr-cloudevent-handler-edit-token -n metadata-sto
re -o jsonpath="{.data.token}" | base64 -d)
```

You use this environment variable in the next step.

Apply the SCST - Store CA certificates and SCST - Store tokens to the Build and Run clusters

After you copy the certificate and tokens, apply them to the Build and Run clusters before deploying the profiles.

Build cluster:

- Metadata Store CA certificate
- Metadata Store authentication token
- CloudEvent Handler CA certificate
- CloudEvent Handler edit token

Run cluster:

- CloudEvent Handler CA certificate
- CloudEvent Handler edit token

Configure SCST - Scan with the Metadata Store CA certificate and authentication token on the Build cluster

Update the Build profile `values.yaml` file to add the following snippet using the contents of $MDS_CA_CERT and $MDS_AUTH_TOKEN copied in an earlier step. It configures SCST - Scan with the Metadata Store CA certificate and authentication token.

```
```console
scanning:
  metadataStore:
    exports:
      ca:
        pem: |
          <CONTENTS OF $MDS_CA_CERT>
      auth:
        token: <CONTENTS OF $MDS_AUTH_TOKEN>
```
```

Apply the CloudEvent Handler CA certificate data and edit token to the Build and Run clusters

You can apply the CloudEvent Handler CA certificate and edit the token to the Build and Run clusters. These values must be accessible during the Build and Run profile deployments.

1. Update your kubectl to target the Build cluster.
2. If you already installed Build Cluster you can skip this step. Create a namespace for the CloudEvent Handler CA certificate and edit token.

   ```
   kubectl create ns amr-observer-system
   ```

3. Update the Build profile `values.yaml` file to add the following snippet. It configures the CA certificate and endpoint. In `amr.observer.cloudevent_handler.endpoint` you specify the location of the CloudEvent Handler which was deployed to the View cluster. In `amr.observer.ca_cert_data` you paste the contents of `$CEH_CA_CERT_DATA` which you copied earlier.

   ```
   amr:
     observer:
       auth:
         kubernetes_service_accounts:
           enable: true
       cloudevent_handler:
         endpoint: https://amr-cloudevent-handler.<VIEW-CLUSTER-INGRESS-DOMAIN>
       ca_cert_data: |
           <CONTENTS OF $CEH_CA_CERT_DATA>
   ```

4. Create a secret to store the CloudEvent Handler edit token. This uses the `CEH_EDIT_TOKEN` environment variable.

   ```
   kubectl create secret generic amr-observer-edit-token \
     --from-literal=token=$CEH_EDIT_TOKEN -n amr-observer-system
   ```

5. Repeat the earlier steps, but configure kubectl to target the Run cluster instead of the Build cluster.

After all the steps are done, both the Build and Run clusters each have a CloudEvent Handler CA certificate and edit token named `amr-observer-edit-token` in the namespaces `metadata-store-secrets` and `amr-observer-system`. Now you are ready to deploy the Build and Run profiles.

Install the Build and Run profiles

If you came to this topic from Install multicluster Tanzu Application Platform profiles after installing the View profile, return to that topic to install the Build profile and install the Run profile.

How to configure Grype in the Build profile values file

The Build profile `values.yaml` uses the secrets you created to configure the Grype scanner which talks to SCST - Store. After performing a vulnerabilities scan, the Grype scanner sends the results to SCST - Store.

For example:

```
...
grype:
  targetImagePullSecret: "TARGET-REGISTRY-CREDENTIALS-SECRET"
  metadataStore:
    url: METADATA-STORE-URL-ON-VIEW-CLUSTER # Url with http / https
    caSecret:
        name: store-ca-cert
        importFromNamespace: metadata-store-secrets # Must match with `ingress-cert.da
ta."ca.crt"` of store on view cluster
    authSecret:
        name: store-auth-token # Must match with valid store token of metadata-store o
n view cluster
        importFromNamespace: metadata-store-secrets
...
```

Where:

- `METADATA-STORE-URL-ON-VIEW-CLUSTER` is the ingress URL of SCST - Store deployed to the View cluster. For example, `https://metadata-store.example.com`. See Ingress support.
- `TARGET-REGISTRY-CREDENTIALS-SECRET` is the name of the secret that contains the credentials to pull an image from the registry for scanning.

Configure developer namespaces

After you finish installing Tanzu Application Platform, configure developer namespaces. To prepare developer namespaces, you must export the Metadata Store secrets you created earlier to those namespaces.

Exporting SCST - Store secrets to a developer namespace in a Tanzu Application Platform multicluster deployment

Export secrets to a developer namespace by creating `SecretExport` resources on the developer namespace. You must have created and populated the `metadata-store-secrets` namespace. To create the `SecretExport` resources, run:

```
cat <<EOF | kubectl apply -f -
---
apiVersion: secretgen.carvel.dev/v1alpha1
kind: SecretExport
metadata:
  name: store-ca-cert
  namespace: metadata-store-secrets
spec:
  toNamespaces: [DEV-NAMESPACES]
---
apiVersion: secretgen.carvel.dev/v1alpha1
kind: SecretExport
metadata:
  name: store-auth-token
```

```
  namespace: metadata-store-secrets
spec:
  toNamespaces: [DEV-NAMESPACES]
EOF
```

Where `DEV-NAMESPACES` is an array of developer namespaces where the Metadata Store secrets are exported.

For information about `metadata` configuration, see Cluster Specific Store Configuration.

Additional resources

- Ingress support
- Custom certificate configuration

Get started with multicluster Tanzu Application Platform

This topic tells you how to validate the implementation of a multicluster topology by taking a sample workload and passing it by using the supply chains on the Build and Run clusters.

Use this topic to build an application on the Build profile clusters and run the application on the Run profile clusters.

You can view the workload and associated objects from Tanzu Developer Portal interface on the View profile cluster.

You can take various approaches to configuring the supply chain in this topology, but the following procedures validate the most basic capabilities.

Prerequisites

Before implementing a multicluster topology, complete the following:

1. Complete all installation steps for the four profiles: Build, Run, View and Iterate.
2. For the sample workload, VMware uses the same Application Accelerator - Tanzu Java Web App in the non-multicluster Get Started guide. You can download this accelerator to your own Git infrastructure of choice. You might need to configure additional permissions. Alternatively, you can also use the application-accelerator-samples GitHub repository.
3. The two supply chains are `ootb-supply-chain-basic` on the Build/Iterate profile and `ootb-delivery-basic` on the Run profile. For the Build/Iterate and Run profiled clusters, perform the steps described in Setup Developer Namespace. This guide assumes that you use the `default` namespace.
4. To set the value of `DEVELOPER_NAMESPACE` to the namespace you setup in the previous step, run:

   ```
   export DEVELOPER_NAMESPACE=YOUR-DEVELOPER-NAMESPACE
   ```

   Where:

   - `YOUR-DEVELOPER-NAMESPACE` is the namespace you set up in Set up developer namespaces to use your installed packages. `default` is used in this example.

Start the workload on the Build profile cluster

The Build cluster starts by building the necessary bundle for the workload that is delivered to the Run cluster.

1. Use the Tanzu CLI to start the workload down the first supply chain:

```
tanzu apps workload create tanzu-java-web-app \
--git-repo https://github.com/vmware-tanzu/application-accelerator-samples \
--sub-path tanzu-java-web-app \
--git-branch main \
--type web \
--label app.kubernetes.io/part-of=tanzu-java-web-app \
--yes \
--namespace ${DEVELOPER_NAMESPACE}
```

2. To monitor the progress of this process, run:

```
tanzu apps workload tail tanzu-java-web-app --since 10m --timestamp --namespace
${DEVELOPER_NAMESPACE}
```

3. To exit the monitoring session, press **CTRL** + **C**.

4. Verify that your supply chain has produced the necessary `ConfigMap` containing `Deliverable` content produced by the `Workload`:

```
kubectl get configmap tanzu-java-web-app-deliverable --namespace ${DEVELOPER_NA
MESPACE} -o go-template='{{.data.deliverable}}'
```

   The output resembles the following:

```
apiVersion: carto.run/v1alpha1
kind: Deliverable
metadata:
  name: tanzu-java-web-app-deliverable
  labels:
    apis.apps.tanzu.vmware.com/register-api: "true"
    app.kubernetes.io/part-of: tanzu-java-web-app
    apps.tanzu.vmware.com/workload-type: web
    app.kubernetes.io/component: deliverable
    app.tanzu.vmware.com/deliverable-type: web
spec:
  params:
  - name: source_credentials_secret
    value: ""
  source:
    git:
      url: http://git-server.default.svc.cluster.local/app-namespace/tanzu-java
-web-app
      ref:
        branch: main
```

5. Store the `Deliverable` content, which you can take to the Run profile clusters from the `ConfigMap` by running:

```
kubectl get configmap tanzu-java-web-app-deliverable -n ${DEVELOPER_NAMESPACE}
-o go-template='{{.data.deliverable}}' > deliverable.yaml
```

6. Take this `Deliverable` file to the Run profile clusters by running:

```
kubectl apply -f deliverable.yaml --namespace ${DEVELOPER_NAMESPACE}
```

7. Verify that this `Deliverable` is started and `Ready` by running:

```
kubectl get deliverables --namespace ${DEVELOPER_NAMESPACE}
```

   The output resembles the following:

```
kubectl get deliverables --namespace default
NAME                SOURCE
DELIVERY         READY   REASON   AGE
tanzu-java-web-app   tapmulticloud.azurecr.io/tap-multi-build-dev/tanzu-java-we
b-app-default-bundle:xxxx-xxxx-xxxx-xxxx-1a7beafd6389   delivery-basic   True
Ready    7m2s
```

8. To test the application, query the URL for the application. Look for the `httpProxy` by running:

   ```
   kubectl get httpproxy --namespace ${DEVELOPER_NAMESPACE}
   ```

   The output resembles the following:

   ```
   kubectl get httpproxy --namespace default
   NAME                                                                FQDN
   TLS SECRET   STATUS   STATUS DESCRIPTION
   tanzu-java-web-app-contour-a98df54e3629c5ae9c82a395501ee1fdtanz   tanzu-java-we
   b-app.default.svc.cluster.local                                  valid    Valid HTTPP
   roxy
   tanzu-java-web-app-contour-e1d997a9ff9e7dfb6c22087e0ce6fd7ftanz   tanzu-java-we
   b-app.default.apps.run.multi.kapplegate.com                      valid    Valid HTTPP
   roxy
   tanzu-java-web-app-contour-tanzu-java-web-app.default             tanzu-java-we
   b-app.default                                                    valid    Valid HTTPP
   roxy
   tanzu-java-web-app-contour-tanzu-java-web-app.default.svc         tanzu-java-we
   b-app.default.svc                                                valid    Valid HTTPP
   roxy
   ```

   Select the URL that corresponds to the domain you specified in your Run cluster's profile and enter it into a browser. Expect to see the message "Greetings from Spring Boot + Tanzu!".

9. View the component in Tanzu Developer Portal, by following these steps and using the catalog file from the sample accelerator in GitHub.

Install Tanzu Application Platform Build profile

This topic tells you how to install Build profile cluster by using a reduced values file.

Prerequisites

Before installing the Build profile, follow all the steps in Install View cluster.

Example values.yaml

The following is the YAML file sample for the build-profile:

```
profile: build
ceip_policy_disclosed: FALSE-OR-TRUE-VALUE # Installation fails if this is not set to
true. Not a string.

shared:
  ingress_domain: "INGRESS-DOMAIN"
  kubernetes_distribution: "openshift" # To be passed only for OpenShift. Defaults to
"".
  kubernetes_version: "K8S-VERSION"
  image_registry:
    project_path: "SERVER-NAME/REPO-NAME" # To be used by Build Service by appending
```

```
"/buildservice" and used by Supply chain by appending "/workloads".
    secret:
      name: "KP-DEFAULT-REPO-SECRET"
      namespace: "KP-DEFAULT-REPO-SECRET-NAMESPACE"
  ca_cert_data: | # To be passed if using custom certificates.
    -----BEGIN CERTIFICATE-----
    MIIFXzCCA0egAwIBAgIJAJYm37SFocjlMA0GCSqGSIb3DQEBDQUAMEY...
    -----END CERTIFICATE-----

# The above shared keys can be overridden in the below section.

buildservice:
# Takes the value from the shared section by default, but can be overridden by setting
a different value.
  kp_default_repository: "KP-DEFAULT-REPO"
  kp_default_repository_secret:
    name: "KP-DEFAULT-REPO-SECRET"
    namespace: "KP-DEFAULT-REPO-SECRET-NAMESPACE"
supply_chain: testing_scanning
ootb_supply_chain_testing_scanning: # Optional if the corresponding shared keys are pr
ovided.
  source:
    credentials_secret: "GIT-SOURCE-CREDENTIAL-SECRET-NAME" # (Optional) Defaults to
"".
  registry:
    server: "SERVER-NAME"
    repository: "REPO-NAME"
  gitops:
    credentials_secret: "GITOPS-CREDENTIAL-SECRET-NAME" # (Optional) Defaults to "".
tap_telemetry:
  customer_entitlement_account_number: "CUSTOMER-ENTITLEMENT-ACCOUNT-NUMBER" # (Option
al) Identify data for creating Tanzu Application Platform usage reports.

app_scanning:
  amr:
    url: https://amr-graphql.VIEW-CLUSTER-INGRESS-DOMAIN # AMR GraphQL location at the
View profile cluster.
    accessToken: "AMR-GRAPHQL-READ-ACCESS-TOKEN"

scanning:
  metadataStore:
    exports:
      ca:
        pem: |
          "METADATA STORE CA" # (Optional) Defaults to "".
      auth:
        token: METADATA STORE AUTHENTICATION TOKEN
amr:
  observer:
    auth:
      kubernetes_service_accounts:
        enable: true
    cloudevent_handler:
      endpoint: https://amr-cloudevent-handler.VIEW-CLUSTER-INGRESS-DOMAIN # AMR Cloud
Event Handler location at the View profile cluster.
    ca_cert_data: |
        "AMR-CLOUDEVENT-HANDLER-CA"
```

Important

Installing Grype by using `tap-values.yaml` as follows is deprecated in v1.6 and will be removed in v1.8:

```
grype:
  targetImagePullSecret: "TARGET-REGISTRY-CREDENTIALS-SECRET"
```

You can install Grype by using Namespace Provisioner instead.

Where:

- `K8S-VERSION` is the Kubernetes version used by your OpenShift cluster. It must be in the form of `1.23.x` or `1.24.x`, where `x` stands for the patch version. Examples:
  - Red Hat OpenShift Container Platform v4.10 uses the Kubernetes version `1.23.3`.
  - Red Hat OpenShift Container Platform v4.11 uses the Kubernetes version `1.24.1`.
- `KP-DEFAULT-REPO` is a writable repository in your registry. The Tanzu Build Service dependencies are written to this location. Examples:
  - Harbor has the form `kp_default_repository: "my-harbor.io/my-project/build-service"`
  - Docker Hub has the form `kp_default_repository: "my-dockerhub-user/build-service"` or `kp_default_repository: "index.docker.io/my-user/build-service"`
  - Google Cloud Registry has the form `kp_default_repository: "gcr.io/my-project/build-service"`
  - For Google Cloud Registry, use the contents of the service account JSON file.
- `KP-DEFAULT-REPO-SECRET` is the secret with user credentials that can write to `KP-DEFAULT-REPO`. You can `docker push` to this location with this credential.
  - For Google Cloud Registry, use `kp_default_repository_username: _json_key`.
  - You must create the secret before the installation. For example, you can use the `registry-credentials` secret created earlier.
- `KP-DEFAULT-REPO-SECRET-NAMESPACE` is the namespace where `KP-DEFAULT-REPO-SECRET` is created.
- `SERVER-NAME` is the host name of the registry server. Examples:
  - Harbor has the form `server: "my-harbor.io"`.
  - Docker Hub has the form `server: "index.docker.io"`.
  - Google Cloud Registry has the form `server: "gcr.io"`.
- `REPO-NAME` is where workload images are stored in the registry. Images are written to `SERVER-NAME/REPO-NAME/workload-name`. Examples:
  - Harbor has the form `repository: "my-project/supply-chain"`.
  - Docker Hub has the form `repository: "my-dockerhub-user"`.
  - Google Cloud Registry has the form `repository: "my-project/supply-chain"`.
- `GIT-SOURCE-CREDENTIAL-SECRET-NAME` is the name of the Kubernetes secret in the developer namespace that supplies the Git credentials for the supply chain to fetch source code from. See Git authentication for more information.
- `GITOPS-CREDENTIAL-SECRET-NAME` is the name of the Kubernetes secret in the developer namespace that supplies the Git credentials for the supply chain to push configuration to. See Git authentication for more information.
- `MY-DEV-NAMESPACE` is the name of the developer namespace. SCST - Scan deploys the `ScanTemplates` there. This allows the scanning feature to run in this namespace.

- `TARGET-REGISTRY-CREDENTIALS-SECRET` is the name of the Secret that contains the credentials to pull an image from the registry for scanning.
- `CUSTOMER-ENTITLEMENT-ACCOUNT-NUMBER` (optional) refers to the Entitlement Account Number (EAN), which is a unique identifier VMware assigns to its customers. Tanzu Application Platform telemetry uses this number to identify data that belongs to a particular customers and prepare usage reports.
- `VIEW-CLUSTER-INGRESS-DOMAIN` is the subdomain you set up on the View profile cluster. This matches the `shared.ingress_domain` on the View profile cluster.
- `AMR-GRAPHQL-READ-ACCESS-TOKEN` is the read access token. For more information about how to obtain the token, see AMR GraphQL querying.
- `AMR-CLOUDEVENT-HANDLER-CA` contains the AMR CloudEvent Handler CA data. For more information about configuring the `amr` portion of the values file, see Set up multicluster Supply Chain Security Tools (SCST) - Store.

When you install Tanzu Application Platform, it is bootstrapped with the `lite` set of dependencies, including buildpacks and stacks, for application builds. For more information about buildpacks, see the VMware Tanzu Buildpacks Documentation. You can find the buildpack and stack artifacts installed with Tanzu Application Platform on Tanzu Network. You can update the dependencies by upgrading Tanzu Application Platform to the latest patch.

See Set up multicluster Supply Chain Security Tools (SCST) - Store for more information about the value settings of `grype.metadataStore`.

You must set the `scanning.metadatastore.url` to an empty string if you're installing Grype Scanner v1.2.0 and later or Snyk Scanner to deactivate the embedded SCST - Store integration.

If you use custom CA certificates, you must provide one or more PEM-encoded CA certificates under the `ca_cert_data` key. If you configured `shared.ca_cert_data`, Tanzu Application Platform component packages inherit that value by default.

Install Tanzu Application Platform Run profile

This topic tells you how to install Run profile cluster by using a reduced values file.

The following is the YAML file sample for the run-profile:

```
profile: run
ceip_policy_disclosed: FALSE-OR-TRUE-VALUE # Installation fails if this is not set to
true. Not a string.

shared:
  ingress_domain: INGRESS-DOMAIN
  kubernetes_distribution: "openshift" # To be passed only for OpenShift. Defaults to
"".
  kubernetes_version: "K8S-VERSION"
  ca_cert_data: | # To be passed if using custom certificates.
    -----BEGIN CERTIFICATE-----
    MIIFXzCCA0egAwIBAgIJAJYm37SFocjlMA0GCSqGSIb3DQEBDQUAMEY...
    -----END CERTIFICATE-----
supply_chain: basic

contour:
  envoy:
    service:
      type: LoadBalancer # NodePort can be used if your Kubernetes cluster doesn't sup
port LoadBalancing.

appliveview_connector:
  backend:
```

```
    sslDeactivated: TRUE-OR-FALSE-VALUE
    ingressEnabled: true
    host: appliveview.VIEW-CLUSTER-INGRESS-DOMAIN

tap_telemetry:
  customer_entitlement_account_number: "CUSTOMER-ENTITLEMENT-ACCOUNT-NUMBER" # (Option
al) Identify data for creating Tanzu Application Platform usage reports.

amr:
  observer:
    auth:
      kubernetes_service_accounts:
        enable: true
    cloudevent_handler:
      endpoint: https://amr-cloudevent-handler.VIEW-CLUSTER-INGRESS-DOMAIN # AMR Cloud
Event Handler location at the View profile cluster.
    ca_cert_data: |
        "AMR-CLOUDEVENT-HANDLER-CA"
```

Where:

- `INGRESS-DOMAIN` is the subdomain for the host name that you point at the `tanzu-shared-ingress` service's external IP address.
- `K8S-VERSION` is the Kubernetes version used by your OpenShift cluster. It must be in the form of `1.23.x` or `1.24.x`, where `x` stands for the patch version. Examples:
  - Red Hat OpenShift Container Platform v4.10 uses the Kubernetes version `1.23.3`.
  - Red Hat OpenShift Container Platform v4.11 uses the Kubernetes version `1.24.1`.
- `VIEW-CLUSTER-INGRESS-DOMAIN` is the subdomain you setup on the View profile cluster. This matches the value key `appliveview.ingressDomain` or `shared.ingress_domain` on the view cluster. Include the default host name `appliveview.` ahead of the domain.
- `CUSTOMER-ENTITLEMENT-ACCOUNT-NUMBER` (optional) refers to the Entitlement Account Number (EAN), which is a unique identifier VMware assigns to its customers. Tanzu Application Platform telemetry uses this number to identify data that belongs to a particular customers and prepare usage reports.
- `AMR-CLOUDEVENT-HANDLER-CA` contains the AMR CloudEvent Handler CA data. For more information about configuring the `amr` portion of the values file, see Set up multicluster Supply Chain Security Tools (SCST) - Store.

If you use custom CA certificates, you must provide one or more PEM-encoded CA certificates under the `ca_cert_data` key. If you configured `shared.ca_cert_data`, Tanzu Application Platform component packages inherit that value by default.

If you set `shared.ingress_domain` in run profile, the `appliveview_connector.backend.host` is automatically configured as `host: appliveview.INGRESS-DOMAIN`. To override the shared ingress for Application Live View to connect to the view cluster, set the `appliveview_connector.backend.host` key to `appliveview.VIEW-CLUSTER-INGRESS-DOMAIN`.

Install Tanzu Application Platform View profile

This topic tells you how to install View profile cluster by using a reduced values file.

The following is the YAML file sample for the view-profile:

```
profile: view
ceip_policy_disclosed: FALSE-OR-TRUE-VALUE # Installation fails if this is not set to
true. Not a string.

shared:
```

```
  ingress_domain: "INGRESS-DOMAIN"
  kubernetes_distribution: "openshift" # To be passed only for OpenShift. Defaults to
"".
  kubernetes_version: "K8S-VERSION"
  ca_cert_data: | # To be passed if using custom certificates.
    -----BEGIN CERTIFICATE-----
    MIIFXzCCA0egAwIBAgIJAJYm37SFocjlMA0GCSqGSIb3DQEBDQUAMEY...
    -----END CERTIFICATE-----

contour:
  envoy:
    service:
      type: LoadBalancer # NodePort can be used if your Kubernetes cluster doesn't sup
port LoadBalancing.

tap_gui:
  app_config:
    auth:
      allowGuestAccess: true  # This allows unauthenticated users to log in to your po
rtal. If you want to deactivate it, make sure you configure an alternative auth provid
er.
    catalog:
      locations:
        - type: url
          target: https://GIT-CATALOG-URL/catalog-info.yaml
    kubernetes:
      serviceLocatorMethod:
        type: 'multiTenant'
      clusterLocatorMethods:
        - type: 'config'
          clusters:
            - url: CLUSTER-URL
              name: CLUSTER-NAME # Build profile cluster can go here.
              authProvider: serviceAccount
              serviceAccountToken: CLUSTER-TOKEN
              skipTLSVerify: TRUE-OR-FALSE-VALUE
            - url: CLUSTER-URL
              name: CLUSTER-NAME # Run profile cluster can go here.
              authProvider: serviceAccount
              serviceAccountToken: CLUSTER-TOKEN
              skipTLSVerify: TRUE-OR-FALSE-VALUE

appliveview:
  ingressEnabled: true

tap_telemetry:
  customer_entitlement_account_number: "CUSTOMER-ENTITLEMENT-ACCOUNT-NUMBER" # (Option
al) Identify data for creating Tanzu Application Platform usage reports.
```

Where:

- `INGRESS-DOMAIN` is the subdomain for the host name that you point at the `tanzu-shared-ingress` service's external IP address.
- `K8S-VERSION` is the Kubernetes version used by your OpenShift cluster. It must be in the form of `1.23.x` or `1.24.x`, where `x` stands for the patch version. Examples:
    - Red Hat OpenShift Container Platform v4.10 uses the Kubernetes version `1.23.3`.
    - Red Hat OpenShift Container Platform v4.11 uses the Kubernetes version `1.24.1`.
- `GIT-CATALOG-URL` is the path to the `catalog-info.yaml` catalog definition file. You can download either a blank or populated catalog file from the Tanzu Application Platform product page. Otherwise, use a Backstage-compliant catalog you've already built and posted on the Git infrastructure in the Integration section.

- `CLUSTER-URL`, `CLUSTER-NAME` and `CLUSTER-TOKEN` are described in the View resources on multiple clusters in Tanzu Developer Portal. Observe the order of operations laid out in the previous steps.
- `CUSTOMER-ENTITLEMENT-ACCOUNT-NUMBER` (optional) refers to the Entitlement Account Number (EAN), which is a unique identifier VMware assigns to its customers. Tanzu Application Platform telemetry uses this number to identify data that belongs to a particular customers and prepare usage reports.

If you use custom CA certificates, you must provide one or more PEM-encoded CA certificates under the `ca_cert_data` key. If you configured `shared.ca_cert_data`, Tanzu Application Platform component packages inherit that value by default.

The `appliveview.ingressEnabled` key is set to `false` by default. In a multicluster setup, `ingressEnabled` key must be set to `true`. If the `shared.ingress_domain` key is set, the Application Live View back end is automatically exposed through the shared ingress.

Install Tanzu Application Platform Iterate profile

This topic tells you how to install Iterate profile cluster by using a reduced values file.

The following is the YAML file sample for the iterate-profile:

```
profile: iterate

shared:
  ingress_domain: "INGRESS-DOMAIN"
  kubernetes_distribution: "openshift" # To be passed only for OpenShift. Defaults to
"".
  kubernetes_version: "K8S-VERSION"
  image_registry:
    project_path: "SERVER-NAME/REPO-NAME" # To be used by Build Service by appending
"/buildservice" and used by Supply chain by appending "/workloads"
    username: "KP-DEFAULT-REPO-USERNAME"
    password: "KP-DEFAULT-REPO-PASSWORD"
  ca_cert_data: | # To be passed if using custom certificates
  -----BEGIN CERTIFICATE-----
  MIIFXzCCA0egAwIBAgIJAJYm37SFocjlMA0GCSqGSIb3DQEBDQUAMEY...
  -----END CERTIFICATE-----

ceip_policy_disclosed: FALSE-OR-TRUE-VALUE # Installation fails if this is not set to
true. Not a string.

# The above shared keys may be overridden in the below section.

buildservice: # Optional if the corresponding shared keys are provided.
  kp_default_repository: "KP-DEFAULT-REPO"
  kp_default_repository_username: "KP-DEFAULT-REPO-USERNAME"
  kp_default_repository_password: "KP-DEFAULT-REPO-PASSWORD"

supply_chain: basic
ootb_supply_chain_basic: # Optional if the shared above mentioned shared keys are prov
ided.
  source:
    credentials_secret: "GIT-SOURCE-CREDENTIAL-SECRET-NAME" # (Optional) Defaults to
"".
  registry:
    server: "SERVER-NAME"
    repository: "REPO-NAME"
  gitops:
    credentials_secret: "GITOPS-CREDENTIAL-SECRET-NAME" # (Optional) Defaults to "".

image_policy_webhook:
```

```
  allow_unmatched_tags: true

contour:
  envoy:
    service:
      type: LoadBalancer # (Optional) Defaults to LoadBalancer.

cnrs:
  domain_name: "TAP-ITERATE-CNR-DOMAIN" # Optional if the shared.ingress_domain is pro
vided.

appliveview_connector:
  backend:
    sslDeactivated: TRUE-OR-FALSE-VALUE
    ingressEnabled: true
    host: appliveview.VIEW-CLUSTER-INGRESS-DOMAIN

tap_telemetry:
  customer_entitlement_account_number: "CUSTOMER-ENTITLEMENT-ACCOUNT-NUMBER" # (Option
al) Identify data for creating Tanzu Application Platform usage reports.
```

Where:

- `K8S-VERSION` is the Kubernetes version used by your OpenShift cluster. It must be in the form of `1.23.x` or `1.24.x`, where `x` stands for the patch version. Examples:
  - Red Hat OpenShift Container Platform v4.10 uses the Kubernetes version `1.23.3`.
  - Red Hat OpenShift Container Platform v4.11 uses the Kubernetes version `1.24.1`.
- `KP-DEFAULT-REPO` is a writable repository in your registry. Tanzu Build Service dependencies are written to this location. Examples:
  - Harbor has the form `kp_default_repository: "my-harbor.io/my-project/build-service"`.
  - Docker Hub has the form `kp_default_repository: "my-dockerhub-user/build-service"` or `kp_default_repository: "index.docker.io/my-user/build-service"`.
  - Google Cloud Registry has the form `kp_default_repository: "gcr.io/my-project/build-service"`.
- `KP-DEFAULT-REPO-USERNAME` is the user name that can write to `KP-DEFAULT-REPO`. You can `docker push` to this location with this credential.
  - For Google Cloud Registry, use `kp_default_repository_username: _json_key`.
- `KP-DEFAULT-REPO-PASSWORD` is the password for the user that can write to `KP-DEFAULT-REPO`. You can `docker push` to this location with this credential. This credential can also be configured by using a Secret reference. For more information, see Install Tanzu Build Service for details.
  - For Google Cloud Registry, use the contents of the service account JSON file.
- `SERVER-NAME` is the host name of the registry server. Examples:
  - Harbor has the form `server: "my-harbor.io"`.
  - Docker Hub has the form `server: "index.docker.io"`.
  - Google Cloud Registry has the form `server: "gcr.io"`.
- `REPO-NAME` is where workload images are stored in the registry. Images are written to `SERVER-NAME/REPO-NAME/workload-name`. Examples:
  - Harbor has the form `repository: "my-project/supply-chain"`.
  - Docker Hub has the form `repository: "my-dockerhub-user"`.
  - Google Cloud Registry has the form `repository: "my-project/supply-chain"`.

- `GIT-SOURCE-CREDENTIAL-SECRET-NAME` is the name of the Kubernetes secret in the developer namespace that supplies the Git credentials for the supply chain to fetch source code from. See Git authentication for more information.
- `GITOPS-CREDENTIAL-SECRET-NAME` is the name of the Kubernetes secret in the developer namespace that supplies the Git credentials for the supply chain to push configuration to. See Git authentication for more information.
- `TAP-ITERATE-CNR-DOMAIN` is the iterate cluster Cloud Native Runtimes domain.
- `VIEW-CLUSTER-INGRESS-DOMAIN` is the subdomain you setup on the View profile cluster. This matches the value key `appliveview.ingressDomain` or `shared.ingress_domain` on the view cluster. Include the default host name `appliveview.` ahead of the domain.
- `CUSTOMER-ENTITLEMENT-ACCOUNT-NUMBER` (optional) refers to the Entitlement Account Number (EAN), which is a unique identifier VMware assigns to its customers. Tanzu Application Platform telemetry uses this number to identify data that belongs to a particular customers and prepare usage reports.

If you use custom CA certificates, you must provide one or more PEM-encoded CA certificates under the `ca_cert_data` key. If you configured `shared.ca_cert_data`, Tanzu Application Platform component packages inherit that value by default.

If you set `shared.ingress_domain` in the iterate profile, the `appliveview_connector.backend.host` is automatically configured as `host: appliveview.INGRESS-DOMAIN`. To override the shared ingress for Application Live View to connect to the view cluster, set the `appliveview_connector.backend.host` key to `appliveview.VIEW-CLUSTER-INGRESS-DOMAIN`.

Get started with Tanzu Application Platform

Welcome to Tanzu Application Platform (commonly known as TAP). The guides in this section provide hands-on instructions for developers and operators to help you get started on Tanzu Application Platform.

In addition to the resources provided in this Get started guide, VMware also provides developer and operator focused courses, and an experimental developer sandbox environment in Tanzu Academy.

Prerequisites

Before you start, verify you have successfully:

- **Installed Tanzu Application Platform**
  See Installing Tanzu Application Platform.
- **Installed Tanzu Application Platform on the target Kubernetes cluster**
  See Installing the Tanzu CLI and Installing the Tanzu Application Platform Package and Profiles.
- **Set the default kubeconfig context to the target Kubernetes cluster**
  See Changing clusters.
- **Installed Out of The Box (OOTB) Supply Chain Basic**
  See Install Out of The Box Supply Chain Basic. If you used the default profiles provided in Installing the Tanzu Application Platform Package and Profiles, you have already installed the Out of The Box (OOTB) Supply Chain Basic.
- **Installed Tekton Pipelines**
  See Install Tekton Pipelines. If you used the default profiles provided in Installing the Tanzu Application Platform Package and Profiles, you have already installed Tekton Pipelines.
- **Set up a developer namespace to accommodate the developer workload**
  See Set up developer namespaces to use your installed packages.
- **Installed Tanzu Developer Portal**
  See Install Tanzu Developer Portal. If you used the Full or View profiles provided in Installing the Tanzu Application Platform Package and Profiles, you have already installed Tanzu Developer Portal.
- **Installed the VS Code Tanzu Extension**
  See Install the Visual Studio Code Tanzu Extension for instructions.

When you have completed these prerequisites, you are ready to get started.

Next steps

For developers:

- Create an application accelerator

- Deploy an app on Tanzu Application Platform
- Deploy Spring Cloud Applications to Tanzu Application Platform

For operators:

- Add testing and scanning to your application
- Configure image signing

Get started with Tanzu Application Platform

Welcome to Tanzu Application Platform (commonly known as TAP). The guides in this section provide hands-on instructions for developers and operators to help you get started on Tanzu Application Platform.

In addition to the resources provided in this Get started guide, VMware also provides developer and operator focused courses, and an experimental developer sandbox environment in Tanzu Academy.

When you have completed these prerequisites, you are ready to get started.

Next steps

For developers:

- Create an application accelerator

- Deploy an app on Tanzu Application Platform
- Deploy Spring Cloud Applications to Tanzu Application Platform

For operators:

- Add testing and scanning to your application
- Configure image signing

Add testing and scanning to your application

This topic guides you through installing the optional OOTB Supply Chain with Testing and the optional OOTB Supply Chain with Testing and Scanning.

For more information about available supply chains, see Supply chains on Tanzu Application Platform.

What you will do

- Install OOTB Supply Chain with Testing.
- Add a Tekton pipeline to the cluster and update the workload to point to the pipeline and resolve errors.
- Install OOTB Supply Chain with Testing and Scanning.
- Update the workload to point to the Tekton pipeline and resolve errors.
- Query for vulnerabilities and dependencies.
- (Optional) Enable recurring scanning for post-build scans.

Overview

The default Out of the Box (OOTB) Supply Chain Basic and its dependencies were installed on your cluster during the Tanzu Application Platform install. As demonstrated in this guide, you can add testing and security scanning to your application. When you activate OOTB Supply Chain with Testing, it deactivates OOTB Supply Chain Basic.

The following installations also provide a sample Tekton pipeline that tests your sample application. The pipeline is configurable. Therefore, you can customize the steps to perform either additional testing or other tasks with Tekton Pipelines.

Install OOTB Supply Chain with Testing

To install OOTB Supply Chain with Testing:

1. You can activate the OOTB Supply Chain with Testing by updating your profile to use `testing` rather than `basic` as the selected supply chain for workloads in this cluster. The `tap-values.yaml` is the file used to customize the profile in `Tanzu package install tap --values-file=...`. Update `tap-values.yaml` with the following changes:

```
- supply_chain: basic
+ supply_chain: testing

- ootb_supply_chain_basic:
+ ootb_supply_chain_testing:
    registry:
      server: "SERVER-NAME"
      repository: "REPO-NAME"
```

Where:

- `SERVER-NAME` is the name of your server.
- `REPO-NAME` is the name of the image repository that hosts the container images.

2. Update the installed profile by running:

```
tanzu package installed update tap -p tap.tanzu.vmware.com -v VERSION-NUMBER --
values-file tap-values.yaml -n tap-install
```

Where `VERSION-NUMBER` is your Tanzu Application Platform version. For example, `1.9.1`.

Tekton pipeline config example

In this section, a Tekton pipeline is added to the cluster. In the next section, the workload is updated to point to the pipeline and resolve any current errors.

Note

Developers can perform this step because they know how their application must be tested. The operator can also add the Tekton pipeline to a cluster before the developer gets access.

To add the Tekton pipeline to the cluster, apply the following YAML to the cluster:

```
apiVersion: tekton.dev/v1beta1
kind: Pipeline
metadata:
  name: developer-defined-tekton-pipeline
  namespace: DEVELOPER-NAMESPACE
  labels:
    apps.tanzu.vmware.com/pipeline: test     # (!) required
spec:
  params:
    - name: source-url                       # (!) required
    - name: source-revision                  # (!) required
  tasks:
    - name: test
      params:
        - name: source-url
          value: $(params.source-url)
        - name: source-revision
          value: $(params.source-revision)
      taskSpec:
        params:
          - name: source-url
          - name: source-revision
        steps:
          - name: test
            image: gradle
            script: |-
              cd `mktemp -d`

              wget -qO- $(params.source-url) | tar xvz -m
              ./mvnw test
```

Where `DEVELOPER-NAMESPACE` is the name of your developer namespace.

The preceding YAML puts a Tekton pipeline in the developer namespace you specify. It defines the Tekton pipeline with a single step. The step contained in the `steps` pulls the code from the repository indicated in the developers `workload` and runs the tests within the repository. The steps

of the Tekton pipeline are configurable and allow the developer to add additional items needed to test their code.

There are many steps in the supply chain. In this case, the next step is an image build. Any additional steps the developer adds to the Tekton pipeline to test their code are independent of the image being built and of any subsequent steps executed in the supply chain. This independence gives the developer freedom to focus on testing their code.

The `params` are templated by Supply Chain Choreographer. Additionally, Tekton pipelines require a Tekton `pipelineRun` to execute on the cluster. Supply Chain Choreographer handles creating the `pipelineRun` dynamically each time that step of the supply chain requires execution.

Workload update

To connect the new supply chain to the workload, the workload must be updated to point at your Tekton pipeline.

1. Update the workload by running the following with the Tanzu CLI:

   ```
   tanzu apps workload apply tanzu-java-web-app \
     --git-repo https://github.com/vmware-tanzu/application-accelerator-samples \
     --sub-path tanzu-java-web-app \
     --git-branch main \
     --type web \
     --label apps.tanzu.vmware.com/has-tests=true \
     --label app.kubernetes.io/part-of=tanzu-java-web-app \
     --yes
   ```

2. After accepting the workload creation, monitor the creation of new resources by the workload by running:

   ```
   kubectl get workload,gitrepository,pipelinerun,images.kpack,podintent,app,servi
   ces.serving
   ```

   The result is output similar to the following example that shows the objects created by Supply Chain Choreographer:

   ```
   NAME                                      AGE
   workload.carto.run/tanzu-java-web-app   109s

   NAME                                                              URL
   READY   STATUS                                                                AGE

Install OOTB Supply Chain with Testing and Scanning

To install OOTB Supply Chain with Testing and Scanning, you must install the Scan Controller and the Grype scanner.

Leveraging both Grype and Tanzu Build Service in your Tanzu Application Platform supply chain enables enhanced scanning coverage for languages and frameworks. For the languages and frameworks supported, see the *Extended Scanning Coverage using Anchore Grype* column in the Language and Framework Support Table.

To install OOTB Supply Chain with Testing and Scanning:

Note

The OOTB Supply Chain with Testing and Scanning capability has been changed to opt-in and is skipped by default starting in Tanzu Application Platform v1.6. For more information, see Scan Types.

1. Supply Chain Security Tools (SCST) - Scan is installed as part of the Tanzu Application Platform profiles. Verify that Scan Controller is installed by running:

   ```
   tanzu package installed get scanning -n tap-install
   ```

   If the package is not already installed, follow the steps in Supply Chain Security Tools - Scan to install the required scanning components.

2. Apply a ScanPolicy in the required namespace. The sample ScanPolicy provided in this step is configured with `notAllowedSeverities := ["Critical","High","UnknownSeverity"]`. This blocks a supply chain when the scanner finds CVEs with critical, high, and unknown ratings.

   You can also configure the supply chain to use your own custom policies and apply exceptions when you want to ignore certain CVEs. See Out of the Box Supply Chain with Testing and Scanning. To apply the sample ScanPolicy, you can either add the namespace flag to the kubectl command or add the namespace field to the template by running:

   ```
   kubectl apply -f - -o yaml << EOF
   ---
   apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
   kind: ScanPolicy
   metadata:
     name: scan-policy
     labels:
       'app.kubernetes.io/part-of': 'enable-in-gui'
   spec:
     regoFile: |
       package main

       # Accepted Values: "Critical", "High", "Medium", "Low", "Negligible", "Unkn
   ownSeverity"
       notAllowedSeverities := ["Critical", "High", "UnknownSeverity"]
       ignoreCves := []
   ```

```
    contains(array, elem) = true {
      array[_] = elem
    } else = false { true }

    isSafe(match) {
      severities := { e | e := match.ratings.rating.severity } | { e | e := mat
ch.ratings.rating[_].severity }
      some i
      fails := contains(notAllowedSeverities, severities[i])
      not fails
    }

    isSafe(match) {
      ignore := contains(ignoreCves, match.id)
      ignore
    }

    deny[msg] {
      comps := { e | e := input.bom.components.component } | { e | e := input.b
om.components.component[_] }
      some i
      comp := comps[i]
      vulns := { e | e := comp.vulnerabilities.vulnerability } | { e | e := com
p.vulnerabilities.vulnerability[_] }
      some j
      vuln := vulns[j]
      ratings := { e | e := vuln.ratings.rating.severity } | { e | e := vuln.ra
tings.rating[_].severity }
      not isSafe(vuln)
      msg = sprintf("CVE %s %s %s", [comp.name, vuln.id, ratings])
    }
EOF
```

3. (optional) The Tanzu Application Platform profiles install the Supply Chain Security Tools - Store package by default. To persist and query the vulnerability results post-scan, confirm it is installed by running:

   ```
   tanzu package installed get metadata-store -n tap-install
   ```

   If the package is not installed, follow the installation instructions at Install Supply Chain Security Tools - Store independent from Tanzu Application Platform profiles.

4. Update the profile to use the supply chain with testing and scanning by updating `tap-values.yaml` (the file used to customize the profile in `tanzu package install tap --values-file=...`) with the following changes:

   ```
   - supply_chain: testing
   + supply_chain: testing_scanning

   - ootb_supply_chain_testing:
   + ootb_supply_chain_testing_scanning:
       registry:
         server: "<SERVER-NAME>"
         repository: "<REPO-NAME>"
   ```

5. Update the `tap` package:

   ```
   tanzu package installed update tap -p tap.tanzu.vmware.com -v VERSION-NUMBER --
   values-file tap-values.yaml -n tap-install
   ```

   Where `VERSION-NUMBER` is your Tanzu Application Platform version. For example, `1.9.1`.

6. Because you set `supply_chain: testing_scanning` in your `tap-values.yaml` earlier, Grype Scanner for SCST - Scan is installed through Namespace Provisioner. Verify that Grype Scanner is present on your workload namespace:

   ```
   tanzu package installed get grype-scanner-YOUR-DEV-NAMESPACE -n tap-install
   ```

   To install Grype Scanner to multiple namespaces, VMware recommends using Namespace Provisioner. ScanTemplates with Grype scanner are automatically installed into namespaces created by Namespace Provisioner.

   Grype scanner must be present in the namespace that the workload is deployed to for scanning.

Workload update

To connect the new supply chain to the workload, update the workload to point to your Tekton pipeline:

1. Update the workload by running the following using the Tanzu CLI:

   ```
   tanzu apps workload apply tanzu-java-web-app \
     --git-repo https://github.com/vmware-tanzu/application-accelerator-samples \
     --sub-path tanzu-java-web-app \
     --git-branch main \
     --type web \
     --label apps.tanzu.vmware.com/has-tests=true \
     --label app.kubernetes.io/part-of=tanzu-java-web-app \
     --yes
   ```

2. After accepting the workload creation, view the new resources that the workload created by running:

   ```
   kubectl get workload,gitrepository,sourcescan,pipelinerun,images.kpack,imagesca
   n,podintent,app,services.serving
   ```

   The following is an example output, which shows the objects that Supply Chain Choreographer created:

   ```
   NAME                                     AGE
   workload.carto.run/tanzu-java-web-app   109s

   NAME                                                              URL
   READY   STATUS                                                                AGE

Important

If the source or image scan has a “Failed” phase this means that the scan failed due to a scan policy violation and the supply chain stops. For information about the CVE triage workflow, see Out of the Box Supply Chain with Testing and Scanning.

Query for vulnerabilities

Scan reports are automatically saved to the Supply Chain Security Tools - Store, and you can query them for vulnerabilities and dependencies. For example, related to open-source software (OSS) or third-party packages.

Query the tanzu-java-web-app image dependencies and vulnerabilities by running:

```
tanzu insight image get --digest DIGEST
tanzu insight image vulnerabilities --digest  DIGEST
```

Where `DIGEST` is the component version or image digest printed in the `KUBECTL GET` command.

For additional information and examples, see Tanzu Insight plug-in overview.

Congratulations! You have successfully added testing and security scanning to your application on the Tanzu Application Platform.

Take the next steps to learn about recommended supply chain security best practices and gain a powerful services journey experience on the Tanzu Application Platform by enabling several advanced use cases.

(Optional) Scan for vulnerabilities after build time

When you add the capability to scan image containers to your supply chain, you can detect vulnerabilities at build time. However, as new vulnerabilities are discovered and reported daily, it is important to frequently scan the container images to detect newly reported vulnerabilities.

You can enable recurring scanning to schedule periodic scans of images built by workloads and containers running in Tanzu Application Platform clusters. When you enable recurring scanning, an

option to **View Latest Scan Results** becomes available on the Supply Chain Choreographer plug-in. For how to enable recurring scanning, see Set up recurring scanning.

Next steps

- Configure image signing and verification in your supply chain

Add testing and scanning to your application

This topic guides you through installing the optional OOTB Supply Chain with Testing and the optional OOTB Supply Chain with Testing and Scanning.

For more information about available supply chains, see Supply chains on Tanzu Application Platform.

What you will do

- Install OOTB Supply Chain with Testing.
- Add a Tekton pipeline to the cluster and update the workload to point to the pipeline and resolve errors.
- Install OOTB Supply Chain with Testing and Scanning.
- Update the workload to point to the Tekton pipeline and resolve errors.
- Query for vulnerabilities and dependencies.
- (Optional) Enable recurring scanning for post-build scans.

Overview

The default Out of the Box (OOTB) Supply Chain Basic and its dependencies were installed on your cluster during the Tanzu Application Platform install. As demonstrated in this guide, you can add testing and security scanning to your application. When you activate OOTB Supply Chain with Testing, it deactivates OOTB Supply Chain Basic.

The following installations also provide a sample Tekton pipeline that tests your sample application. The pipeline is configurable. Therefore, you can customize the steps to perform either additional testing or other tasks with Tekton Pipelines.

Install OOTB Supply Chain with Testing

To install OOTB Supply Chain with Testing:

1. You can activate the OOTB Supply Chain with Testing by updating your profile to use `testing` rather than `basic` as the selected supply chain for workloads in this cluster. The `tap-values.yaml` is the file used to customize the profile in `Tanzu package install tap --values-file=...`. Update `tap-values.yaml` with the following changes:

```
- supply_chain: basic
+ supply_chain: testing

- ootb_supply_chain_basic:
+ ootb_supply_chain_testing:
    registry:
      server: "SERVER-NAME"
      repository: "REPO-NAME"
```

Where:

- `SERVER-NAME` is the name of your server.
- `REPO-NAME` is the name of the image repository that hosts the container images.

2. Update the installed profile by running:

```
tanzu package installed update tap -p tap.tanzu.vmware.com -v VERSION-NUMBER --
values-file tap-values.yaml -n tap-install
```

Where `VERSION-NUMBER` is your Tanzu Application Platform version. For example, `1.9.1`.

Tekton pipeline config example

In this section, a Tekton pipeline is added to the cluster. In the next section, the workload is updated to point to the pipeline and resolve any current errors.

Note

Developers can perform this step because they know how their application must be tested. The operator can also add the Tekton pipeline to a cluster before the developer gets access.

To add the Tekton pipeline to the cluster, apply the following YAML to the cluster:

```
apiVersion: tekton.dev/v1beta1
kind: Pipeline
metadata:
  name: developer-defined-tekton-pipeline
  namespace: DEVELOPER-NAMESPACE
  labels:
    apps.tanzu.vmware.com/pipeline: test     # (!) required
spec:
  params:
    - name: source-url                       # (!) required
    - name: source-revision                  # (!) required
  tasks:
    - name: test
      params:
        - name: source-url
          value: $(params.source-url)
        - name: source-revision
          value: $(params.source-revision)
      taskSpec:
        params:
          - name: source-url
          - name: source-revision
        steps:
          - name: test
            image: gradle
            script: |-
              cd `mktemp -d`

              wget -qO- $(params.source-url) | tar xvz -m
              ./mvnw test
```

Where `DEVELOPER-NAMESPACE` is the name of your developer namespace.

The preceding YAML puts a Tekton pipeline in the developer namespace you specify. It defines the Tekton pipeline with a single step. The step contained in the `steps` pulls the code from the repository indicated in the developers `workload` and runs the tests within the repository. The steps

of the Tekton pipeline are configurable and allow the developer to add additional items needed to test their code.

There are many steps in the supply chain. In this case, the next step is an image build. Any additional steps the developer adds to the Tekton pipeline to test their code are independent of the image being built and of any subsequent steps executed in the supply chain. This independence gives the developer freedom to focus on testing their code.

The `params` are templated by Supply Chain Choreographer. Additionally, Tekton pipelines require a Tekton `pipelineRun` to execute on the cluster. Supply Chain Choreographer handles creating the `pipelineRun` dynamically each time that step of the supply chain requires execution.

Workload update

To connect the new supply chain to the workload, the workload must be updated to point at your Tekton pipeline.

1. Update the workload by running the following with the Tanzu CLI:

   ```
   tanzu apps workload apply tanzu-java-web-app \
     --git-repo https://github.com/vmware-tanzu/application-accelerator-samples \
     --sub-path tanzu-java-web-app \
     --git-branch main \
     --type web \
     --label apps.tanzu.vmware.com/has-tests=true \
     --label app.kubernetes.io/part-of=tanzu-java-web-app \
     --yes
   ```

2. After accepting the workload creation, monitor the creation of new resources by the workload by running:

   ```
   kubectl get workload,gitrepository,pipelinerun,images.kpack,podintent,app,servi
   ces.serving
   ```

   The result is output similar to the following example that shows the objects created by Supply Chain Choreographer:

   ```
   NAME                                      AGE
   workload.carto.run/tanzu-java-web-app   109s

   NAME                                                              URL
   READY   STATUS                                                                AGE

Install OOTB Supply Chain with Testing and Scanning

To install OOTB Supply Chain with Testing and Scanning, you must install the Scan Controller and the Grype scanner.

Leveraging both Grype and Tanzu Build Service in your Tanzu Application Platform supply chain enables enhanced scanning coverage for languages and frameworks. For the languages and frameworks supported, see the *Extended Scanning Coverage using Anchore Grype* column in the Language and Framework Support Table.

To install OOTB Supply Chain with Testing and Scanning:

Note

The OOTB Supply Chain with Testing and Scanning capability has been changed to opt-in and is skipped by default starting in Tanzu Application Platform v1.6. For more information, see Scan Types.

1. Supply Chain Security Tools (SCST) - Scan is installed as part of the Tanzu Application Platform profiles. Verify that Scan Controller is installed by running:

   ```
   tanzu package installed get scanning -n tap-install
   ```

   If the package is not already installed, follow the steps in Supply Chain Security Tools - Scan to install the required scanning components.

2. Apply a ScanPolicy in the required namespace. The sample ScanPolicy provided in this step is configured with `notAllowedSeverities := ["Critical","High","UnknownSeverity"]`. This blocks a supply chain when the scanner finds CVEs with critical, high, and unknown ratings.

   You can also configure the supply chain to use your own custom policies and apply exceptions when you want to ignore certain CVEs. See Out of the Box Supply Chain with Testing and Scanning. To apply the sample ScanPolicy, you can either add the namespace flag to the kubectl command or add the namespace field to the template by running:

   ```
   kubectl apply -f - -o yaml << EOF
   ---
   apiVersion: scanning.apps.tanzu.vmware.com/v1beta1
   kind: ScanPolicy
   metadata:
     name: scan-policy
     labels:
       'app.kubernetes.io/part-of': 'enable-in-gui'
   spec:
     regoFile: |
       package main

       # Accepted Values: "Critical", "High", "Medium", "Low", "Negligible", "Unkn
   ownSeverity"
       notAllowedSeverities := ["Critical", "High", "UnknownSeverity"]
       ignoreCves := []
   ```

```
    contains(array, elem) = true {
      array[_] = elem
    } else = false { true }

    isSafe(match) {
      severities := { e | e := match.ratings.rating.severity } | { e | e := mat
ch.ratings.rating[_].severity }
      some i
      fails := contains(notAllowedSeverities, severities[i])
      not fails
    }

    isSafe(match) {
      ignore := contains(ignoreCves, match.id)
      ignore
    }

    deny[msg] {
      comps := { e | e := input.bom.components.component } | { e | e := input.b
om.components.component[_] }
      some i
      comp := comps[i]
      vulns := { e | e := comp.vulnerabilities.vulnerability } | { e | e := com
p.vulnerabilities.vulnerability[_] }
      some j
      vuln := vulns[j]
      ratings := { e | e := vuln.ratings.rating.severity } | { e | e := vuln.ra
tings.rating[_].severity }
      not isSafe(vuln)
      msg = sprintf("CVE %s %s %s", [comp.name, vuln.id, ratings])
    }
EOF
```

3. (optional) The Tanzu Application Platform profiles install the Supply Chain Security Tools - Store package by default. To persist and query the vulnerability results post-scan, confirm it is installed by running:

   ```
   tanzu package installed get metadata-store -n tap-install
   ```

   If the package is not installed, follow the installation instructions at Install Supply Chain Security Tools - Store independent from Tanzu Application Platform profiles.

4. Update the profile to use the supply chain with testing and scanning by updating `tap-values.yaml` (the file used to customize the profile in `tanzu package install tap --values-file=...`) with the following changes:

   ```
   - supply_chain: testing
   + supply_chain: testing_scanning

   - ootb_supply_chain_testing:
   + ootb_supply_chain_testing_scanning:
       registry:
         server: "<SERVER-NAME>"
         repository: "<REPO-NAME>"
   ```

5. Update the `tap` package:

   ```
   tanzu package installed update tap -p tap.tanzu.vmware.com -v VERSION-NUMBER --
   values-file tap-values.yaml -n tap-install
   ```

   Where `VERSION-NUMBER` is your Tanzu Application Platform version. For example, `1.9.1`.

6. Because you set `supply_chain: testing_scanning` in your `tap-values.yaml` earlier, Grype Scanner for SCST - Scan is installed through Namespace Provisioner. Verify that Grype Scanner is present on your workload namespace:

   ```
   tanzu package installed get grype-scanner-YOUR-DEV-NAMESPACE -n tap-install
   ```

   To install Grype Scanner to multiple namespaces, VMware recommends using Namespace Provisioner. ScanTemplates with Grype scanner are automatically installed into namespaces created by Namespace Provisioner.

   Grype scanner must be present in the namespace that the workload is deployed to for scanning.

Workload update

To connect the new supply chain to the workload, update the workload to point to your Tekton pipeline:

1. Update the workload by running the following using the Tanzu CLI:

   ```
   tanzu apps workload apply tanzu-java-web-app \
     --git-repo https://github.com/vmware-tanzu/application-accelerator-samples \
     --sub-path tanzu-java-web-app \
     --git-branch main \
     --type web \
     --label apps.tanzu.vmware.com/has-tests=true \
     --label app.kubernetes.io/part-of=tanzu-java-web-app \
     --yes
   ```

2. After accepting the workload creation, view the new resources that the workload created by running:

   ```
   kubectl get workload,gitrepository,sourcescan,pipelinerun,images.kpack,imagesca
   n,podintent,app,services.serving
   ```

   The following is an example output, which shows the objects that Supply Chain Choreographer created:

   ```
   NAME                                     AGE
   workload.carto.run/tanzu-java-web-app    109s

   NAME                                                                URL
   READY   STATUS                                                                  AGE

Important

If the source or image scan has a “Failed” phase this means that the scan failed due to a scan policy violation and the supply chain stops. For information about the CVE triage workflow, see Out of the Box Supply Chain with Testing and Scanning.

Query for vulnerabilities

Scan reports are automatically saved to the Supply Chain Security Tools - Store, and you can query them for vulnerabilities and dependencies. For example, related to open-source software (OSS) or third-party packages.

Query the tanzu-java-web-app image dependencies and vulnerabilities by running:

```
tanzu insight image get --digest DIGEST
tanzu insight image vulnerabilities --digest  DIGEST
```

Where `DIGEST` is the component version or image digest printed in the `KUBECTL GET` command.

For additional information and examples, see Tanzu Insight plug-in overview.

Congratulations! You have successfully added testing and security scanning to your application on the Tanzu Application Platform.

Take the next steps to learn about recommended supply chain security best practices and gain a powerful services journey experience on the Tanzu Application Platform by enabling several advanced use cases.

(Optional) Scan for vulnerabilities after build time

When you add the capability to scan image containers to your supply chain, you can detect vulnerabilities at build time. However, as new vulnerabilities are discovered and reported daily, it is important to frequently scan the container images to detect newly reported vulnerabilities.

You can enable recurring scanning to schedule periodic scans of images built by workloads and containers running in Tanzu Application Platform clusters. When you enable recurring scanning, an

option to **View Latest Scan Results** becomes available on the Supply Chain Choreographer plug-in. For how to enable recurring scanning, see Set up recurring scanning.

Next steps

- Configure image signing and verification in your supply chain

Configure image signing and verification in your supply chain

This topic guides you through configuring your Tanzu Application Platform (commonly known as TAP) supply chain to sign and verify your image builds.

What you will do

- Configure your supply chain to sign your image builds.
- Configure an admission control policy to verify image signatures before admitting pods to the cluster.

Configure your supply chain to sign and verify your image builds

1. Use Cosign to configure Tanzu Build Service to sign your container image builds. For instructions, see Configure Tanzu Build Service to sign your image builds.
2. Create a `values.yaml` file, and install the Supply Chain Security Tools - Policy Controller. For instructions, see Install Supply Chain Security Tools - Policy Controller.
3. Create a `ClusterImagePolicy` that passes Tanzu Application Platform images. It is planned for a future release for these to be signed and verifiable, but currently we recommend creating a policy to pass them:

   For example:

   ```
   kubectl apply -f - -o yaml << EOF
   ---
   apiVersion: policy.sigstore.dev/v1beta1
   kind: ClusterImagePolicy
   metadata:
     name: image-policy-exceptions
   spec:
     images:
     - glob: registry.example.org/myproject/*
     - glob: REPO-NAME*
     authorities:
     - static:
         action: pass
   EOF
   ```

   Where:

   - `REPO-NAME` is the repository in your registry where Tanzu Build Service dependencies are stored. This is the exact same value configured in the `kp_default_repository` inside your `tap-values.yaml` or `tbs-values.yaml` files. Examples:
     - Harbor has the form `"my-harbor.io/my-project/build-service"`.

        - Docker Hub has the form `"my-dockerhub-user/build-service"` or `"index.docker.io/my-user/build-service"`.
        - Google Cloud Registry has the form `"gcr.io/my-project/build-service"`.
    - Add any unsigned image that must run in your namespace to the previous policy. For example, if you add a Tekton pipeline that runs a Gradle image for testing, you need to add `glob: index.docker.io/library/gradle*` to `spec.images.glob` in the preceding code.
    - Replace `registry.example.org/myproject/*` with your target registry for your Tanzu Application Platform images. If you did not relocate the Tanzu Application Platform images to your own registry during installation, use `registry.tanzu.vmware.com/tanzu-application-platform/tap-packages*`.

4. Configure and apply a `ClusterImagePolicy` resource to the cluster to verify image signatures when deploying resources. For instructions, see Create a ClusterImagePolicy resource.

   For example:

   ```
   kubectl apply -f - -o yaml << EOF
   ---
   apiVersion: policy.sigstore.dev/v1beta1
   kind: ClusterImagePolicy
   metadata:
     name: example-policy
   spec:
     images:
     - glob: registry.example.org/myproject/*
     authorities:
     - key:
         data: |
           -----BEGIN PUBLIC KEY-----
           <content ...>
           -----END PUBLIC KEY-----
   EOF
   ```

5. Enable the policy controller verification in your namespace by adding the label `policy.sigstore.dev/include: "true"` to the namespace resource.

   For example:

   ```
   kubectl label namespace YOUR-NAMESPACE policy.sigstore.dev/include=true
   ```

   Where `YOUR-NAMESPACE` is the name of your secure namespace.

   > **Note**
   >
   > Supply Chain Security Tools - Policy Controller only validates resources in namespaces that have chosen to opt in.

When you apply the `ClusterImagePolicy` resource, your cluster requires valid signatures for all images that match the `spec.images.glob[]` you define in the configuration. For more information about configuring an image policy, see Configuring Supply Chain Security Tools - Policy.

Next steps

- Consume services on Tanzu Application Platform

Or learn more about Supply Chain Security Tools:

- Overview for Supply Chain Security Tools - Policy
- Configuring Supply Chain Security Tools - Policy
- Supply Chain Security Tools - Policy known issues

Integrate a plug-in into your Tanzu Developer Portal

This topic guides you through integrating the hello-world plug-in into your Tanzu Developer Portal by using the Configurator tool. The hello-world plug-in is a demonstration of the Configurator tool's capabilities.

For general information about the Tanzu Developer Portal Configurator and its basic concepts, see Overview of Configurator.

What you will do

- Create a customized Tanzu Developer Portal containing the hello-world plug-in
- Observe the customized Tanzu Developer Portal instance

Prerequisites

Before you start, you must have:

- All the Prerequisites for the getting started guide.
- The Tanzu Developer Portal Configurator bundle available (`tpb.tanzu.vmware.com`).

  To verify it's present, run:

  ```
  tanzu package available list --namespace tap-install | grep tpb.tanzu.vmware.com
  ```

- An instance of the canonical Tanzu Developer Portal.

  To get the fully-qualified domain name for the portal, run:

  ```
  kubectl get httpproxy tap-gui -n tap-gui
  ```

  Note

  By default, Tanzu Developer Portal uses a self-signed certificate and might cause a security error in the browser. To address this error, see Configure a TLS certificate by using an existing certificate.

Customize your Tanzu Developer Portal by adding the hello-world plug-in

To integrate the hello-world plug-in into your Tanzu Developer Portal:

1. Create the **tpb-config.yaml** file specifying the list of additional plug-ins that you want to integrate. In this example, you only specify the hello-world plug-in that has both front end and back end parts:

   ```
   app:
     plugins:
       - name: '@tpb/plugin-hello-world'
   ```

```
        version: '^1.6.0-release-1.6.x.1'
    backend:
      plugins:
        - name: '@tpb/plugin-hello-world-backend'
          version: '^1.6.0-release-1.6.x.1'
```

Note

If the version of the plug-in is not specified, the workload that uses the config file as input is likely to fail.

2. Encode the file in base64, to later embed `tpb-config.yaml` in the workload definition file, by running:

```
base64 -i tdp-config.yaml
```

Example output:

```
YXBwOgogIHBsdWdpbnM6CiAgICAtIG5hbWU6ICdAdHBiL3BsdWdpbi1oZWxsby13b3JsZCcKICAgICA
gdmVyc2lvbjogJ14xLjYuMC1yZWxlYXNlLTEuNi54LjEnIApiYWNrZW5kOgogIHBsdWdpbnM6CiAgIC
AtIG5hbWU6ICdAdHBiL3BsdWdpbi1oZWxsby13b3JsZC1iYWNrZW5kJwogICAgICB2ZXJzaW9uOiAnX
jEuNi4wLXJlbGVhc2UtMS42LnguMScK
```

You use this value later as `ENCODED-TDP-CONFIG-VALUE`.

3. Identify the location of the Configurator's image by running these commands:

```
export OUTPUT_IMAGE=$(kubectl -n tap-install get package tpb.tanzu.vmware.com.
0.1.2 -o "jsonpath={.spec.template.spec.fetch[0].imgpkgBundle.image}")
```

```
imgpkg pull -b ${OUTPUT_IMAGE} -o tpb-package
```

```
yq -r ".images[0].image" <tpb-package/.imgpkg/images.yml
```

You use this value later as `TDP-IMAGE-LOCATION`.

4. Prepare your workload definition file. Create a file called `tdp-workload.yaml` with the following content:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: tdp-configurator
  namespace: DEVELOPER-NAMESPACE
  labels:
    apps.tanzu.vmware.com/workload-type: web
    app.kubernetes.io/part-of: tdp-configurator
spec:
  build:
    env:
      - name: BP_NODE_RUN_SCRIPTS
        value: 'set-tpb-config,portal:pack'
      - name: TPB_CONFIG
        value: /tmp/tpb-config.yaml
      - name: TPB_CONFIG_STRING
        value: ENCODED-TDP-CONFIG-VALUE

  source:
    image: TDP-IMAGE-LOCATION
    subPath: builder
```

Where:

- `DEVELOPER-NAMESPACE` is the developer namespace configured on the cluster.
- `ENCODED-TDP-CONFIG-VALUE` is the base64-encoded **tpb-config.yaml** that you encoded earlier.
- `TDP-IMAGE-LOCATION` is the location of the Configurator image that you identified earlier.

Important

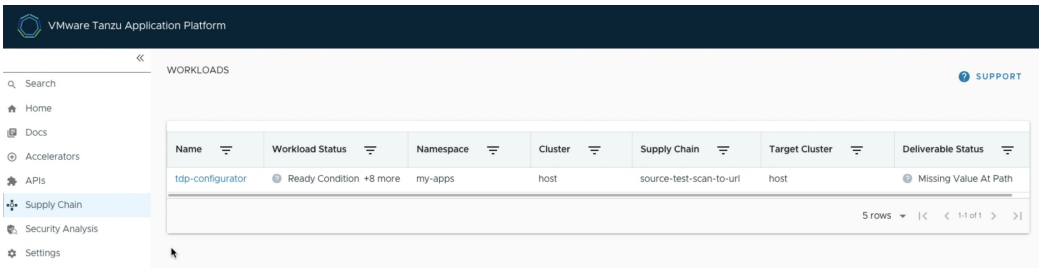
Depending on which supply chain you're using and how you configured it, you might have to add extra sections to your workload definition file to accommodate activities such as testing.

5. Deploy your workload on your Tanzu Application Platform cluster by running:

```
tanzu apps workload create -f tdp-workload.yaml -n DEVELOPER-NAMESPACE
```

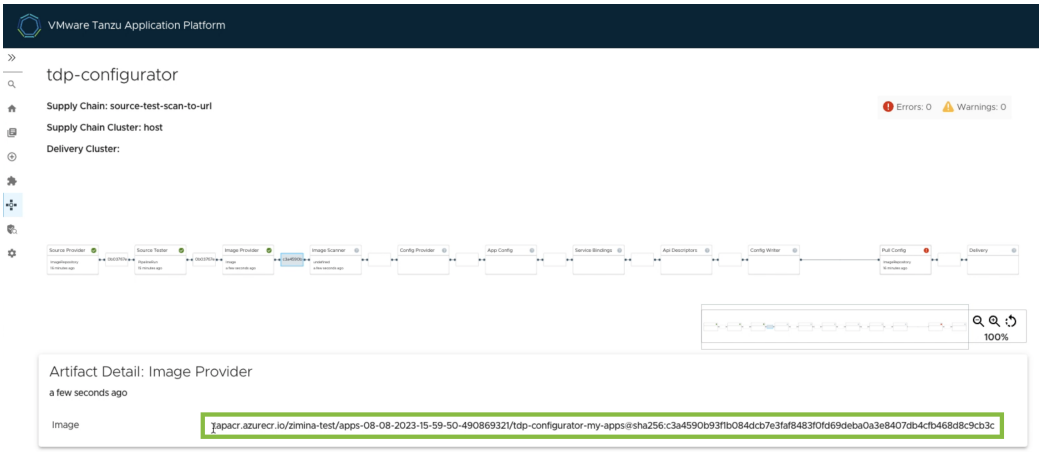
Where `DEVELOPER-NAMESPACE` is the developer namespace configured on the cluster.

6. After the workload has deployed, view it in the **Supply Chains** tab of the Tanzu Developer Portal.



Wait for the **Image Provider** step of the supply chain to complete.

7. From the **Supply Chains** tab of the Tanzu Developer Portal, click the box that follows the **Image Provider** step and copy the address to the customized Tanzu Developer Portal's image from the **Artifact Detail: Image Provider** section.



You use this value as `IMAGE-REFERENCE` in the next step.

8. Create the **tdp-overlay-secret.yaml** to insert the new image into the Tanzu Developer Portal instance.

```
apiVersion: v1
kind: Secret
metadata:
  name: tpb-app-image-overlay-secret
  namespace: tap-install
stringData:
  tpb-app-image-overlay.yaml: |
    #@ load("@ytt:overlay", "overlay")

    #! makes an assumption that tap-gui is deployed in the namespace: "tap-gui"
    #@overlay/match by=overlay.subset({"kind": "Deployment", "metadata": {"nam
e": "server", "namespace": "tap-gui"}}), expects="1+"
    ---
    spec:
      template:
        spec:
          containers:
            #@overlay/match by=overlay.subset({"name": "backstage"}),expects="1
+"
            #@overlay/match-child-defaults missing_ok=True
            - image: IMAGE-REFERENCE
            #@overlay/replace
              args:
              - -c
              - |
                export KUBERNETES_SERVICE_ACCOUNT_TOKEN="$(cat /var/run/secret
s/kubernetes.io/serviceaccount/token)"
                exec /layers/tanzu-buildpacks_node-engine-lite/node/bin/node po
rtal/dist/packages/backend  \
                --config=portal/app-config.yaml \
                --config=portal/runtime-config.yaml \
                --config=/etc/app-config/app-config.yaml
```

Where `IMAGE-REFERENCE` is address of the customized Tanzu Developer Portal image identified in the previous step.

Important

Any changes in the overlay of the YAML file will cause an error.

9. Deploy the secret to the Tanzu Application Platform cluster by running:

```
kubectl apply -f tdp-overlay-secret.yaml
```

10. Amend the `tap-values.yaml` file to include the overlay secret by adding the following lines:

```
    profile: full
    tap_gui:
      ...
    package_overlays:
    - name: tap-gui
      secrets:
      - name: tpb-app-image-overlay-secret
```

11. Apply the new `tap-values.yaml` to your cluster. The exact steps vary depending on your installation method such as GitOps, online install, or offline install.

    For how to do so for an online installation, see Install your Tanzu Application Platform package.

    For example, you can use the following Tanzu CLI command:

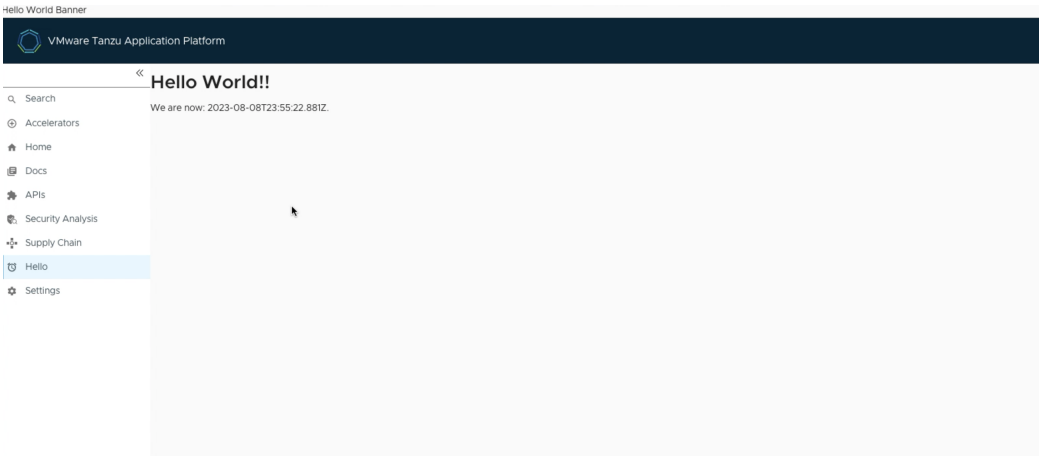
```
tanzu package installed update tap -f tap-values.yaml -n tap-install
```

12. After all packages have reconciled, the Tanzu Developer Portal pod restarts and your customized portal takes the place of the default one.

> **Note**
>
> You might have to clear your browser cache or hard refresh to see the updated Tanzu Developer Portal.

If the old Tanzu Developer Portal pod does not automatically delete, manually delete it by running:

```
kubectl delete pod POD-NAME -n tap-gui
```



Next steps

Now that you have your hello-world plug-in integrated into your Tanzu Developer Portal, explore how to Add external plug-ins to Tanzu Developer Portal.

Generate an application with Application Accelerator

This topic guides you through how to generate a new project using Application Accelerator and how to deploy the project onto a Tanzu Application Platform (commonly known as TAP) cluster. For background information, see Application Accelerator.

Prerequisites

Before you start, complete all Getting Started prerequisites.

Generate a project using an Application Accelerator

There are multiple interfaces that you can use to generate a new project. The options are:

- Application Accelerator extension for VS Code
- Application Accelerator plug-in for IntelliJ
- Tanzu Developer Portal

Choose one of the following tabs for how to generate and deploy applications using your selected interface. If you have already generated a project and want to skip this step, you can go to Deploying your application with Tanzu Application Platform.

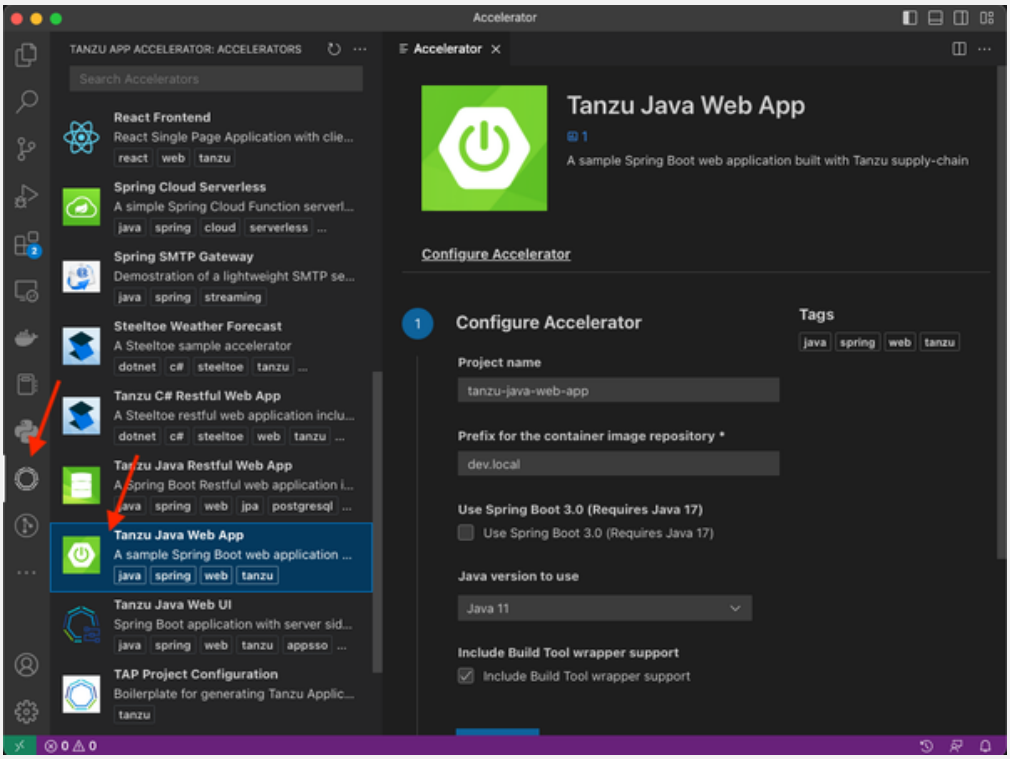
VS Code

What you will do:

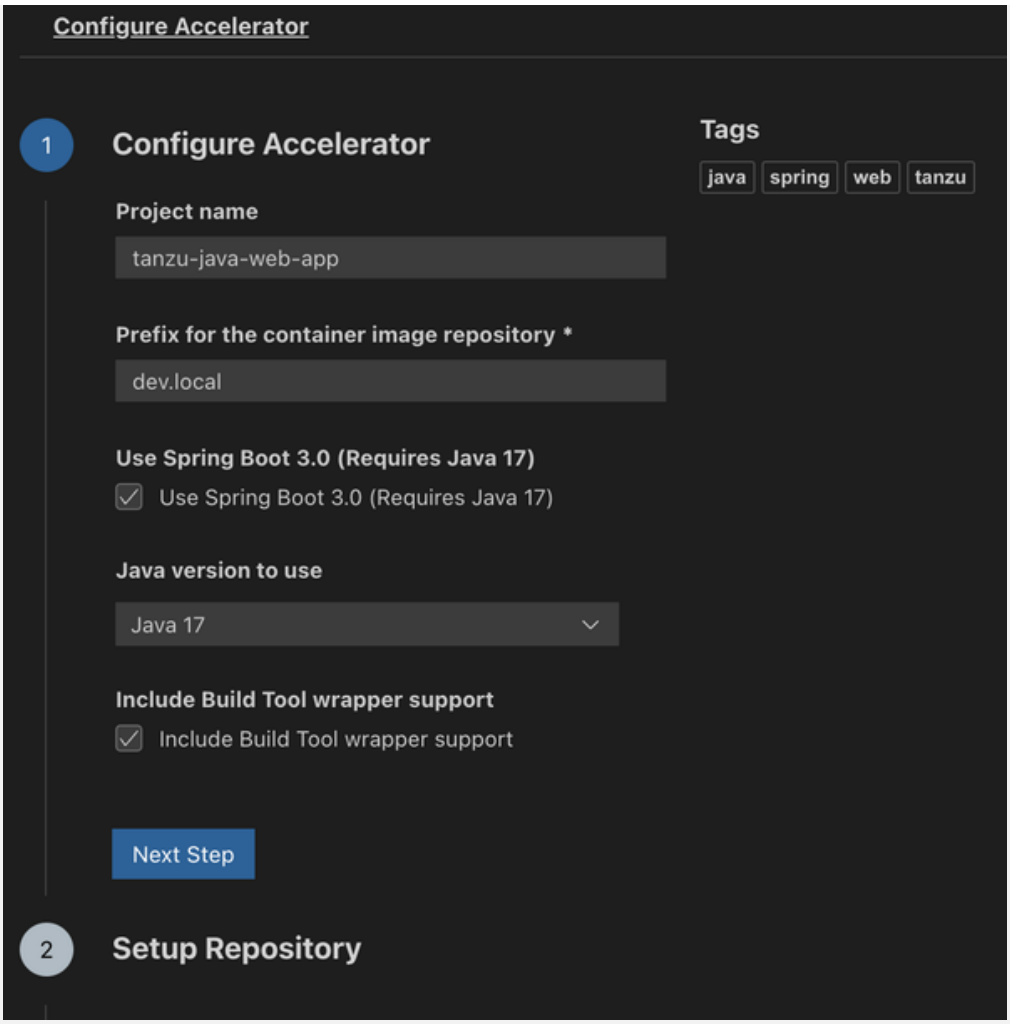
- Install the Application Accelerator extension for VS Code.
- (Optional) Provision a new GitHub repository and upload the project to the repository.
- Generate a project using an Application Accelerator.

To generate a new project using an Application Accelerator:

1. Install and configure the Application Accelerator extension for VS Code, see Application Accelerator Visual Studio Code extension.
2. Select an accelerator from the catalog. This example uses `Tanzu Java Web App`.



3. In **Configure Accelerator**, configure the accelerator as defined by your project's requirements. This example configures the project to use Spring Boot v3.0 and Java v17.



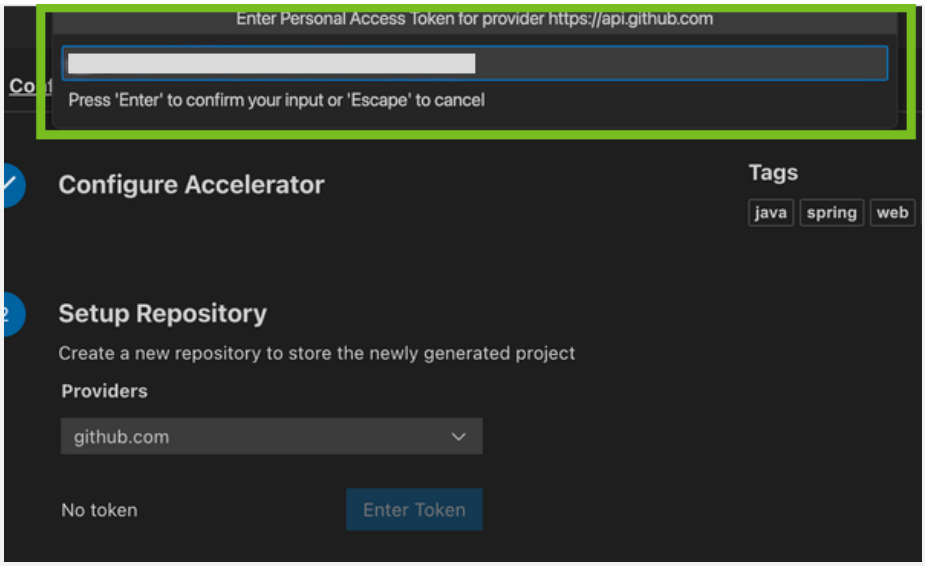
4. Click **Next Step**.
5. If your organization's Tanzu Application Platform is configured for Git repository creation, configure the **Setup Repository** step using the following sub-steps. If not, click **Skip** and go to step 5.

   Note

   For information about configuring optional Git repository creation and supported repositories, see Create an Application Accelerator Git repository during project creation.

   1. Using the **Providers** drop-down menu, select your Git provider. For example, `github.com`.
   2. After you select the provider, a dialog box appears for you to enter an API token for your Git provider. Populate the text box with your provider's API token and press Enter.

      This API key must be able to create new repositories for an organization or user. For information about how to create an API token for Git repository creation, see Creating a personal access token in the GitHub documentation.



3. In the **Owner** text box, enter the name of either the GitHub organization or user name to create the repository under.
4. In the **Repository Name** text box, enter the name of the project repository.
5. In the **Repository Branch** text box, enter the name of the default branch for the project repository. Typically, this is set to `main`.
6. Click **Next Step**.

6. In the **Review and Generate** step, verify that all the information you provided is accurate, then click **Generate Project**.
7. A dialog box appears for you to choose a location for the project to be stored on the local file system. Choose a directory or create a new one.
8. After the project has generated, a second dialog box appears for you to open the new project in a new window. Click **Yes**.
9. When opened, the project is ready for development.

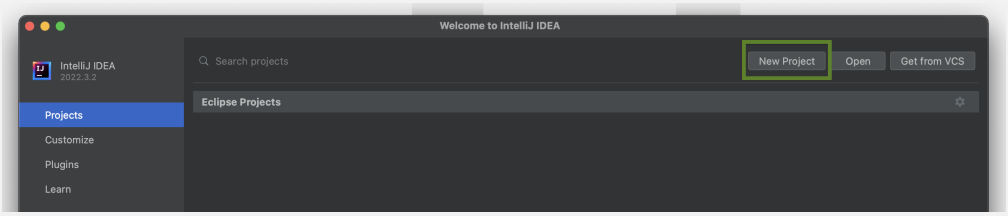
IntelliJ

What you will do:

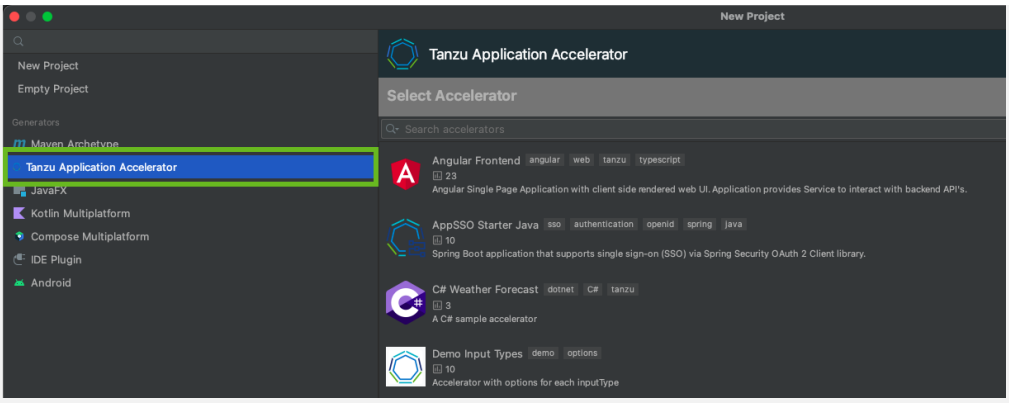
- Install the Application Accelerator plug-in for IntelliJ.
- Generate a project using an Application Accelerator.

To generate a new project using an Application Accelerator:

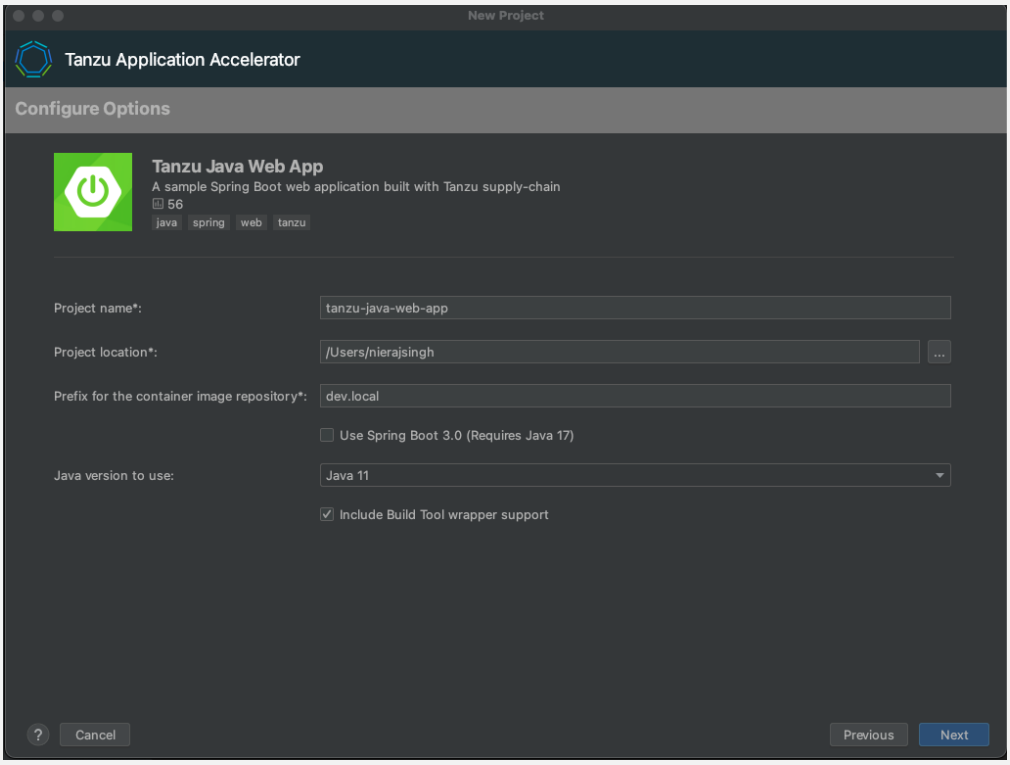
1. Install and configure the Application Accelerator plug-in for IntelliJ, see Application Accelerator plugin for IntelliJ.
2. On the Welcome to IntelliJ IDEA page, click **New Project**.



3. Click **Tanzu Application Accelerator** in the left side panel.



4. Select an accelerator from the catalog. This example uses `Tanzu Java Web App`.
5. Click **Next**.
6. In the **Configure Options** step, configure the accelerator as defined by your project's requirements.



7. Click **Next**.
8. In the **Review and Generate** step, verify that all the information provided is accurate then click **Next**.
9. After the project has generated, click **Create** to open the new project in IntelliJ.
10. When opened, the project is ready for development.

Tanzu Developer Portal

In this example, you use the `Tanzu-Java-Web-App` accelerator. You also use Tanzu Developer Portal. For information about connecting to Tanzu Developer Portal, see Access Tanzu Developer Portal.

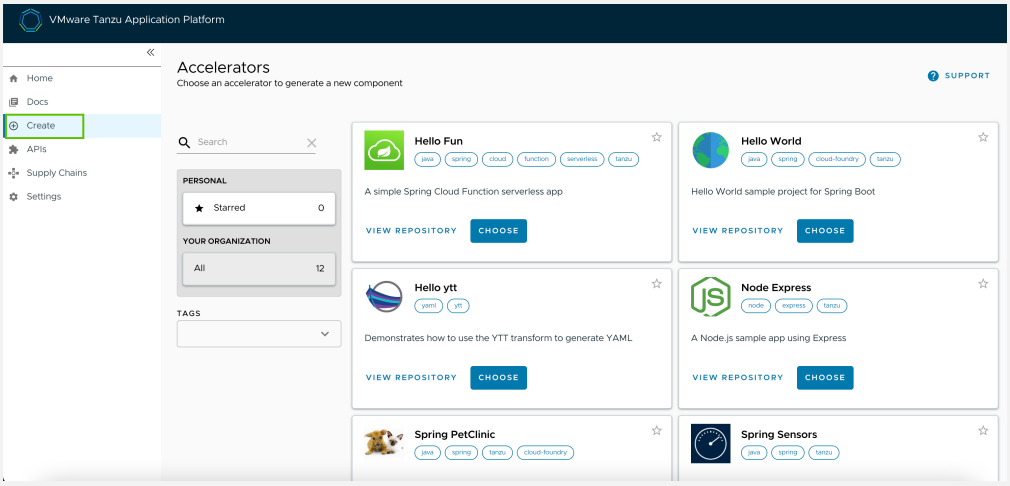
What you will do:

- Generate a project from an Application Accelerator.
- (Optional) Provision a new Git repository for the project.

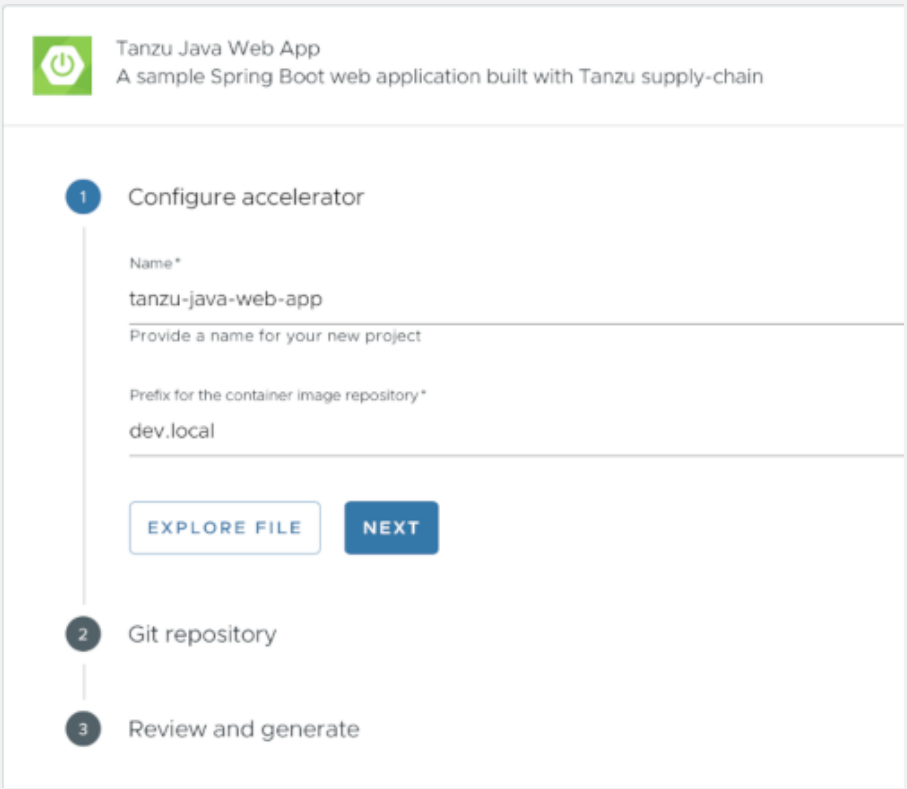
- Upload it to your Git repository of choice.

To generate a new project using an Application Accelerator:

1. From Tanzu Developer Portal, click **Create** located on the left side of the navigation pane to see the list of available accelerators.



2. Locate the Tanzu Java Web App accelerator and click **CHOOSE**.
3. In the **Generate Accelerators** dialog box, replace the default value `dev.local` in the **prefix for container image registry** text box with the registry in the form of `SERVER-NAME/REPO-NAME`. The `SERVER-NAME/REPO-NAME` must match what was specified for `registry` as part of the installation values for `ootb_supply_chain_basic`. See the Full Profile section on Installing Tanzu Application Platform package and../install-online/install.hbs.md profiles.

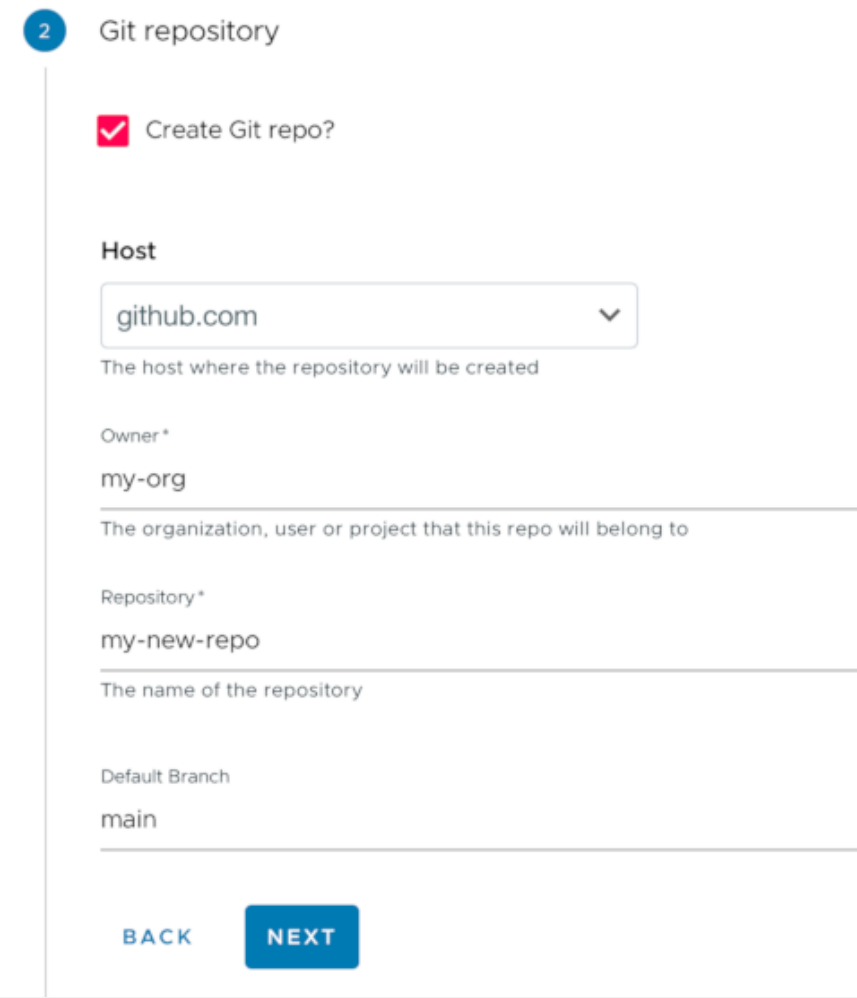


4. Click **NEXT**.
5. If your instance has optional Git repository support enabled, continue with the following sub-steps. If your instance does not support this, skip to step 5.

Note

For information about configuring optional Git repository creation and supported repositories, see Create an Application Accelerator Git repository during project creation.

1. Select the **Create Git repo?** check box.
2. Select the host Git repository provider from the **Host** drop-down menu. For example, `github.com`.
3. Populate the **Owner** and **Repository** text boxes.



4. While you are populating the form, a dialog box appears asking for permission to provision Git repositories. Follow the prompts and continue.
5. Click **NEXT**.
6. Verify the provided information, and click **GENERATE ACCELERATOR**.
7. After the Task Activity processes complete, click **DOWNLOAD ZIP FILE**.
8. After downloading the ZIP file, expand it in a workspace directory. If you did not create a Git repository in the preceding steps, follow your preferred procedure for uploading the generated project files to a Git repository for your new project.

Learn more about Application Accelerator

- For information about how to configure optional Git repository creation, see Configure in *Create an Application Accelerator Git repository during project creation*.
- For information about Application Accelerator configurations, see Configure Application Accelerator.
- For information about installing the Application Accelerator extension for Visual Studio Code, see Application Accelerator Visual Studio Code extension.
- For general accelerator troubleshooting, see Troubleshooting Application Accelerator for VMware Tanzu.

Next Steps

Now that you have generated a project that is ready for Tanzu Application Platform, learn how to quickly deploy the application on a Tanzu Application Platform cluster in Deploy an app on Tanzu Application Platform.

Generate an application with Application Accelerator

This topic guides you through how to generate a new project using Application Accelerator and how to deploy the project onto a Tanzu Application Platform (commonly known as TAP) cluster. For background information, see Application Accelerator.

Prerequisites

Before you start, complete all Getting Started prerequisites.

Generate a project using an Application Accelerator

There are multiple interfaces that you can use to generate a new project. The options are:

- Application Accelerator extension for VS Code
- Application Accelerator plug-in for IntelliJ
- Tanzu Developer Portal

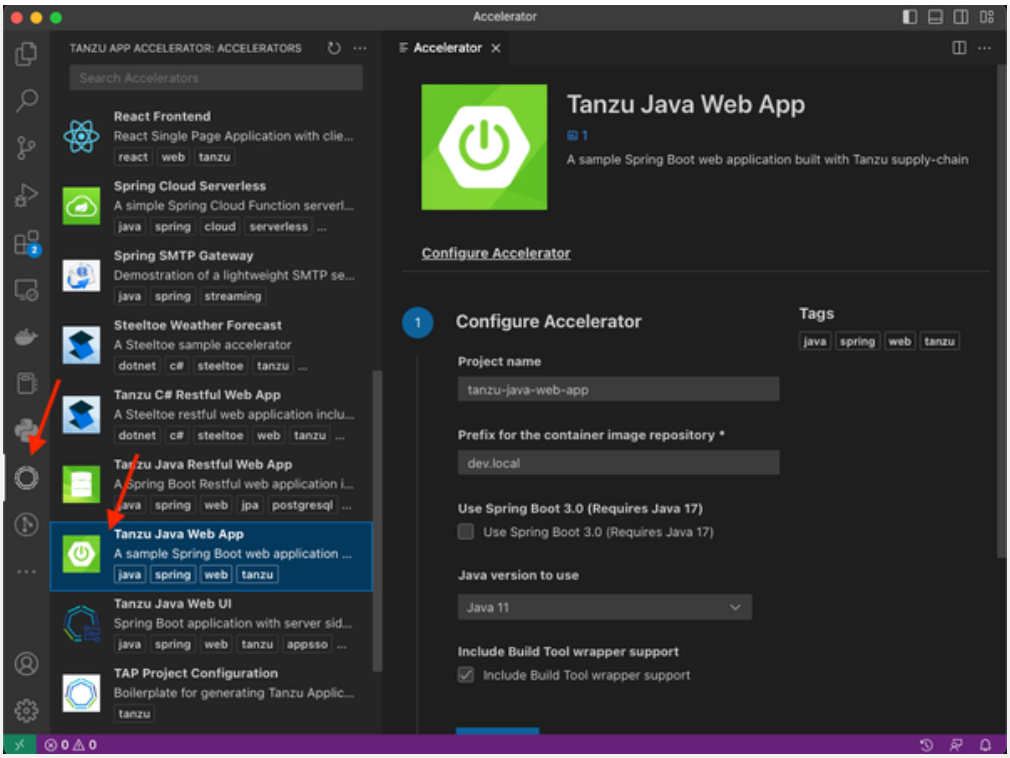
Choose one of the following tabs for how to generate and deploy applications using your selected interface. If you have already generated a project and want to skip this step, you can go to Deploying your application with Tanzu Application Platform.

VS Code
What you will do:

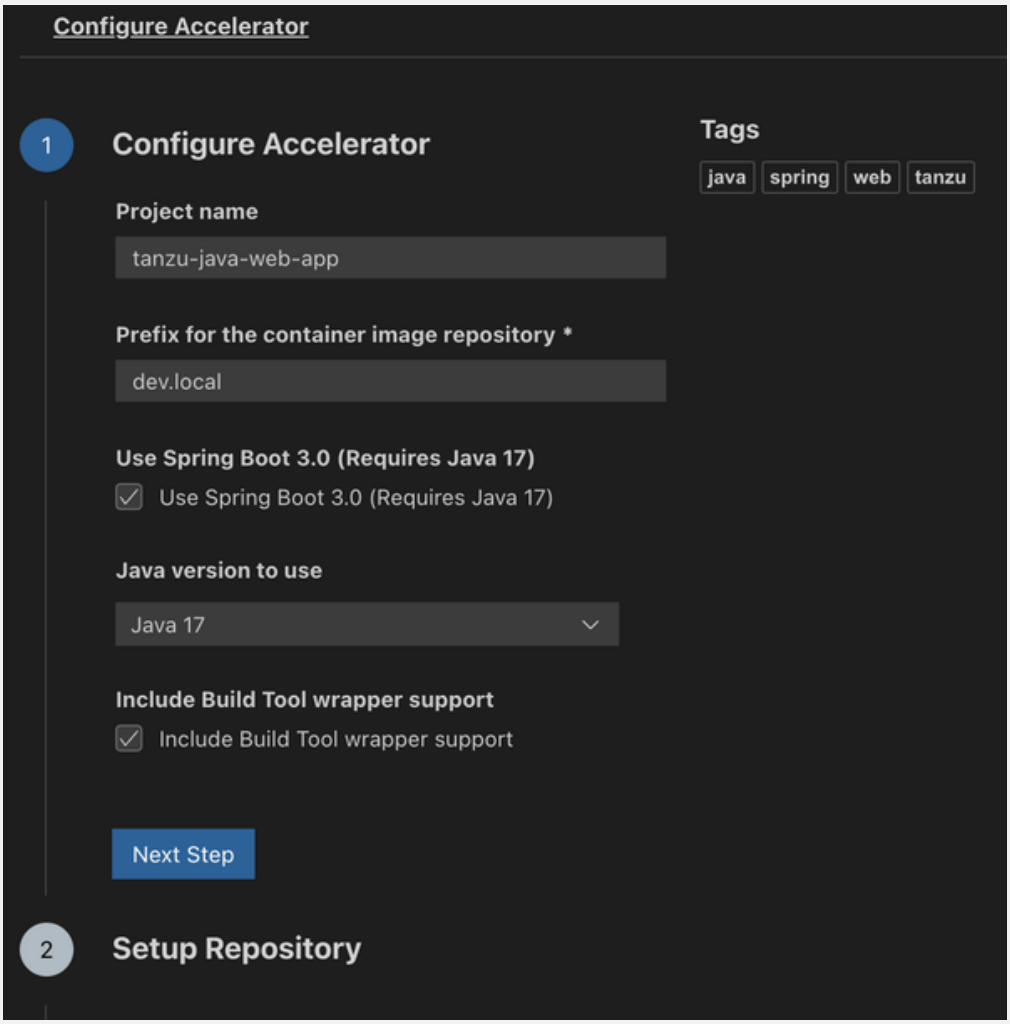
- Install the Application Accelerator extension for VS Code.
- (Optional) Provision a new GitHub repository and upload the project to the repository.
- Generate a project using an Application Accelerator.

To generate a new project using an Application Accelerator:

1. Install and configure the Application Accelerator extension for VS Code, see Application Accelerator Visual Studio Code extension.
2. Select an accelerator from the catalog. This example uses `Tanzu Java Web App`.



3. In **Configure Accelerator**, configure the accelerator as defined by your project's requirements. This example configures the project to use Spring Boot v3.0 and Java v17.



4. Click **Next Step**.
5. If your organization's Tanzu Application Platform is configured for Git repository creation, configure the **Setup Repository** step using the following sub-steps. If not, click **Skip** and go to step 5.

   > **Note**
   >
   > For information about configuring optional Git repository creation and supported repositories, see Create an Application Accelerator Git repository during project creation.

   1. Using the **Providers** drop-down menu, select your Git provider. For example, `github.com`.
   2. After you select the provider, a dialog box appears for you to enter an API token for your Git provider. Populate the text box with your provider's API token and press Enter.

      This API key must be able to create new repositories for an organization or user. For information about how to create an API token for Git repository creation, see Creating a personal access token in the GitHub documentation.

      
   3. In the **Owner** text box, enter the name of either the GitHub organization or user name to create the repository under.
   4. In the **Repository Name** text box, enter the name of the project repository.
   5. In the **Repository Branch** text box, enter the name of the default branch for the project repository. Typically, this is set to `main`.
   6. Click **Next Step**.
6. In the **Review and Generate** step, verify that all the information you provided is accurate, then click **Generate Project**.
7. A dialog box appears for you to choose a location for the project to be stored on the local file system. Choose a directory or create a new one.
8. After the project has generated, a second dialog box appears for you to open the new project in a new window. Click **Yes**.
9. When opened, the project is ready for development.

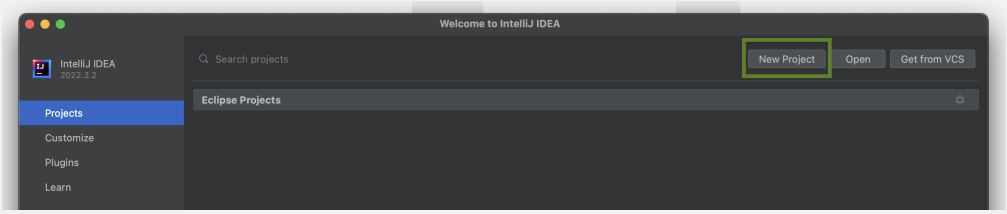
IntelliJ

What you will do:

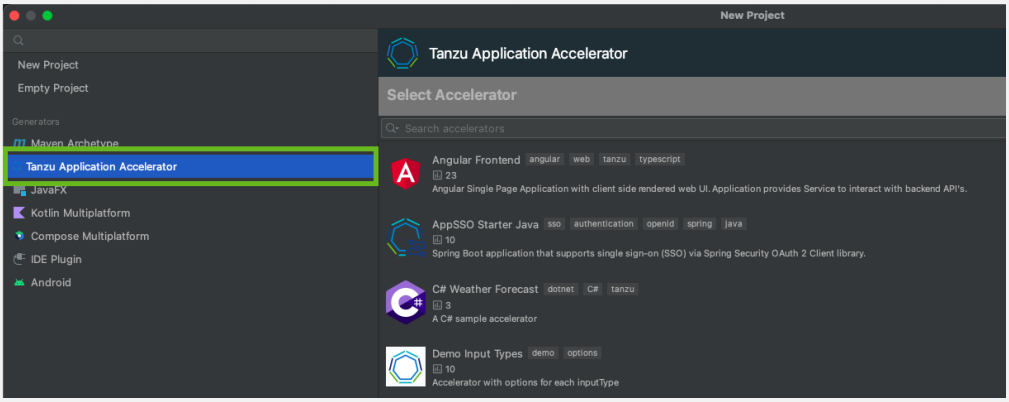
- Install the Application Accelerator plug-in for IntelliJ.
- Generate a project using an Application Accelerator.

To generate a new project using an Application Accelerator:

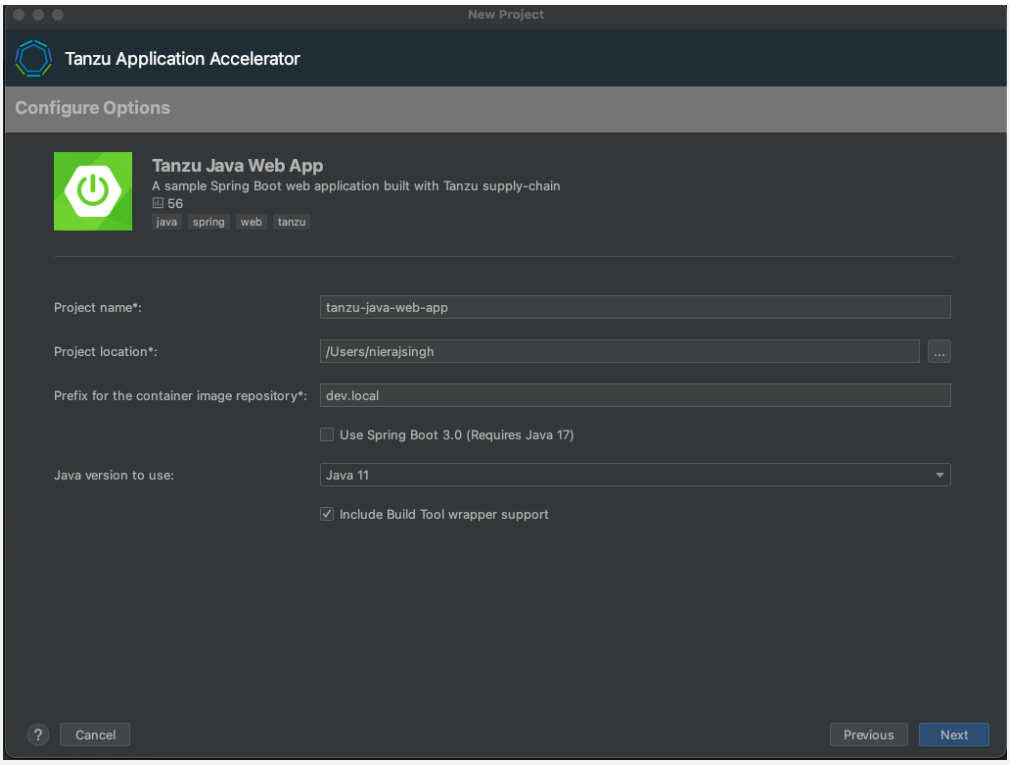
1. Install and configure the Application Accelerator plug-in for IntelliJ, see Application Accelerator plugin for IntelliJ.
2. On the Welcome to IntelliJ IDEA page, click **New Project**.



3. Click **Tanzu Application Accelerator** in the left side panel.



4. Select an accelerator from the catalog. This example uses `Tanzu Java Web App`.
5. Click **Next**.
6. In the **Configure Options** step, configure the accelerator as defined by your project's requirements.



7. Click **Next**.
8. In the **Review and Generate** step, verify that all the information provided is accurate then click **Next**.
9. After the project has generated, click **Create** to open the new project in IntelliJ.
10. When opened, the project is ready for development.

Tanzu Developer Portal

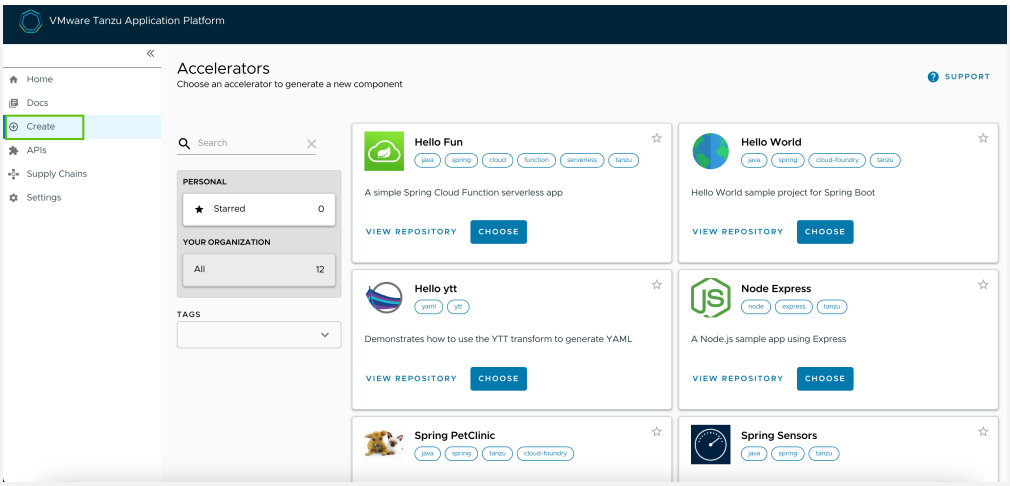
In this example, you use the `Tanzu-Java-Web-App` accelerator. You also use Tanzu Developer Portal. For information about connecting to Tanzu Developer Portal, see Access Tanzu Developer Portal.

What you will do:

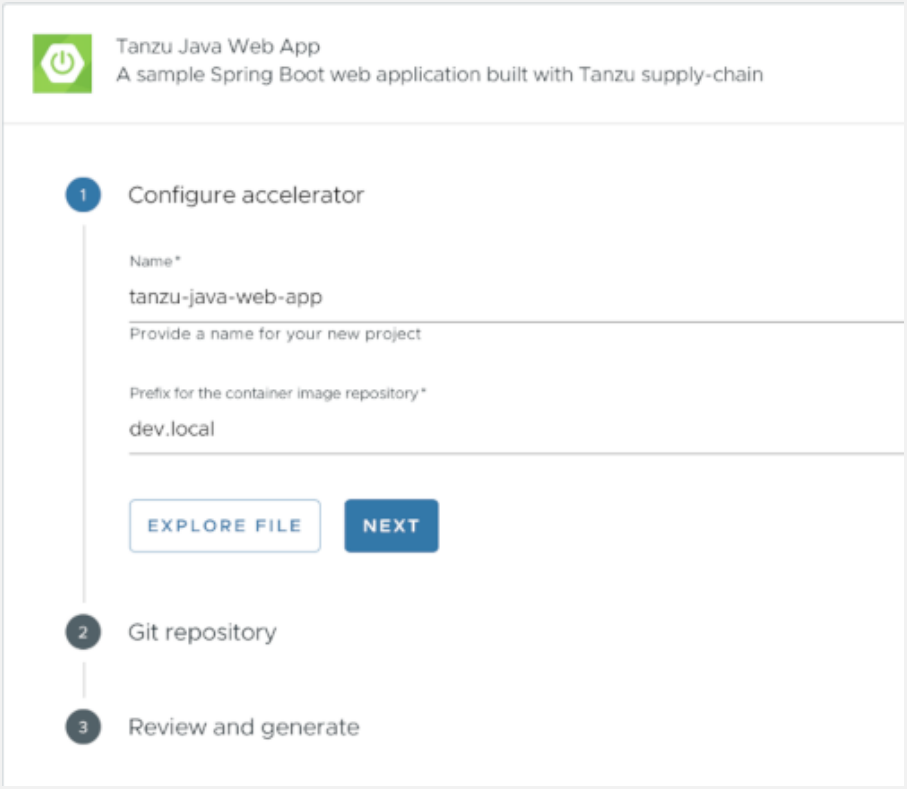
- Generate a project from an Application Accelerator.
- (Optional) Provision a new Git repository for the project.
- Upload it to your Git repository of choice.

To generate a new project using an Application Accelerator:

1. From Tanzu Developer Portal, click **Create** located on the left side of the navigation pane to see the list of available accelerators.



2. Locate the Tanzu Java Web App accelerator and click **CHOOSE**.
3. In the **Generate Accelerators** dialog box, replace the default value `dev.local` in the **prefix for container image registry** text box with the registry in the form of `SERVER-NAME/REPO-NAME`. The `SERVER-NAME/REPO-NAME` must match what was specified for `registry` as part of the installation values for `ootb_supply_chain_basic`. See the Full Profile section on Installing Tanzu Application Platform package and../install-online/install.hbs.md profiles.

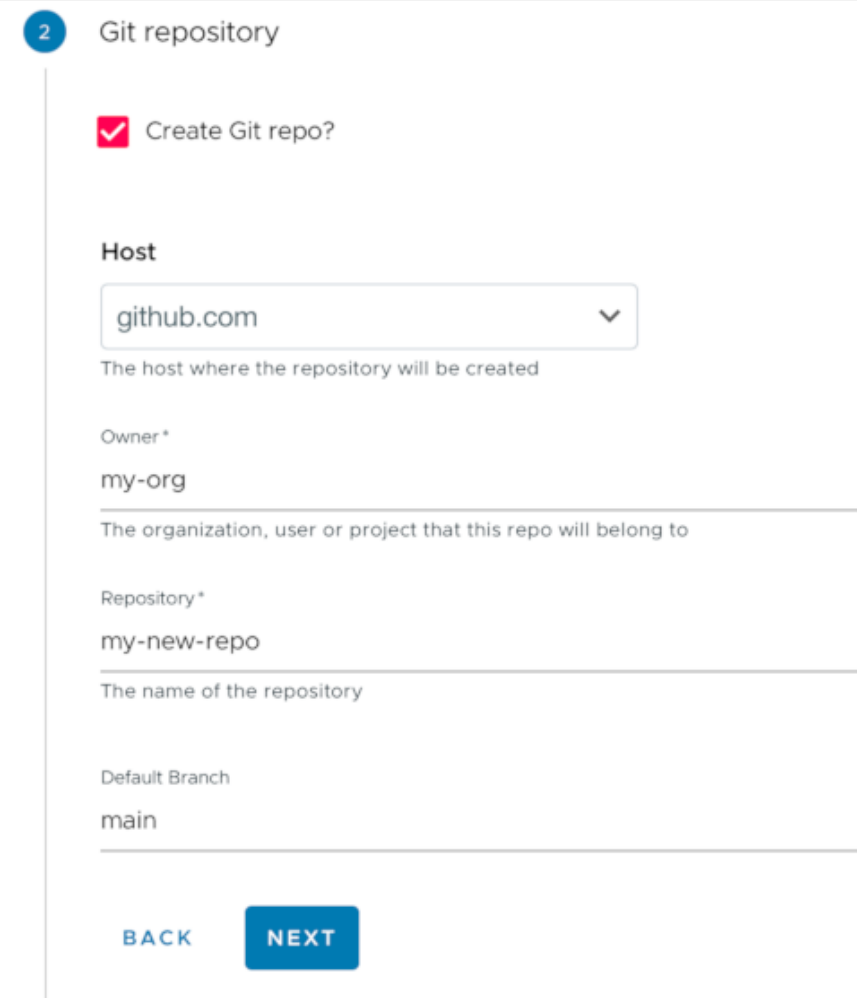


4. Click **NEXT**.
5. If your instance has optional Git repository support enabled, continue with the following sub-steps. If your instance does not support this, skip to step 5.

Note

For information about configuring optional Git repository creation and supported repositories, see Create an Application Accelerator Git repository during project creation.

1. Select the **Create Git repo?** check box.
2. Select the host Git repository provider from the **Host** drop-down menu. For example, `github.com`.
3. Populate the **Owner** and **Repository** text boxes.



4. While you are populating the form, a dialog box appears asking for permission to provision Git repositories. Follow the prompts and continue.
5. Click **NEXT**.
6. Verify the provided information, and click **GENERATE ACCELERATOR**.
7. After the Task Activity processes complete, click **DOWNLOAD ZIP FILE**.
8. After downloading the ZIP file, expand it in a workspace directory. If you did not create a Git repository in the preceding steps, follow your preferred procedure for uploading the generated project files to a Git repository for your new project.

Learn more about Application Accelerator

- For information about how to configure optional Git repository creation, see Configure in *Create an Application Accelerator Git repository during project creation*.
- For information about Application Accelerator configurations, see Configure Application Accelerator.
- For information about installing the Application Accelerator extension for Visual Studio Code, see Application Accelerator Visual Studio Code extension.
- For general accelerator troubleshooting, see Troubleshooting Application Accelerator for VMware Tanzu.

Next Steps

Now that you have generated a project that is ready for Tanzu Application Platform, learn how to quickly deploy the application on a Tanzu Application Platform cluster in Deploy an app on Tanzu Application Platform.

Deploy an app on Tanzu Application Platform

This topic guides you through deploying your first application on Tanzu Application Platform (commonly known as TAP) by using the Tanzu CLI, and optionally adding your application to the Tanzu Developer Portal software catalog.

This guide is a continuation from the previous step, Generate an application with Application Accelerator.

What you will do

- Deploy an app using the Tanzu CLI.
- View the build and runtime logs for your app.
- View the web app in your browser.
- (Optional) Add your application to Tanzu Developer Portal software catalog.

Prerequisites

Before you start, you must have:

- Completed all Getting Started prerequisites.
- Created a project. To do so, you can follow the steps in Generate an application with Application Accelerator.
- Created a Git repository during the project creation stage. If the project does not have an associated Git repository, create a repository and update the `workload.yaml` the repository URL and branch.

Deploy your application using the Tanzu CLI

Complete the following steps to deploy your application using the Tanzu CLI.

Prerequisites

Ensure that you meet the following prerequisites:

- Before you deploy your application using the Tanzu CLI, ensure that you have created a Git repository during the project creation stage.

- If the project does not have an associated Git repository, you must create one, and then update the `workload.yaml` with the repository URL and branch.

Procedure

1. Deploy the Tanzu Java Web App project that you generated in Generate an application with Application Accelerator by running the `tanzu apps workload create` command:

   ```
   tanzu apps workload create --file config/workload.yaml --namespace YOUR-NAMESPA
   CE
   ```

   Alternatively, you can create a workload using the command line:

   ```
   tanzu apps workload create tanzu-java-web-app \
   --git-repo GIT-REPO-URL \
   --git-branch main \
   --type web \
   --label app.kubernetes.io/part-of=tanzu-java-web-app \
   --label apps.tanzu.vmware.com/has-tests="true" \
   --yes \
   --namespace YOUR-NAMESPACE
   ```

   Where:

   - `GIT-REPO-URL` is the Git repository URL for where your project is stored. For example, `https://github.com/vmware-tanzu/my-tanzu-java-web-app-project`.
   - `YOUR-NAMESPACE` is the namespace where workloads are deployed. For example, `my-app-dev-namespace`. This depends on your organization's Tanzu Application Platform configuration. For more information, consult with your Tanzu Application Platform administrators.

   For more information, see Create or update a workload.

2. View the build and runtime logs for your app by running the `get` command:

   ```
   tanzu apps workload get tanzu-java-web-app --namespace YOUR-DEVELOPER-NAMESPACE
   ```

   Where `YOUR-DEVELOPER-NAMESPACE` is the namespace configured earlier.

   Note

   To watch updates in real time, prepend `watch -n1` to the `tanzu apps workload get` command to see the result update every second.

   An example of the output from an early-stage deployment looks like the following:

   ```
   Overview
       name:         tanzu-java-web-app
       type:         web
       namespace:    dev-namespace

   Source
       type:      git
       url:       https://github.com/my-organization/tanzu-java-web-app
       branch:    main

   Supply Chain
       name:    source-to-url

       NAME                READY     HEALTHY    UPDATED    RESOURCE

my-organization.com
```

3. After the workload is built and deployed, fetch the URL of the deployed app. The URL of the web app is in the `Knative Services` section at the bottom of the output of the `tanzu apps workload get` command:

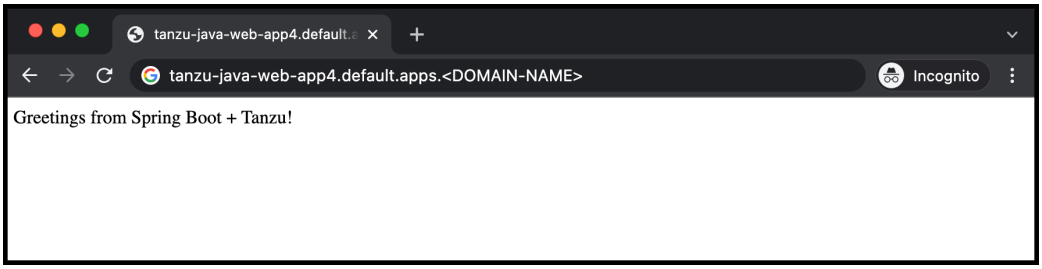
   ```
   tanzu apps workload get tanzu-java-web-app --namespace YOUR-DEVELOPER-NAMESPACE
   ```

   Where `YOUR-DEVELOPER-NAMESPACE` is the namespace configured earlier.

   The output looks similar to the following:

   ```
   Knative Services
       NAME                READY   URL
       tanzu-java-web-app  Ready   https://tanzu-java-web-app.dev-namespace.apps.
   my-organization.com
   ```

4. View the web app in your browser.

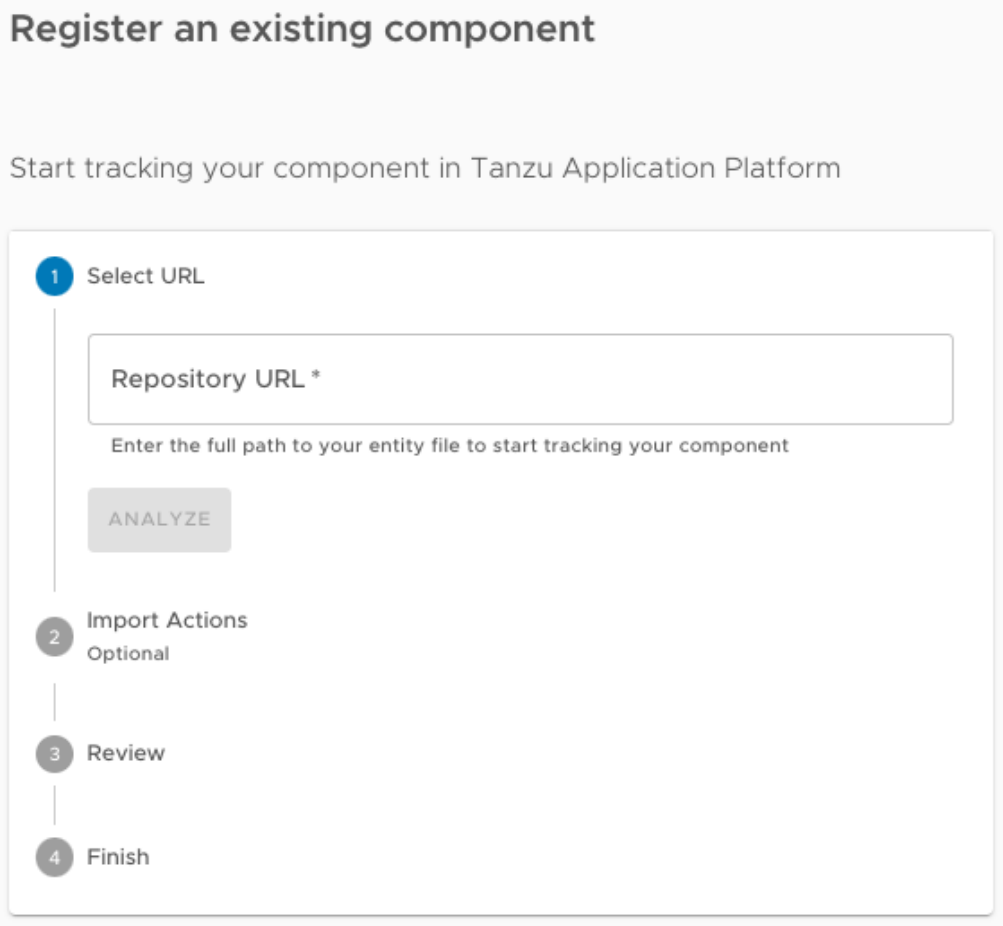


Add your application to Tanzu Developer Portal software catalog

1. Navigate to the home page of Tanzu Developer Portal and click **Home**, located on the left navigation pane.
2. Click **REGISTER ENTITY**.

   Alternatively, you can add a link for the `catalog-info.yaml` to the `tap-values.yaml` configuration file in the `tap_gui.app_config.catalog.locations` section. For more information, see Installing the Tanzu Application Platform Package and Profiles.

3. **Register an existing component** prompts you to type a repository URL. Type the link to the `catalog-info.yaml` file of the `tanzu-java-web-app` in the Git repository text box. For example, `https://github.com/USERNAME/PROJECTNAME/blob/main/catalog-info.yaml`.



4. Click **ANALYZE**.
5. Review the catalog entities to be added and click **IMPORT**.
6. Navigate back to the home page. The catalog changes and entries are visible for further inspection.

Note

If your Tanzu Developer Portal instance does not have a PostgreSQL database configured, you must re-register the `catalog-info.yaml` location after the instance is restarted or upgraded.

Next steps

Now that you have your application deployed on your Tanzu Application Platform cluster, the next step is to iterate on your application.

- If you are an IntelliJ user, see the Iterate on your new app using IntelliJ guide.
- If you are a Visual Studio user, see the Iterate on your new app using Visual Studio guide.
- If you are a VS Code user, see the Iterate on your new app using VS Code guide.

Iterate on your new app using Tanzu Developer Tools for IntelliJ

This topic guides you through starting to iterate on your first application on Tanzu Application Platform (commonly known as TAP). You deployed the app in the previous how-to Deploy your first application.

What you will do

- Prepare to iterate on your application.
    - Prepare your project to support Live Update.
    - Prepare your IDE to iterate on your application.
- Apply your application to the cluster.
- Live update your application to view code changes updating live on the cluster.
- Debug your application.
- Delete your application from the cluster.

Prepare to iterate on your application

In the previous Getting started how-to topic, Deploy your first application, you deployed your first application on Tanzu Application Platform. Now that you have developed a skeleton workload, you are ready to begin to iterate on your new application and test code changes on the cluster.

Tanzu Developer Tools for IntelliJ is VMware Tanzu's official IDE extension for IntelliJ. It helps you develop and receive fast feedback on your workloads running on the Tanzu Application Platform.

The IntelliJ extension enables live updates of your application while running on the cluster and allows you to debug your application directly on the cluster.

For information about installing the prerequisites and the Tanzu Developer Tools for IntelliJ extension, see Install Tanzu Developer Tools for IntelliJ.

Important

Use Tilt v0.30.12 or later for the sample application.

To prepare to iterate on your application, you must:

1. Prepare your project to support Live Update
2. Set up the IDE

Prepare your project to support Live Update

Tanzu Live Update uses Tilt. This requires a suitable `Tiltfile` to exist at the root of your project. Both Gradle and Maven projects are supported, but each requires a `Tiltfile` specific to that type of project.

The Tanzu Java Web App accelerator allows you to choose between Maven and Gradle and includes a `Tiltfile`. If you used the accelerator, your project is already set up correctly.

To verify your project is set up correctly, review the following requirements depending on your chosen build system.

Maven Spring Boot project requirements

If you are using Maven, your `Tiltfile` must be similar to the following:

```
SOURCE_IMAGE = os.getenv("SOURCE_IMAGE", default='your-registry.io/project/tanzu-java-
web-app-source')
LOCAL_PATH = os.getenv("LOCAL_PATH", default='.')
NAMESPACE = os.getenv("NAMESPACE", default='default')

k8s_custom_deploy(
    'tanzu-java-web-app',
    apply_cmd="tanzu apps workload apply -f config/workload.yaml --update-strategy rep
lace --debug --live-update" +
                " --local-path " + LOCAL_PATH +
                " --source-image " + SOURCE_IMAGE +
                " --namespace " + NAMESPACE +
                " --yes --output yaml",
    delete_cmd="tanzu apps workload delete -f config/workload.yaml --namespace " + NAM
ESPACE + " --yes",
    container_selector='workload',
    deps=['pom.xml', './target/classes'],
    live_update=[
      sync('./target/classes', '/workspace/BOOT-INF/classes')
    ]
)

k8s_resource('tanzu-java-web-app', port_forwards=["8080:8080"],
             extra_pod_selectors=[{'carto.run/workload-name': 'tanzu-java-web-app', 'ap
p.kubernetes.io/component': 'run'}])
```

Gradle Spring Boot project requirements

If you are using Gradle, review the following requirements:

- The `Tiltfile` looks like a Maven Tiltfile except for some key differences in the `deps=` and `live-update=` sections:

  ```
      ...
      deps=['build.gradle.kts', './build/classes/java/main', './build/resources/m
  ain'],
      live_update=[
         sync('./build/classes/java/main', '/workspace/BOOT-INF/classes'),
         sync('./build/resources/main', '/workspace/BOOT-INF/classes')
      ]
      ...
  ```

- The project must be built as an exploded JAR. This is not the default behavior for a Gradle-based build. For a typical Spring Boot Gradle project, you must deactivate the `jar` task in the `build.gradle.kts` file as follows:

  ```
  ...
  tasks.named<Jar>("jar") {
      enabled = false
  }
  ```

Set up the IDE

After verifying your project has the required `Tiltfile` and Maven or Gradle build support, you are ready to set up your development environment.

1. Open the Tanzu Java Web App as a project within your IntelliJ IDE by selecting **File** > **Open**, then selecting the Tanzu Java Web App folder and clicking **Open**. If you don't have the Tanzu Java Web App you can obtain it by following the instructions in Generate a new

project using an Application Accelerator, or from the Application Accelerator Samples GitHub page.

2. Confirm that your current Kubernetes context contains a default namespace. The Tanzu Panel, found by clicking **Tanzu Panel** at the bottom-left of the IntelliJ window, uses the default namespace associated with your current Kubernetes context to populate the workloads from the cluster.

    1. Open the Terminal by clicking **View** > **Terminal**.
    2. Ensure that your current context has a default namespace by running:

        ```
        kubectl config get-contexts
        ```

        This command returns a list of all of your Kubernetes contexts with an asterisk (`*`) in front of your current context. Verify that your current context has a namespace in the namespace column.

    3. If your current context does not have a namespace in the namespace column, run:

        ```
        kubectl config set-context --current --namespace=YOUR-DEVELOPER-NAMESPACE
        ```

        Where `YOUR-DEVELOPER-NAMESPACE` is the namespace value you want to assign to your current Kubernetes context.

You are now ready to iterate on your application.

Apply your application to the cluster

Apply the workload to see your application running on the cluster:

1. In the **Project** tab in IntelliJ, right-click any file under the application name `tanzu-java-web-app` and click **Tanzu** > **Apply Workload**.
2. In the dialog box enter your **Source Image**, **Local Path**, and optionally a **Namespace**.

    1. Customize the installation of Local Source Proxy.

        If you don't have Local Source Proxy configured, you can use the source image parameter instead. The source image value tells the Tanzu Developer Tools for IntelliJ extension where to publish the container image with your non-compiled source code, and what to name that image. The image must be published to a container image registry where you have write access. For example, `gcr.io/myteam/tanzu-java-web-app-source`.

        Note

        See the documentation for the registry you're using to find out which steps are necessary to authenticate and gain push access.

        For example, if you use Docker, see the Docker documentation, or if you use Harbor, see the Harbor documentation.

    2. In the **Local Path** text box, provide the path to the directory containing the Tanzu Java Web App. The current directory is the default.

        The local path value tells the Tanzu Developer Tools for IntelliJ extension which directory on your local file system to bring into the source image. For example, dot (`.`) uses the working directory, or you can specify a full file path.

3. (Optional) In the **Namespace** text box, provide the namespace to be associated with the workload on the cluster. If you followed the steps to Prepare your IDE to iterate on your application earlier, you do not need to enter a namespace because IntelliJ uses the namespace you associated with your context.
4. Click the **OK** button.

The `apply workload` command runs, which opens a terminal and shows you the output of the command. The `apply workload` command can take a few minutes to deploy your application onto the cluster.

You can also use the **Tanzu Panel** to monitor your application as it's being deployed to the cluster. The **Tanzu Panel** shows information about the workloads in the namespace associated with your current Kubernetes context. On the left side, it shows the workloads in the namespace. In the center, it shows the details of the Kubernetes resources for the running workloads.

Enable Live Update for your application

Live Update allows you to save changes to your code and see those changes reflected within seconds in the workload running on the cluster.

To enable Live Update for your application:

1. Create a Run Configuration.
    1. In IntelliJ, select the **Edit Run/Debug configurations** drop-down menu at the top-right corner. Alternatively, navigate to **Run** > **Edit Configurations**.
    2. Select **Tanzu Live Update**.
    3. Select **Add new run configuration**, or click the plus icon at the top of the list.
    4. Give your new run configuration a name, for example, `Tanzu Live Update - tanzu-java-web-app`.
    5. In the **Tiltfile Path** text box, provide the path to the `Tiltfile` in the Tanzu Java Web App project directory.
    6. Select the folder icon on the right-side of the text box, go to the `Tanzu Java Web App` directory, select the `Tiltfile`, and click **Open**. The `Tiltfile` facilitates Live Update using Tilt.
    7. In the **Local Path** text box, provide the path to the directory containing the Tanzu Java Web App.

        The local path value tells the Tanzu Developer Tools for IntelliJ extension which directory on your local file system to bring into the source image.

        For example, `/Users/developer/Documents/tanzu-java-web-app`.
    8. Customize the installation of Local Source Proxy.

        If you don't have Local Source Proxy configured, you can use the source image parameter instead. The source image value tells the Tanzu Developer Tools for IntelliJ extension where to publish the container image with your non-compiled source code, and what to name that image. The image must be published to a container image registry where you have write access. For example, `gcr.io/myteam/tanzu-java-web-app-source`.

        Note

        See the documentation for the registry you're using to find out which steps are necessary to authenticate and gain push access.

For example, if you use Docker, see the Docker documentation, or if you use Harbor, see the Harbor documentation.

9. Click **Apply**, and then click the **OK** button.

2. Begin Live Updating the application on the cluster by doing one of the following:
    - In the Project tab of IntelliJ, right-click the `Tiltfile` file under the application name `tanzu-java-web-app` and click **Run 'Tanzu Live Update - tanzu-java-web-app'**.
    - Alternatively, click the **Edit Run/Debug configurations** drop-down menu in the top-right corner, select **Tanzu Live Update - tanzu-java-web-app**, and then click the green play button to the right of the **Edit Run/Debug configurations** drop-down menu.

    The **Run** tab opens and displays the output from Tanzu Application Platform and from Tilt indicating that the container is being built and deployed.

    On the **Tanzu Panel** tab, the status of Live Update is reflected under the `tanzu-java-web-app` workload entry. Live update can take up to three minutes while the workload deploys and the Knative service becomes available.

    Note

    Depending on the type of cluster you use, you might see an error similar to the following:

    ```
    ERROR: Stop! cluster-name might be production. If you're sure you want to deploy there, add: allow_k8s_contexts('cluster-name') to your Tiltfile. Otherwise, switch k8scontexts and restart Tilt.
    ```

    Follow the instructions and add the line, `allow_k8s_contexts('cluster-name')` to your `Tiltfile`.

3. When the Live Update task in the **Run** tab is successful, it resolves to `Live Update Started`. Use the hyperlink at the top of the Run output following the words **Tilt started on** to view your application in your browser.
4. In the IDE, make a change to the source code. For example, in `HelloController.java`, edit the string returned to say `Hello!` and save.
5. (Optional) Build your project by clicking **Build** > **Build Project** if you do not have **Build project automatically** activated under **Preferences** > **Build, Execution, Deployment** > **Compiler**.
6. The container is updated when the logs stop streaming. Navigate to your browser and refresh the page.
7. View the changes to your workload running on the cluster.
8. Either continue making changes, or stop the Live Update process when finished. To stop Live Update navigate to the **Run** tab at the bottom left of the IntelliJ window and click the red stop icon on the left side of the screen.

Debug your application

Debug the cluster either on the application or in your local environment.

To debug the cluster:

1. Set a breakpoint in your code. For example, in `HelloController.java`, set a breakpoint on the line returning text.
2. Create a Run Configuration.
    1. In IntelliJ, select the **Edit Run/Debug configurations** drop-down menu at the top-right corner. Alternatively, navigate to **Run** > **Edit Configurations**.
    2. Select **Tanzu Debug Workload**.
    3. Select **Add new run configuration**, or click the plus icon at the top of the list.
    4. Give your new run configuration a name, for example, `Tanzu Debug Workload - tanzu-java-web-app`.
    5. In the **Workload File Path** text box, provide the path to the `workload.yaml` file in the Tanzu Java Web App project directory located at **Config** > **workload.yaml**.
    6. Select the folder icon on the right-side of the text box, navigate to the Tanzu Java Web App directory, select the `workload.yaml` file and click the **Open** button. The `workload.yaml` provides configuration instructions about your application to the Tanzu Application Platform.
    7. In the **Local Path** text box, provide the path to the directory containing the Tanzu Java Web App.

        The local path value tells the Tanzu Developer Tools for IntelliJ extension which directory on your local file system to bring into the source image. For example, `/Users/developer/Documents/tanzu-java-web-app`.
    8. Customize the installation of Local Source Proxy.

        If you don't have Local Source Proxy configured, you can use the source image parameter instead. The source image value tells the Tanzu Developer Tools for IntelliJ extension where to publish the container image with your non-compiled source code, and what to name that image. The image must be published to a container image registry where you have write access. For example, `gcr.io/myteam/tanzu-java-web-app-source`.

        Note

        See the documentation for the registry you're using to find out which steps are necessary to authenticate and gain push access.

        For example, if you use Docker, see the Docker documentation, or if you use Harbor, see the Harbor documentation.
    9. (Optional) In the **Namespace** text box, provide the namespace to be associated with the workload on the cluster. If you followed the steps to Prepare your IDE to iterate on your application, you do not need to enter a namespace because IntelliJ uses the namespace you associated with your context.
    10. Click **Apply**, and then click **OK**.
3. Apply your application to the cluster.
4. Obtain the URL for your workload by doing one of the following:
    - **If your app deploys a Knative URL:** Click the URL from the Workloads panel.

    - **If your app does not deploy a Knative URL but exposes an app port:** Access your app through a `portforward`. For instructions, see Use a portforward to access an application locally.

5. In the Project tab of IntelliJ, right-click the `workload.yaml` file under the application name `tanzu-java-web-app` and select **Run 'Tanzu Debug Workload - tanzu-java-web-app'** to begin debugging the application on the cluster.
    1. Alternatively, select the **Edit Run/Debug configurations** drop-down menu in the top-right corner, select **Tanzu Debug Workload - tanzu-java-web-app**, and then click the green debug button to the right of the **Edit Run/Debug configurations** drop-down menu.
6. The Debug tab opens and displays a message that it has connected.
7. In your web browser, reload your workload. IntelliJ opens to show your breakpoint.
8. You can now use the resume program action, or stop debugging, in the **Debug** tab.

Delete your application from the cluster

You can use the delete action to remove your application from the cluster as follows:

1. In the **Project** tab, right-click any file under the application name `tanzu-java-web-app` and select **Tanzu** > **Delete Workload**.
2. Alternatively, right-click `tanzu-java-web-app` in the **TANZU WORKLOADS** panel and select **Delete Workload**.
3. In the confirmation dialog box that appears, click **OK** to delete the application from the cluster.

Next steps

- Consume services on Tanzu Application Platform

Iterate on your new app using Tanzu Developer Tools for Visual Studio

This topic guides you through starting to iterate on your first application on Tanzu Application Platform (commonly known as TAP). You deployed the app in the previous how-to Deploy your first application.

What you will do

- Prepare to iterate on your application.
    - Prepare your project to support Live Update.
    - Prepare your IDE to iterate on your application.
- Apply your application to the cluster.

- Live update your application to view code changes updating live on the cluster.
- Debug your application.
- Monitor your running application on the Application Live View UI.
- Delete your application from the cluster.

Prepare to iterate on your application

In the previous Getting started how-to topic, Deploy your first application, you deployed your first application on Tanzu Application Platform. Now that you have developed a skeleton workload, you are ready to begin to iterate on your new application and test code changes on the cluster.

Tanzu Developer Tools for Visual Studio is VMware Tanzu's official IDE extension for Visual Studio. It helps you develop and receive fast feedback on your workloads running on the Tanzu Application Platform.

The Visual Studio extension enables live updates of your application while running on the cluster and allows you to debug your application directly on the cluster.

For information about installing the prerequisites and the Tanzu Developer Tools for Visual Studio extension, see Install Tanzu Developer Tools for Visual Studio.

Important

Use Tilt v0.30.12 or later for the sample application.

To prepare to iterate on your application, you must:

1. Prepare your project to support Live Update
2. Set up the IDE

Prepare your project to support Live Update

Tanzu Live Update uses Tilt. This requires a suitable `Tiltfile` to exist at the root of your project.

Your `Tiltfile` must be similar to the following:

```
SOURCE_IMAGE = os.getenv("SOURCE_IMAGE", default='your-registry.io/project/csharp-weat
herforecast-source')
LOCAL_PATH = os.getenv("LOCAL_PATH", default='.')
NAMESPACE = os.getenv("NAMESPACE", default='default')
NAME = os.getenv("NAME", default='sample-app')

k8s_custom_deploy(
    NAME,
    apply_cmd="tanzu apps workload apply -f config/workload.yaml --update-strategy rep
lace --debug --live-update" +
                " --local-path " + LOCAL_PATH +
                " --namespace " + NAMESPACE +
                " --yes --output yaml",
    delete_cmd="tanzu apps workload delete " + NAME + " --namespace " + NAMESPACE + "
--yes",
    deps=['./bin'],
    container_selector='workload',
    live_update=[
      sync('./bin/Debug/net6.0', '/workspace')
    ]
)

k8s_resource('tanzu-java-web-app', port_forwards=["8080:8080"],
```

```
            extra_pod_selectors=[{'carto.run/workload-name': 'sample-app', 'app.kubern
etes.io/component': 'run'}])
```

Set up the IDE

After verifying your project has the required `Tiltfile`, you are ready to set up your development environment.

1. Open the Weather Forecast solution in Visual Studio by selecting **File** > **Open** > **Project/Solution...**. If you don't have the Weather Forecast app you can obtain it by following the instructions in Generate an application with Application Accelerator, or from the Application Accelerator Samples GitHub page.

You are now ready to iterate on your application.

Apply your application to the cluster

Apply the workload to see your application running on the cluster:

1. In **Solution Explorer**, right-click any file under the application name and click **Tanzu** > **Apply Workload**.
2. In the dialog box, enter the following:
    1. In the **Local Path** text box, provide the path to the directory containing the Weather Forecast app. The current directory is the default.

        The local path value tells the Tanzu Developer Tools for Visual Studio extension which directory on your local file system to bring into the source image. For example, dot (`.`) uses the working directory, or you can specify a full file path.
    2. In the **Namespace** text box, provide the namespace to be associated with the workload on the cluster.
    3. (Optional) In the **Source Image** text box, provide the destination image repository to publish the image containing your workload source code.

        The source image value tells the Tanzu Developer Tools for Visual Studio extension where to publish the container image with your uncompiled source code, and what to name that image. The image must be published to a container image registry where you have write (push) access. For example, `gcr.io/myteam/weather-forecast-source`.

        Note

        See the documentation for the registry you're using to find out which steps are necessary to authenticate and gain push access.

        For example, if you use Docker, see the Docker documentation, or if you use Harbor, see the Harbor documentation.
    4. Click the **OK** button.

The `apply workload` command runs and opens a an output window in which you can monitor the output of the command. The `apply workload` command can take a few minutes to deploy your application onto the cluster.

Enable Live Update for your application

Live Update allows you to save changes to your code and see those changes reflected within seconds in the workload running on the cluster.

To enable Live Update for your application:

1. In **Solution Explorer**, right-click any file under the application name and click **Tanzu** > **Start Live Update**.
2. Live update can take up to three minutes while the workload deploys and the Knative service becomes available.

   > **Note**
   >
   > Depending on the type of cluster you use, you might see an error similar to the following:
   >
   > ```
   > ERROR: Stop! cluster-name might be production. If you're sure you want to deploy there, add: allow_k8s_contexts('cluster-name') to your Tiltfile. Otherwise, switch k8scontexts and restart Tilt.
   > ```
   >
   > Follow the instructions and add the line, `allow_k8s_contexts('cluster-name')` to your `Tiltfile`.

3. In the IDE, make a change to the source code.
4. Build your project.
5. The container is updated when the logs stop streaming. Go to your browser and refresh the page.
6. View the changes to your workload running on the cluster.
7. Either continue making changes, or stop the Live Update process when finished. To stop Live Update, in **Solution Explorer**, right-click any file under the application name and click **Tanzu** > **Stop Live Update**.

Debug your application

Debug the cluster either on the application or in your local environment.

To start debugging the cluster:

1. Set a breakpoint in your code.
2. Apply your application to the cluster.
3. In **Solution Explorer**, right-click any file under the application name and click **Tanzu** > **Debug Workload**.

To stop debugging the cluster:

1. In main, click **Debug** > **Detach All**

Delete your application from the cluster

You can use the delete action to remove your application from the cluster as follows:

1. In **Solution Explorer**, right-click any file under the application name and click **Tanzu** > **Delete Workload**.
2. In the confirmation dialog box that appears, click **OK** to delete the application from the cluster.

Next steps

- Consume services on Tanzu Application Platform

Iterate on your new app using Tanzu Developer Tools for VS Code

This topic guides you through starting to iterate on your first application on Tanzu Application Platform (commonly known as TAP). You deployed the app in the previous how-to Deploy your first application.

What you will do

- Prepare to iterate on your application.
  - Prepare your project to support Live Update.
  - Prepare your IDE to iterate on your application.
- Apply your application to the cluster.
- Live update your application to view code changes updating live on the cluster.
- Debug your application.
- Monitor your running application on the Application Live View UI.
- Delete your application from the cluster.

Prepare to iterate on your application

In the previous Getting started how-to topic, Deploy your first application, you deployed your first application on Tanzu Application Platform. Now that you have developed a skeleton workload, you are ready to begin to iterate on your new application and test code changes on the cluster.

Tanzu Developer Tools for VS Code is VMware Tanzu's official IDE extension for VS Code. It helps you develop and receive fast feedback on your workloads running on the Tanzu Application Platform.

The VS Code extension enables live updates of your application while running on the cluster and allows you to debug your application directly on the cluster. For information about installing the prerequisites and the Tanzu Developer Tools for VS Code extension, see Install Tanzu Developer Tools for your VS Code.

Important

Use Tilt v0.30.12 or a later version for the sample application.

To prepare to iterate on your application, you must:

1. Prepare your project to support Live Update
2. Set up the IDE

Prepare your project to support Live Update

Tanzu Live Update uses Tilt. This requires a suitable `Tiltfile` to exist at the root of your project. Both Gradle and Maven projects are supported, but each requires a `Tiltfile` specific to that type of project.

The Tanzu Java Web App accelerator allows you to choose between Maven and Gradle and includes a `Tiltfile`. If you used the accelerator, your project is already set up correctly.

To verify your project is set up correctly, review the following requirements depending on your chosen build system.

Maven Spring Boot project requirements

If you are using Maven, your `Tiltfile` must be similar to the following:

```
SOURCE_IMAGE = os.getenv("SOURCE_IMAGE", default='your-registry.io/project/tanzu-java-
web-app-source')
LOCAL_PATH = os.getenv("LOCAL_PATH", default='.')
NAMESPACE = os.getenv("NAMESPACE", default='default')

k8s_custom_deploy(
    'tanzu-java-web-app',
    apply_cmd="tanzu apps workload apply -f config/workload.yaml --update-strategy rep
lace --debug --live-update" +
                " --local-path " + LOCAL_PATH +
                " --source-image " + SOURCE_IMAGE +
                " --namespace " + NAMESPACE +
                " --yes --output yaml",
    delete_cmd="tanzu apps workload delete -f config/workload.yaml --namespace " + NAM
ESPACE + " --yes",
    container_selector='workload',
    deps=['pom.xml', './target/classes'],
    live_update=[
      sync('./target/classes', '/workspace/BOOT-INF/classes')
    ]
)

k8s_resource('tanzu-java-web-app', port_forwards=["8080:8080"],
             extra_pod_selectors=[{'carto.run/workload-name': 'tanzu-java-web-app', 'ap
p.kubernetes.io/component': 'run'}])
```

Gradle Spring Boot project requirements

If you are using Gradle, review the following requirements:

- The `Tiltfile` looks like a Maven Tiltfile except for some key differences in the `deps=` and `live-update=` sections:

  ```
      ...
      deps=['build.gradle.kts', './bin/main'],
      live_update=[
          sync('./bin/main', '/workspace/BOOT-INF/classes')
      ]
      ...
  ```

- The project must be built as an exploded JAR. This is not the default behavior for a Gradle-based build. For a typical Spring Boot Gradle project, you must deactivate the `jar` task in the `build.gradle.kts` file as follows:

  ```
  ...
  tasks.named<Jar>("jar") {
      enabled = false
  }
  ```

Set up the IDE

After verifying your project has the required `Tiltfile` and Maven or Gradle build support, you are ready to set up your development environment.

1. Open the Tanzu Java Web App as a project within your VS Code IDE by clicking **File** > **Open Folder**, select the Tanzu Java Web App folder and click **Open**.

   If you don't have the Tanzu Java Web App you can obtain it by following the instructions in Generate a new project using an Application Accelerator, or from the Application Accelerator Samples GitHub page.

2. To ensure that your extension assists you with iterating on the correct project, configure its settings as follows:

   1. In Visual Studio Code, navigate to **Preferences** > **Settings** > **Extensions** > **Tanzu Developer Tools**.
   2. In the **Local Path** text box, provide the path to the directory containing the Tanzu Java Web App. The current directory is the default.

      The local path value tells the Tanzu Developer Tools for VS Code extension which directory on your local file system to bring into the source image. For example, dot (`.`) uses the working directory, or you can specify a full file path.

   3. Customize the installation of Local Source Proxy.

      If you don't have Local Source Proxy configured, you can use the source image parameter instead. The source image value tells the Tanzu Developer Tools for VS Code extension where to publish the container image with your non-compiled source code, and what to name that image. The image must be published to a container image registry where you have write access. For example, `gcr.io/myteam/tanzu-java-web-app-source`.

      Note

      See the documentation for the registry you're using to find out which steps are necessary to authenticate and gain push access.

      For example, if you use Docker, see the Docker documentation, or if you use Harbor, see the Harbor documentation.

      For troubleshooting failed registry authentication, see Troubleshoot using Tanzu Application Platform

3. Confirm that your current Kubernetes context has a namespace associated with it. The **TANZU WORKLOADS** section of the **Explorer** view in the left Side Bar uses the namespace associated with your current Kubernetes context to populate the workloads from the cluster.

   1. Open the Terminal by clicking **View** > **Terminal**.
   2. Ensure your current context has a default namespace by running:

      ```
      kubectl config get-contexts
      ```

      This command returns a list of all of your Kubernetes contexts with an asterisk (`*`) in front of your current context. Verify that your current context has a namespace in the namespace column.

   3. If your current context does not have a namespace in the namespace column, run:

```
kubectl config set-context --current --namespace=YOUR-DEVELOPER-NAMESPACE
```

Where `YOUR-DEVELOPER-NAMESPACE` is the namespace value you want to assign to your current Kubernetes context.

You are now ready to iterate on your application.

Apply your application to the cluster

Apply the workload to see your application running on the cluster by doing one of the following:

- In the **Explorer** view in the left Side Bar, right-click any file under the application name `tanzu-java-web-app` and click **Tanzu: Apply Workload** to begin applying the workload to the cluster.
- Alternatively, use the Command Palette, ⇧⌘P on Mac and Ctrl+Shift+P on Windows or **View** > **Command Palette**, to run the `Tanzu: Apply Workload` command.

The `apply workload` command runs, which opens a terminal and shows you the output of the workload apply.

You can also monitor your application as it's being deployed to the cluster using the **TANZU ACTIVITY** tab in the Panel at the bottom of VS Code. The **TANZU ACTIVITY** tab shows the details of the Kubernetes resources for the workloads running in the namespace associated with your current Kubernetes context.

To view the **TANZU ACTIVITY** tab, open the Panel at the bottom of VS Code (**View** > **Appearance** > **Panel**) and then click the **TANZU ACTIVITY** tab. The apply workload command can take a few minutes to deploy your application onto the cluster. After complete, you can see the workload running in the **TANZU WORKLOADS** section of the **Explorer** view in the left Side Bar.

Enable Live Update for your application

Live Update allows you to save changes to your code and see those changes reflected within seconds in the workload running on the cluster.

To enable Live Update for your application:

1. To begin Live Updating the workload on the cluster, do one of the following:
    - In the **Explorer** view in the left Side Bar, right-click any file under the application name `tanzu-java-web-app` and click `Tanzu: Live Update Start`.
    - Right-click the `tanzu-java-web-app` in the **TANZU WORKLOADS** section of the **Explorer** view and click `Tanzu: Live Update Start`.
    - From the Command Palette, ⇧⌘P on Mac and Ctrl+Shift+P on Windows, type in and select `Tanzu: Live Update Start`.

    You can view output from Tanzu Application Platform indicating that the container is being built and deployed.

    The status of Live Update is reflected in the **TANZU WORKLOADS** view under the `tanzu-java-web-app` workload entry. You can also see `Live Update starting...` in the status bar at the bottom right. Live update can take up to three minutes while the workload deploys and the Knative service becomes available.

    Note

    Depending on the type of cluster you use, you might see an error similar to the following:

> `ERROR: Stop! cluster-name might be production. If you're sure you want to deploy there, add: allow_k8s_contexts('cluster-name') to your Tiltfile. Otherwise, switch k8scontexts and restart Tilt.`
>
> Follow the instructions and add the line, `allow_k8s_contexts('cluster-name')` to your `Tiltfile`.

2. When the Live Update status in the **TANZU WORKLOADS** view changes from `Live Update Stopped` to `Live Update Running`, navigate to `http://localhost:8080` in your browser to view your running application.
3. In the IDE, make a change to the source code. For example, in `HelloController.java`, edit the string returned to say `Hello!`, and save.
4. The container is updated when the logs stop streaming. Go to your browser and refresh the page.
5. View the changes to the workload running on the cluster.
6. Either continue making changes, or stop the Live Update process when finished. To stop Live Update, open the Terminal by navigating to **View** > **Terminal**, and click the trash can icon that appears when you place your hover over the **tilt: up - tanzu-java-web-app** process, or select the process and use hot key ⌘+Backspace.

Debug your application

Debug your application in a production-like environment by debugging on your Kubernetes cluster.

To debug the cluster:

1. Set a breakpoint in your code. For example, in `HelloController.java`, set a breakpoint on the line returning text.
2. Apply your application to the cluster.
3. Access your app in your browser by doing one of the following:
   - **If your app deploys a Knative URL:** Click the URL from the Workloads panel.

   - **If your app does not deploy a Knative URL but exposes an app port:** Access your app through a `portforward`. For instructions, see Use a `portforward` to access an application locally.
4. Begin debugging the workload on the cluster by doing one of the following:
   - In the **Explorer** view in the left Side Bar, right-click any file under the application name `tanzu-java-web-app` and click **Tanzu: Java Debug Start**.
   - Alternatively, right-click the `tanzu-java-web-app` in the **TANZU WORKLOADS** view and click **Tanzu: Java Debug Start**.

5. In a few moments, debugging is enabled on the workload. The **Deploy and Connect** task completes and the debug actions are made available to you in the debug overlay, indicating that the debugger has attached.

   The **TANZU WORKLOADS** view shows **Debug Running** under the `tanzu-java-web-app` workload.

6. In your web browser, reload your workload. VS Code opens to show your breakpoint.
7. You can now continue the program, or stop debugging, using the debug controls overlay.

Monitor your running application

Inspect the runtime characteristics of your running application using the Application Live View UI to monitor:

- Resource consumption
- Java Virtual Machine (JVM) status
- Incoming traffic
- Change log level

You can also troubleshoot environment variables and fine-tune the running application.

Use the following steps to diagnose Spring Boot-based applications by using Application Live View:

1. Confirm that the Application Live View components are installed. For instructions, see Install Application Live View.
2. Access the Application Live View UI plug-in in Tanzu Developer Portal. For instructions, see Entry point to Application Live View plug-in.
3. Select your running application to view the diagnostic options and inside the application. For more information, see Application Live View features.

Delete your application from the cluster

You can use the delete action to remove your application from the cluster by doing one of the following:

- In the **Explorer** view in the left Side Bar, right-click any file under the application name `tanzu-java-web-app` and click **Tanzu: Delete Workload** to delete the workload from the cluster.
- Alternatively, right-click the `tanzu-java-web-app` in the **TANZU WORKLOADS** view and click **Tanzu: Delete Workload**.

Next steps

- Consume services on Tanzu Application Platform

Claim services on Tanzu Application Platform

This topic for application operators guides you through claiming a service instance and therefore making credentials available to workloads within your namespace. The topic uses RabbitMQ as an example, but the process is the same regardless of the service you want to consume.

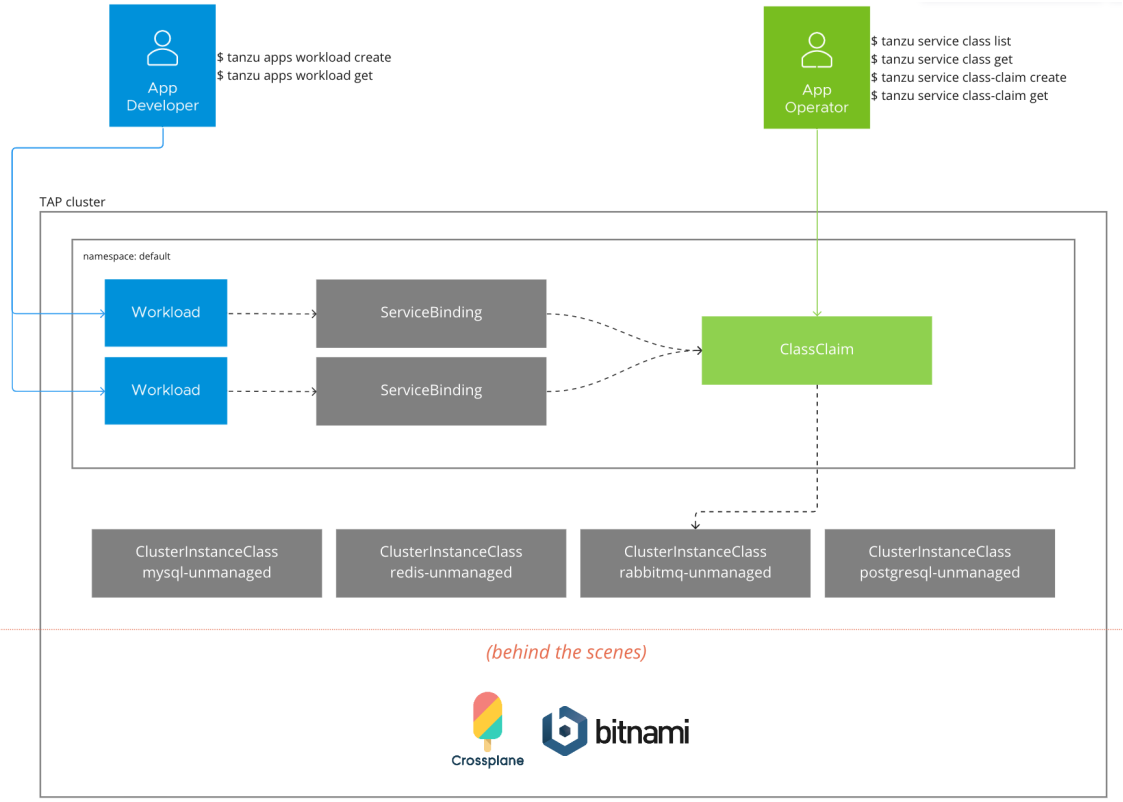
You will use the `tanzu service` CLI plug-in and will learn about classes, claims, and bindings.

What you will do

- Discover the range of services available to you
- Create a claim for an instance of one of the services

Overview

The following diagram depicts a summary of what this tutorial covers.



Bear the following observations in mind as you work through this guide:

1. There are a set of four service classes preinstalled on the cluster.
2. Service operators do not need to configure or setup these four services.
3. The life cycle of a service binding is implicitly tied to the life cycle of a workload, and is managed by the application developer.
4. The life cycles of claims are explicitly managed by the application operator.
5. The diagram and tutorial in this guide are predominantly focused on the application operator, therefore the inner workings of how service instances are provisioned are not in the diagram and are labeled as “behind the scenes”.

Prerequisites

Before following this tutorial, an application operator must:

1. Have access to a cluster with Tanzu Application Platform installed.
2. Have the Tanzu CLI and the corresponding plug-ins.
3. Have access to the `default` namespace which has been set up to use installed packages. For more information, see Set up developer namespaces to use your installed packages.

Discover available services

This section covers using `tanzu service class list` and `tanzu service class get` to find information about the classes of services.

- To discover the range of available services, run the `tanzu service class list` command:

  ```
  tanzu service class list
  ```

  Expected output:

  ```
    NAME                  DESCRIPTION
    mysql-unmanaged       MySQL by Bitnami
    postgresql-unmanaged  PostgreSQL by Bitnami
    rabbitmq-unmanaged    RabbitMQ by Bitnami
    redis-unmanaged       Redis by Bitnami
  ```

  The output lists four classes that cover a range of services: MySQL, PostgreSQL, RabbitMQ and Redis. This is the default set of services that come preconfigured with Tanzu Application Platform. They are backed by Bitnami Helm charts that run on the Tanzu Application Platform cluster. You can consider these to be unmanaged services with no guarantees of service provided.

- To see more detailed information for a class, run the `tanzu service class get` command:

  ```
  tanzu service class get rabbitmq-unmanaged
  ```

  Expected output:

  ```
    NAME:           rabbitmq-unmanaged
    DESCRIPTION:    RabbitMQ by Bitnami
    READY:          true

    PARAMETERS:
      KEY         DESCRIPTION
  TYPE     DEFAULT  REQUIRED
      replicas    The desired number of replicas forming the cluster
  integer  1        false
      storageGB   The desired storage capacity of a single replica, in Gigabytes.
  integer  1        false
  ```

  The `PARAMETERS` section is of particular interest because it lists the range of configuration options available to you when creating a claim for the given class.

Create a claim for a service instance

This section covers using `tanzu service class-claim create` to create a claim for an instance of a class and using `tanzu service class-claim get` to get detailed information about the status of the claim.

- To create a claim for an instance of a class, run the `tanzu service class-claim create` command:

  ```
  tanzu service class-claim create rabbitmq-1 --class rabbitmq-unmanaged --parame
  ter storageGB=3
  ```

  In this example, you create a claim for the `rabbitmq-unmanaged` class and pass a parameter to the command to set the storage capacity of the resulting instance to 3 Gigabytes, rather than using the default 1 Gigabyte.

Expected output:

```
  Creating claim 'rabbitmq-1' in namespace 'default'.
```

- To get detailed information about the claim, run the `tanzu service class-claim get` command:

  ```
  tanzu service class-claim get rabbitmq-1
  ```

  Expected output:

  ```
    Name: rabbitmq-1
    Namespace: default
    Claim Reference: services.apps.tanzu.vmware.com/v1alpha1:ClassClaim:rabbitmq-
  1
    Class Reference:
      Name: rabbitmq-unmanaged
    Parameters:
      storageGB: 3
    Status:
      Ready: True
      Claimed Resource:
        Name: b5982046-a1e9-40cf-8282-00fe67a2f868
        Namespace: default
        Group:
        Version: v1
        Kind: Secret
  ```

  It might take a moment or two for the claim to report `Ready: True`.

In the background, the creation of the claim triggers the on-demand creation of a Helm release of the Bitnami RabbitMQ Helm chart. Credentials and connectivity information required to connect to the RabbitMQ cluster are formatted according to the Service Binding Specification for Kubernetes and stored in a `Secret` in your namespace.

As an application operator you don't need to know what's happening in the background. Tanzu Application Platform promotes a strong separation of concerns between service operators, who are responsible for managing service instances for the platform, and application operators, who want to use those service instances with their application workloads. The class and claims abstractions enable that separation of concerns. Application operators create claims and service operators help to fulfil them.

Now that you have a claim for a RabbitMQ service instance, you can now follow instructions to Consume services on Tanzu Application Platform.

Next steps

Now that you completed the Getting started guides, learn about:

- Multicluster Tanzu Application Platform

Consume services on Tanzu Application Platform

This topic for application developers guides you through deploying two application workloads and configuring them to communicate using a service instance. The topic uses RabbitMQ as an example, but the process is the same regardless of the service you want to consume.

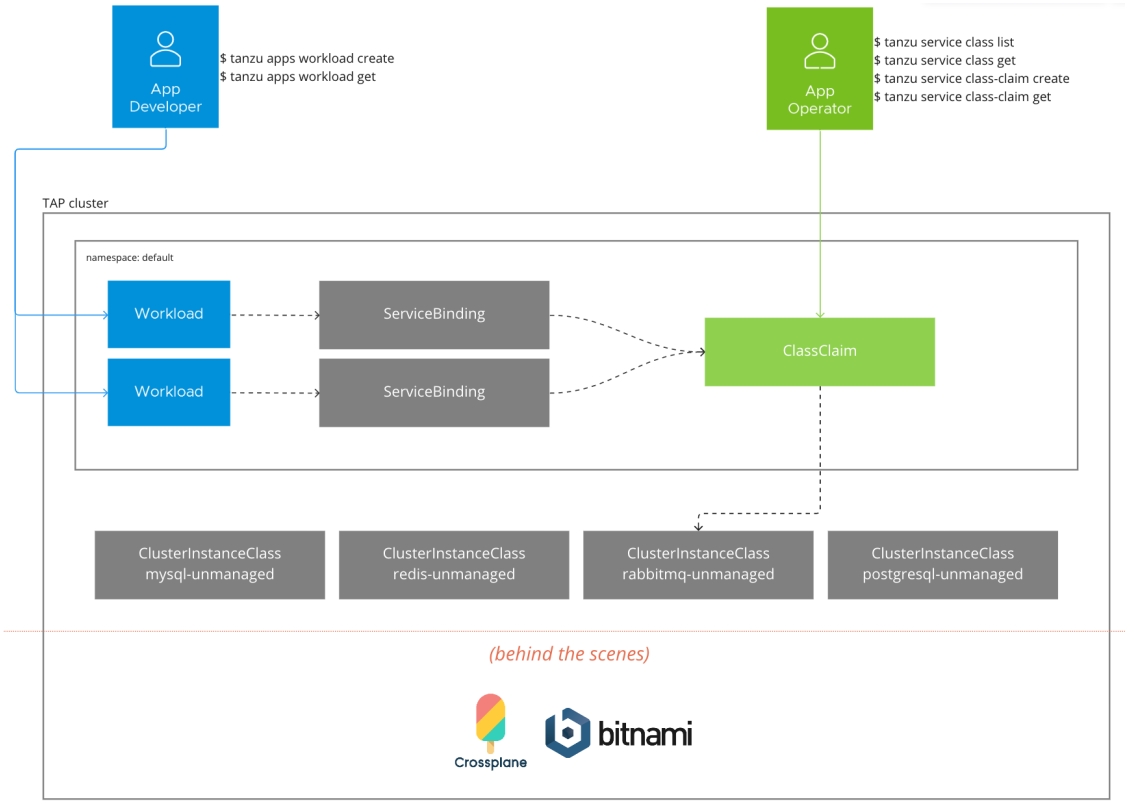
You will use the Tanzu Service CLI plug-in and will learn about classes, claims, and bindings.

What you will do

- Discover existing claims on service instances within your namespace
- Create two application workloads and bind them to an existing claim so that the workloads use the service instance.

Overview

The following diagram depicts a summary of what this tutorial covers.



Bear the following observations in mind as you work through this guide:

1. There is a set of four service classes preinstalled on the cluster.
2. Service operators do not need to configure or setup these four services.
3. The life cycle of a service binding is implicitly tied to the life cycle of a workload, and is managed by the application developer.
4. The life cycles of claims are explicitly managed by the application operator.
5. The diagram and tutorial in this guide are predominantly focused on the application operator and developer user roles, as such the inner workings of how service instances are provisioned are not in the diagram and are labeled as “behind the scenes”.

Prerequisites

Before following this tutorial, an application developer must:

1. Have access to a cluster with Tanzu Application Platform installed.
2. Have the Tanzu CLI and the corresponding plug-ins.
3. Have access to the `default` namespace which has been set up to use installed packages. For more information, see Set up developer namespaces to use your installed packages.
4. Have a Tanzu Application Platform cluster that can pull source code from GitHub.

Discovering existing claims

This section covers using `tanzu service class-claim list` and `tanzu service class-class get` to discover existing claims within your namespace and obtaining information needed to bind your workload to them.

1. To get the list of claims within your namespace, run:

   ```
   tanzu service class-claim list
   ```

   Expected output:

   ```
   NAME        CLASS                READY  REASON
   rabbitmq-1  rabbitmq-unmanaged   True   Ready
   ```

2. To get detailed information about the claim, run:

   ```
   tanzu service class-claim get rabbitmq-1
   ```

   Expected output:

   ```
     Name: rabbitmq-1
     Namespace: default
     Claim Reference: services.apps.tanzu.vmware.com/v1alpha1:ClassClaim:rabbitmq-
   1
     Class Reference:
       Name: rabbitmq-unmanaged
     Parameters:
       storageGB: 3
     Status:
       Ready: True
       Claimed Resource:
         Name: b5982046-a1e9-40cf-8282-00fe67a2f868
         Namespace: default
         Group:
         Version: v1
         Kind: Secret
   ```

Binding application workloads to the service instance

This section covers using `tanzu apps workload create` with the `--service-ref` flag to create workloads and to bind them to the service instance through the claim.

In Tanzu Application Platform, service bindings are created when you create application workloads using the `--service-ref` flag of the `tanzu apps workload create` command.

To create an application workload:

1. Review the output of the `tanzu service class-claim get` command you ran in Discovering existing claims earlier, and note the value of the `Claim Reference`. This is the value to pass to `--service-ref` when creating the application workloads.
2. Create the application workload by running:

```
tanzu apps workload create spring-sensors-consumer-web \
  --git-repo https://github.com/tanzu-end-to-end/spring-sensors \
  --git-branch rabbit \
  --type web \
  --label app.kubernetes.io/part-of=spring-sensors \
  --annotation autoscaling.knative.dev/minScale=1 \
  --service-ref="rmq=services.apps.tanzu.vmware.com/v1alpha1:ClassClaim:rabbitm
q-1"

tanzu apps workload create \
  spring-sensors-producer \
  --git-repo https://github.com/tanzu-end-to-end/spring-sensors-sensor \
  --git-branch main \
  --type web \
  --label app.kubernetes.io/part-of=spring-sensors \
  --annotation autoscaling.knative.dev/minScale=1 \
  --service-ref="rmq=services.apps.tanzu.vmware.com/v1alpha1:ClassClaim:rabbitm
q-1"
```

3. After the workloads are ready, visit the URL of the `spring-sensors-consumer-web` app. Confirm that sensor data is passing from the `spring-sensors-producer` workload to the `spring-sensors-consumer-web` workload using the `RabbitmqCluster` service instance.

Now that you completed the Getting started guides, learn about:

- Multicluster Tanzu Application Platform

Deploy an air-gapped workload on Tanzu Application Platform

This topic for developers guides you through deploying your first workload on Tanzu Application Platform (commonly known as TAP) in an air-gapped environment.

For information about installing Tanzu Application Platform in an air-gapped environment, see Install Tanzu Application Platform in an air-gapped environment.

What you will do

- Create a workload from Git.

- Create a basic supply chain workload.
- Create a testing supply chain workload.
- Create a testing scanning supply chain workload.

Prerequisites

Before a developer can deploy an air-gapped workload, a platform operator must:

- Configure the air-gapped environment using Namespace Provisioner. For instructions, see Work with Git repositories in air-gapped environments with Namespace Provisioner.
- For the testing supply chain workload: Follow the steps in Install OOTB Supply Chain with Testing.
- For the testing scanning supply chain workload:
  - Follow the steps in Install OOTB Supply Chain with Testing and Scanning.
  - Set up vulnerability scanning. For instructions, see Use vulnerability scanning in offline and air-gapped environments.

Create a workload from Git

To create a workload from Git through HTTPS, follow these steps:

1. (Optional) To pass in login credentials for a Git repository with the certificate authority (CA) certificate, create a file called `git-credentials.yaml`. For example:

   ```
   apiVersion: v1
   kind: Secret
   metadata:
     name: git-ca
     # namespace: default
   type: Opaque
   stringData:
     username: USERNAME
     password: PASSWORD
     caFile: |
       CADATA
   ```

   Where:

   - `USERNAME` is the user name.
   - `PASSWORD` is the password.
   - `CADATA` is the PEM-encoded CA certificate for the Git repository.

2. To pass in a custom `settings.xml` for Java or NuGet:

   - For Java, create a file called `settings-xml.yaml`. For example:

     ```
     apiVersion: v1
     kind: Secret
     metadata:
       name: settings-xml
     type: service.binding/maven
     stringData:
       type: maven
       provider: sample
       settings.xml: |
         <settings xmlns="http://maven.apache.org/SETTINGS/1.0.0" xmlns:xsi="h
     ttp://www.w3.org/2001/XMLSchema-instance"
           xsi:schemaLocation="http://maven.apache.org/SETTINGS/1.0.0 https://
     ```

```
maven.apache.org/xsd/settings-1.0.0.xsd">
        <mirrors>
            <mirror>
                <id>reposilite</id>
                <name>Tanzu seal Internal Repo</name>
                <url>https://reposilite.tap-trust.cf-app.com/releases</ur
l>
                <mirrorOf>*</mirrorOf>
            </mirror>
        </mirrors>
        <servers>
            <server>
                <id>reposilite</id>
                <username>USERNAME</username>
                <password>PASSWORD</password>
            </server>
        </servers>
    </settings>
```

- For NuGet, create a file called `settings-xml.yaml`. For example:

```
apiVersion: v1
kind: Secret
metadata:
  name: settings-xml
type: service.binding/nugetconfig
stringData:
  type: nugetconfig
  provider: sample
  nuget.config: |
    <?xml version="1.0" encoding="utf-8"?>
      <configuration>
        <packageSources>
          <clear />
          <add key="nuget-proxy" value=https://internal_nuget-proxy_fqdn/
repository/nuget.org-proxy/index.json />
        </packageSources>
      </configuration>
```

3. Apply the file:

```
kubectl create -f settings-xml.yaml -n DEVELOPER-NAMESPACE
```

Create a basic supply chain workload

Next, create your basic supply chain workload.

To pass the CA certificate in when you create the workload, run:

```
tanzu apps workload create APP-NAME --git-repo  https://GITREPO --git-branch BRANCH --
type web --label app.kubernetes.io/part-of=CATALOGNAME --yes --param-yaml buildService
Bindings='[{"name": "settings-xml", "kind": "Secret"}]' --param "source_credentials_se
cret=git-ca" --param "gitops_credentials_secret=git-ca"
```

Create a testing supply chain workload

To add the Tekton supply chain to the cluster, apply the following YAML to the cluster:

```
apiVersion: tekton.dev/v1beta1
kind: Pipeline
metadata:
  name: developer-defined-tekton-pipeline
```

```
  labels:
    apps.tanzu.vmware.com/pipeline: test     # (!) required
spec:
  params:
    - name: source-url                       # (!) required
    - name: source-revision                  # (!) required
  tasks:
    - name: test
      params:
        - name: source-url
          value: $(params.source-url)
        - name: source-revision
          value: $(params.source-revision)
      taskSpec:
        params:
          - name: source-url
          - name: source-revision
        steps:
          - name: test
            image: MY-REGISTRY/gradle
            script: |-
              cd `mktemp -d`
```

Where `MY-REGISTRY` is your container image registry. Relocate all the images given in the pipeline YAML to your private container registry.

Create the workload by running:

```
tanzu apps workload create APP-NAME --git-repo  https://GITURL --git-branch BRANCH --t
ype web --label app.kubernetes.io/part-of=CATALOGNAME --yes --param-yaml --label apps.
tanzu.vmware.com/has-tests=true buildServiceBindings='[{"name": "settings-xml", "kin
d": "Secret"}]'
```

To instead pass the CA certificate when you create the workload, run:

```
tanzu apps workload create APP-NAME --git-repo  https://GITREPO --git-branch BRANCH --
type web --label app.kubernetes.io/part-of=CATALOGNAME --yes --param-yaml --label app
s.tanzu.vmware.com/has-tests=true buildServiceBindings='[{"name": "settings-xml", "kin
d": "Secret"}]' --param "source_credentials_secret=git-ca" --param "gitops_credentials
_secret=git-ca"
```

Create a testing scanning supply chain workload

Create workload by running:

```
tanzu apps workload create APP-NAME --git-repo  https://GITURL --git-branch BRANCH --t
ype web --label app.kubernetes.io/part-of=CATALOGNAME --yes --param-yaml --label apps.
tanzu.vmware.com/has-tests=true buildServiceBindings='[{"name": "settings-xml", "kin
d": "Secret"}]'
```

To instead pass the CA certificate when you create the workload, run:

```
tanzu apps workload create APP-NAME --git-repo  https://GITREPO --git-branch BRANCH --
type web --label app.kubernetes.io/part-of=CATALOGNAME --yes --param-yaml --label app
s.tanzu.vmware.com/has-tests=true buildServiceBindings='[{"name": "settings-xml", "kin
d": "Secret"}]' --param "source_credentials_secret=git-ca" --param "gitops_credentials
_secret=git-ca"
```

Deploy Spring Cloud applications to Tanzu Application Platform

This sub-section tells you how to run Spring applications that rely on various Spring Cloud services as workloads on Tanzu Application Platform (commonly known as TAP).

In this sub-section:

- Deploy Spring Cloud Config applications
- Deploy Spring Cloud DiscoveryClient applications
- Use Spring Cloud Gateway for Kubernetes

Deploy Spring Cloud applications to Tanzu Application Platform

This sub-section tells you how to run Spring applications that rely on various Spring Cloud services as workloads on Tanzu Application Platform (commonly known as TAP).

In this sub-section:

- Deploy Spring Cloud Config applications
- Deploy Spring Cloud DiscoveryClient applications
- Use Spring Cloud Gateway for Kubernetes

Deploy Spring Cloud Config applications to Tanzu Application Platform

This topic tells you how to run Spring applications that depend on Spring Cloud Config Server as workloads on Tanzu Application Platform (commonly known as TAP).

Identify Spring Cloud Config applications

The Spring Cloud Config project is used within many common configuration services for Spring applications, including the following:

- The Config Server in the managed service tile Spring Cloud Services for VMware Tanzu that is supported by VMware Tanzu Application Service for VMs.
- Application Configuration Service for Tanzu in Azure Spring Apps. For more information about Azure Spring Apps, see the Microsoft Azure documentation.

Spring applications that use these configuration services often include a client dependency that interacts with the Spring Cloud Config Server:

- Applications that use the Spring Cloud Services Config Server on Tanzu Application Service typically include the `spring-cloud-services-starter-config-client` dependency from the `io.pivotal.spring.cloud` group. For more information, see the Config Server in the Spring Cloud Services documentation.
- Applications that use the open-source Spring Cloud Config Server typically include the `spring-cloud-starter-config` dependency from the `org.springframework.cloud` group. For more information, see the Spring Cloud Config documentation.

Prerequisites

Before you can deploy Spring Cloud Config applications, you must Install Application Configuration Service for VMware Tanzu.

The Application Configuration Service for VMware Tanzu component in Tanzu Application Platform distributes configuration information to applications through Kubernetes Secrets that contain Spring

properties.

Configure workloads

For instructions for how to run existing Spring applications that rely on the Spring Cloud Config Server as workloads in Tanzu Application Platform, see Configuring Workloads in Tanzu Application Platform using Application Configuration Service in the Application Configuration Service for VMware Tanzu documentation.

Deploy Spring Cloud DiscoveryClient applications to Tanzu Application Platform

This topic tells you how to run Spring applications that use the Spring Cloud DiscoveryClient as workloads on Tanzu Application Platform (commonly known as TAP).

Identify Spring Cloud DiscoveryClient applications

The Spring Cloud DiscoveryClient abstraction underlies several common libraries and services for Spring applications to register themselves as services for other applications and to look up connection details of registered applications. These services include the following:

- The Service Registry in the managed service tile Spring Cloud Services for VMware Tanzu supported by VMware Tanzu Application Service for VMs.
- The Tanzu Service Registry in Azure Spring Apps. For more information about Azure Spring Apps, see the Microsoft Azure documentation.
- The Spring Cloud Netflix project, which includes the Eureka client library and the Eureka server.

Spring applications that use these discovery services include a client dependency that implements the Spring Cloud DiscoveryClient:

- Applications that use the Spring Cloud Services Service Registry on Tanzu Application Service typically include the `spring-cloud-services-starter-service-registry` dependency from the `io.pivotal.spring.cloud` group. For more information, see Service Registry in the Spring Cloud Services documentation.
- Applications that use the Tanzu Service Registry in Azure Spring Apps or that use the Spring Cloud Netflix libraries typically include the `spring-cloud-starter-netflix-eureka-client` dependency from the `org.springframework.cloud` group. For more information about how to use the Tanzu Service Registry, see the Microsoft Azure documentation. For more information about how to include Eureka Client, see the Spring documentation.

Each of these client dependencies includes the Spring Cloud SimpleDiscoveryClient from the Spring Cloud Commons project as a base dependency. The approach in this topic uses this common dependency to configure service resolution for client applications.

Prerequisites

Before you can continue with the example in this topic, you must Install Application Configuration Service for VMware Tanzu.

In this example, the Application Configuration Service for VMware Tanzu component in Tanzu Application Platform distributes service discovery information to client applications as Spring properties.

Example: The Greeting application

The following sections show how to run the Greeting sample application as a pair of workloads on Tanzu Application Platform.

Create a properties file in your configuration repository

In a Git repository that is reachable from your Run cluster, create a `greeter-dev.yaml` file as follows:

```
eureka:
  client:
    # this disables the Eureka Spring Cloud discovery client
    enabled: false
spring:
  cloud:
    discovery:
      client:
        simple:
          instances:
            greeter-messages:
            - uri: http://greeter-messages.my-apps.svc.cluster.local
```

The values under `spring.cloud.discovery.client.simple.instances` list all the services that your application requires. The example `greeter-dev.yaml` file shows how to connect to another workload running on the same cluster.

In the example in Create application workload resources, the `greeter-messages` microservice is deployed as a workload of type `web`, so the discovery client configuration must use the fully qualified domain name for the service within the Kubernetes cluster. If you instead choose to run the `greeter-messages` microservice as a workload of type `server`, this address still works, but the `greeter` microservice can also connect using the shorter URI `http://greeter-messages`.

Create Application Configuration Service resources

On your Run cluster, create the `ConfigurationSource` and `ConfigurationSlice` resources that tell Application Configuration Service (ACS) how to fetch the discovery configuration from the Git repository you are using.

The following example uses a public repository and no encryption. For more information about how to connect to private repositories, encrypt configuration, and load properties in other formats, see the ACS documentation.

```
---
apiVersion: "config.apps.tanzu.vmware.com/v1alpha4"
kind: ConfigurationSource
metadata:
  name: greeter-config-source
  namespace: my-apps
spec:
  backends:
    - type: git
      uri: https://github.com/your-org/your-config-repo
---
apiVersion: config.apps.tanzu.vmware.com/v1alpha4
kind: ConfigurationSlice
metadata:
  name: greeter-config
  namespace: my-apps
spec:
  configurationSource: greeter-config-source
  content:
  - greeter/dev
```

```
  secretStrategy: applicationProperties
  interval: 10m
```

A Kubernetes secret is created in the `my-apps` namespace with a name starting with `greeter-config-`.

Create application workload resources

The `ConfigurationSlice` object you created in the previous section is a Provisioned Service. You can use a `ResourceClaim` to claim it within the `my-apps` namespace. You then supply the resource claim in the `serviceClaims` list in the `Workload` object to provide the configuration inside the runtime environment of the workload.

The `SPRING_CONFIG_IMPORT` variable passes this configuration to Spring. If your application already uses that variable to apply other Spring configuration, use the `SPRING_CONFIG_ADDITIONAL_LOCATION` variable instead.

In the following example, one workload is created for the `greeter-messages` microservice, and a second workload is created for the greeter microservice. Both apps bind to the `ConfigurationSlice` to add Spring configuration:

```
---
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: greeter-messages
  namespace: my-apps
  labels:
    apps.tanzu.vmware.com/workload-type: web
    apps.tanzu.vmware.com/has-tests: "true"
    app.kubernetes.io/part-of: greeter
spec:
  build:
    env:
    - name: BP_JVM_VERSION
      value: "17"
    # this tells the Gradle buildpack which module to build
    - name: BP_GRADLE_BUILT_MODULE
      value: "greeter-messages"
  env:
  # the Greeting app enables basic authentication unless the
  # development profile is used
  - name: SPRING_PROFILES_ACTIVE
    value: "development"
  - name: SPRING_CONFIG_IMPORT
    value: "${SERVICE_BINDING_ROOT}/spring-properties/"
  serviceClaims:
  - name: spring-properties
    ref:
      apiVersion: services.apps.tanzu.vmware.com/v1alpha1
      kind: ResourceClaim
      name: greeter-config-claim
  source:
    git:
      url: https://github.com/spring-cloud-services-samples/greeting
      ref:
        branch: main
---
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: greeter
  namespace: my-apps
  labels:
```

```
    apps.tanzu.vmware.com/workload-type: web
    apps.tanzu.vmware.com/has-tests: "true"
    app.kubernetes.io/part-of: greeter
spec:
  build:
    env:
    - name: BP_JVM_VERSION
      value: "17"
    - name: BP_GRADLE_BUILT_MODULE
      value: "greeter"
  env:
  - name: SPRING_PROFILES_ACTIVE
    value: "development"
  - name: SPRING_CONFIG_IMPORT
    value: "${SERVICE_BINDING_ROOT}/spring-properties/"
  serviceClaims:
  - name: spring-properties
    ref:
      apiVersion: services.apps.tanzu.vmware.com/v1alpha1
      kind: ResourceClaim
      name: greeter-config-claim
  source:
    git:
      url: https://github.com/spring-cloud-services-samples/greeting
      ref:
        branch: main
---
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ResourceClaim
metadata:
  name: greeter-config-claim
  namespace: my-apps
spec:
  ref:
    apiVersion: config.apps.tanzu.vmware.com/v1alpha4
    kind: ConfigurationSlice
    name: greeter-config
```

The greeter application builds, starts up, and finds the `greeter-messages` URI using the SimpleDiscoveryClient.

Using Spring Cloud Gateway for Kubernetes with Tanzu Application Platform

This topic tells you how to use Spring Cloud Gateway for Kubernetes as an API gateway for workloads running on Tanzu Application Platform (commonly known as TAP).

Spring Cloud Gateway is a popular project library for creating an API Gateway that is built on top of the Spring ecosystem. The open source library is a foundational component of VMware Spring Cloud Gateway for Kubernetes and Spring Cloud Gateway for VMware Tanzu Application Service commercial offerings with commercial-only capabilities and platform-integrated operator experiences. You can use the open source and commercial offerings as a reverse proxy with extra API Gateway functions to handle request and response to upstream application services.

Spring Cloud Gateway for Kubernetes is included with Tanzu Application Platform v1.5 and later. You can migrate upstream applications that expose API routes on Spring Cloud Gateway from Tanzu Application Service and custom open source implementations to Tanzu Application Platform. For how to do so, see the VMware Spring Cloud Gateway for Kubernetes documentation.

Run Spring Boot apps on Tanzu Application Platform as GraalVM native images

This topic guides you through how to run Spring Boot applications on Tanzu Application Platform as native images using GraalVM, including the available options.

What you will do

- Configure your Spring Boot application and `workload.yaml` file to run on Tanzu Application Plaform as a native image.
- Configure your app and `workload.yaml` file to enable Application Live View for Spring Boot native applications.

Introduction

Running a native image has several advantages:

- **Lower memory footprint:** This translates into lower resource use or increased scalability, such as deploying more replicas for the same memory cost.
- **Faster start times:** Component initialization is reduced to milliseconds, which makes pod recovery time and horizontal scalability faster.

Requirements for your Spring Boot application

To compile your Spring Boot applications into native images using GraalVM on Tanzu Application Platform, they must use Spring Boot 3 and Java 17 as a minimum. VMware recommends that you use the latest version of Spring Boot 3. To learn more about turning your Spring Boot applications into GraalVM native images in general, see the Spring Boot documentation.

Running Spring Boot applications as native images using GraalVM independent of Tanzu Application Platform might require some manual work to make your application work correctly when compiled to a native image. Changes to your application include avoiding the use of patterns such as reflection and implementing compiler hints. Therefore, VMware recommends that you make your application ready to run as a native image from the beginning and run extensive tests before trying to run them as native images on the platform. To confirm Spring Boot support for native testing, see the Spring Boot Documentation.

If your application can run as native images in general, Tanzu Application Platform allows you to run your applications as native executable files on the platform as well and tries to make it as easy as possible to manage your applications over time.

Run your Spring Boot workload as a native image

This section explains how to configure Tanzu Application Platform to compile your Spring Boot application into a native executable file and how to run that native executable file on the platform.

Configure the application side

For your application, use the usual process for developing and testing workloads that support native images. For general information about native image support, see the Spring documentation.

You must include the GraalVM native plug-in in your Maven POM file or Gradle build file.

- Example for Maven:

```
<build>
  <plugins>
    <plugin>
      <groupId>org.graalvm.buildtools</groupId>
```

```
      <artifactId>native-maven-plugin</artifactId>
    </plugin>
    <plugin>
    .
    .
    .
</build>
```

- Example for Gradle:

```
plugins {
  id("org.graalvm.buildtools.native") version "0.9.20"
  .
  .
  .
}
```

Configure the workload

To enable a native build, configure the buildpack to perform the native compilation step. You might also need to enable the native profile, mainly for Maven/Spring Boot 3.x projects.

You configure these settings using the `spec.build` environment parameters in the workload.

The following example works for all use cases. If you are using Gradle, remove the additional Maven build arguments. This example has the full `spec.build` configuration:

```
spec:
  build:
  env:
  - name: BP_JVM_VERSION
    value: "17"
  - name: BP_NATIVE_IMAGE
    value: "true"
  - name: BP_MAVEN_BUILD_ARGUMENTS
    value: '-Pnative -Dmaven.test.skip=true --no-transfer-progress package -Dspring-bo
ot.aot.jvmArguments=''-Dmanagement.endpoint.health.probes.add-additional-paths=''tru
e''
      -Dmanagement.endpoint.health.show-details=''always'' -Dmanagement.endpoints.web.
base-path=''/actuator''
      -Dmanagement.endpoints.web.exposure.include=''*'' -Dmanagement.health.probes.ena
bled=''true''
      -Dmanagement.server.port=8081 -Dserver.port=8080'' '
```

Because native images implement a closed world philosophy, you cannot set configuration at runtime deterministically. As a consequence, the Spring Boot Convention cannot automatically set options for native images to optimize running the application on the platform. However, the `tanzu-java-web-app` Tanzu Application Platform accelerator provides an example that you can refer to.

The most important elements from the configuration are `BP_JVM_VERSION`, `BP_NATIVE_IMAGE` and `BP_MAVEN_BUILD_ARGUMENTS`. They provide the instructions for buildpacks to `init` the native compilation. Without these, a normal Java virtual machine (JVM) compilation to generate a regular JAR file occurs.

The `BP_JVM_VERSION` configures buildpacks to use a JDK 17, because Spring Boot 3.x requires a JDK 17 as a minimum.

Note

Values used at build time do not specify the values that will be used at runtime. If you provide build time instrumentation, it only enables configuration to be set at

runtime. You must provide runtime values separately.

Depending on the app type, such as web, server, or worker, different methods for monitoring the health of the application are employed that might require configuring certain runtime parameters. For applications that do not need automatically configured actuators, you can generically achieve this using the following `build.spec` environment parameters:

```
 - name: MANAGEMENT_ENDPOINT_HEALTH_PROBES_ADD_ADDITIONAL_PATHS
         value: "true"
       - name: MANAGEMENT_HEALTH_PROBES_ENABLED
         value: "true"
       - name: SERVER_PORT
         value: "8080"
```

To set the actual runtime values, you can use the preceding settings in the `spec.env` parameters in the workload.

Example workload enabling native images

The following is an example of a full `workload.yaml` file that enables native image support:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
 name: myworkload
 labels:
   apps.tanzu.vmware.com/workload-type: web
   apps.tanzu.vmware.com/has-tests: "true"
   app.kubernetes.io/part-of: myworkload
spec:
 build:
   env:
   - name: BP_JVM_VERSION
     value: "17"
   - name: BP_NATIVE_IMAGE
     value: "true"
   - name: BP_MAVEN_ADDITIONAL_BUILD_ARGUMENTS
     value: -Pnative
   - name: MANAGEMENT_HEALTH_PROBES_ENABLED
     value: "true"
   - name: MANAGEMENT_ENDPOINT_HEALTH_PROBES_ADD_ADDITIONAL_PATHS
     value: "true"
   - name: SERVER_PORT
     value: "8080"
 env:
 - name: MANAGEMENT_HEALTH_PROBES_ENABLED
   value: "true"
 - name: MANAGEMENT_ENDPOINT_HEALTH_PROBES_ADD_ADDITIONAL_PATHS
   value: "true"
 - name: MANAGEMENT_ENDPOINT_HEALTH_SHOW_DETAILS
   value: always
 - name: SERVER_PORT
   value: "8080"
 source:
   git:
     url: https://github.com/myorg/myworkload
     ref:
       branch: main
```

What about the Spring Boot Convention?

When Spring Boot Convention detects a Spring Boot application, it automatically configures the workload for the platform, such as configuring the server port. The Spring Boot Convention does this by setting the `JAVA_TOOL_OPTIONS` environment variable and including various system property settings.

Because the setting `JAVA_TOOL_OPTIONS` doesn't work for native compiled Spring Boot applications, many of the configurations that the Spring Boot Convention applies don't have any effect. This is why you must configure this manually using separate environment variables as described earlier.

The goal for future versions of the Spring Boot Convention is to have it automatically do much of the current manual work.

Using Application Live View with Spring Boot native images

The Application Live View component of Tanzu Application Platform is designed around the Spring Boot Actuator extension for Spring Boot and therefore also works for Spring Boot apps that are compiled to native executable files.

However, due to current limits to automation, to enable Application Live View for your application you must configure specific options when building and running your Spring Boot apps as native images on Tanzu Application Platform.

Configure the application side

Application Live View relies on information obtained from the actuator endpoints of an application and therefore requires the actuator library to be present.

Configure your application to include the actuator library:

- Example for Maven:

```
<dependencies>
  <dependency>
    <groupId>org.springframework.boot</groupId>
    <artifactId>spring-boot-starter-actuator</artifactId>
  </dependency>
  .
  .
  .
<dependencies>
```

- Example for Gradle:

```
dependencies {
  implementation("org.springframework.boot:spring-boot-starter-actuator")
  .
  .
  .
}
```

Configure the workload

For an application to integrate with Application Live View:

1. The application must declare the integration by either:
    - In the `workload.yaml` file, set the `apps.tanzu.vmware.com/auto-configure-actuators` label. For more information, see Workload-level configuration.

- In the `tap-values.yaml` file, enable platform level configuration for actuator automatic configuration in the Spring Boot convention. For more information, see Platform-level configuration.

2. Configure additional runtime properties for Application Live View, which requires additional AOT (ahead-of-time) instrumentation at build time.

   Similar to general native image workloads, supply additional AOT configuration in the `workload.yaml` using `spec.build` environment parameters. Application Live View requires the following build environment parameters:

   ```
   - name: MANAGEMENT_HEALTH_PROBES_ENABLED
     value: "true"
   - name: MANAGEMENT_ENDPOINT_HEALTH_PROBES_ADD_ADDITIONAL_PATHS
     value: "true"
   - name: MANAGEMENT_ENDPOINT_HEALTH_SHOW_DETAILS
     value: always
   - name: MANAGEMENT_ENDPOINTS_WEB_BASE_PATH
     value: /actuator
   - name: MANAGEMENT_ENDPOINTS_WEB_EXPOSURE_INCLUDE
     value: '*'
   - name: MANAGEMENT_SERVER_PORT
     value: "8081"
   - name: SERVER_PORT
     value: "8080"
   ```

   Also similar to general native image workloads, runtime configuration is also provided through the use of environment variables.

Example workload enabling Application Live View

The following is an example of a full `workload.yaml` file that enables both native image compilation and integration with Application Live View:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
 name: myworkload
 labels:
   apps.tanzu.vmware.com/workload-type: web
   apps.tanzu.vmware.com/has-tests: "true"
   app.kubernetes.io/part-of: myworkload
   apps.tanzu.vmware.com/auto-configure-actuators: "true"
spec:
 build:
   env:
   - name: BP_JVM_VERSION
     value: "17"
   - name: BP_NATIVE_IMAGE
     value: "true"
   - name: BP_MAVEN_ADDITIONAL_BUILD_ARGUMENTS
     value: -Pnative
   - name: MANAGEMENT_HEALTH_PROBES_ENABLED
     value: "true"
   - name: MANAGEMENT_ENDPOINT_HEALTH_PROBES_ADD_ADDITIONAL_PATHS
     value: "true"
   - name: MANAGEMENT_ENDPOINT_HEALTH_SHOW_DETAILS
     value: always
   - name: MANAGEMENT_ENDPOINTS_WEB_BASE_PATH
     value: /actuator
   - name: MANAGEMENT_ENDPOINTS_WEB_EXPOSURE_INCLUDE
     value: '*'
   - name: MANAGEMENT_SERVER_PORT
```

```
    value: "8081"
  - name: SERVER_PORT
    value: "8080"
env:
- name: MANAGEMENT_HEALTH_PROBES_ENABLED
  value: "true"
- name: MANAGEMENT_ENDPOINT_HEALTH_PROBES_ADD_ADDITIONAL_PATHS
  value: "true"
- name: MANAGEMENT_ENDPOINT_HEALTH_SHOW_DETAILS
  value: always
- name: MANAGEMENT_ENDPOINTS_WEB_BASE_PATH
  value: /actuator
- name: MANAGEMENT_ENDPOINTS_WEB_EXPOSURE_INCLUDE
  value: '*'
- name: MANAGEMENT_SERVER_PORT
  value: "8081"
- name: SERVER_PORT
  value: "8080"
source:
  git:
    url: https://github.com/myorg/myworkload
    ref:
      branch: main
```

Usually, this configuration is automatically applied by the Spring Boot Convention when it detects a Spring Boot application. In the case of a natively compiled Spring Boot application, this configuration has to be done manually.

The Application Live View specific part of the Spring Boot Convention automatically flags the workload with a specific label to enable the Application Live View feature for the workload.

Register the app in the UI

The previous steps help Application Live View to detect your app, but it still won't show in the UI until you register the app.

To register the app in the UI, you must:

1. Navigate to **Tanzu Developer Portal**.
2. Click **REGISTER ENTITY**.
3. Follow the instructions onscreen.

For further instructions, see Deploy an app on Tanzu Application Platform.

Important

Not all the usual information will be available. For example, JVM memory information won't be available because native images have a slightly different mode, and there are other elements that won't be available in the actuator endpoints.

Create a new application accelerator

This topic guides you through creating an accelerator and registering it in a Tanzu Application Platform (commonly known as TAP) instance.

Tanzu Application Platform offers a selection of built-in accelerators to streamline your development process. However, if these accelerators don't meet your needs, you can create a new accelerator. By creating an accelerator, you can ensure that your technology stacks and organizational best practices are adhered to.

Note

This guide follows a quick start format. See the Application Accelerator documentation for advanced features.

What you will do

- Create a new accelerator project that contains an `accelerator.yaml` file and `README.md` file.
- Configure the `accelerator.yaml` file to alter the project's `README.md`.
- Test your accelerator locally using the Tanzu CLI `generate-from-local` command.
- Create a new Git repository for the project and push the project to it.
- Register the accelerator in a Tanzu Application Platform instance.
- Verify project generation with the new accelerator by using Tanzu Developer Portal.

Set up Visual Studio Code

1. To simplify accelerator authoring, code assist capabilities are available. To install the extension, navigate to the Marketplace page for the YAML plug-in and click **Install**.

   Note

   Code assist for authoring accelerators is also available in the IntelliJ IDE. You can enable this by selecting **Application Accelerator** in the schema mapping drop-down menu. For more information about how to enable this, see the IntelliJ Using schemas from JSON Schema Store documentation.

2. After you install the plug-in, editing files entitled `accelerator.yaml` automatically uses the code assist capabilities.

Create a simple project

To create your project, follow these instructions to set up the project directory, prepare the `README.md` and `accelerator.yaml`, and test your accelerator.

Set up the project directory

1. Create a new directory for the project named `myProject` and change to the newly created directory.

   ```
   mkdir myProject
   cd myProject
   ```

2. Create two new files in the `myProject` directory named `README.md` and `accelerator.yaml`.

   ```
   touch README.MD accelerator.yaml
   ```

Prepare the `README.md` and `accelerator.yaml`

The following instructions require using Visual Studio Code to edit the files.

1. Using Visual Studio Code, open the `README.md`, copy and paste the following code block into it, and save the file. `CONFIGURABLE_PARAMETER_#` is targeted to be transformed during project generation in the upcoming `accelerator.yaml` definition.

```
## Tanzu Application Accelerator Sample Project

This is some very important placeholder text that should describe what this pro
ject can do and how to use it.

Here are some configurable parameters:

* CONFIGURABLE_PARAMETER_1
* CONFIGURABLE_PARAMETER_2
```

2. Open `accelerator.yaml` and begin populating the file section using the snippet below. This section contains important information, such as the accelerator's display name, description, tags, and more.

   For all possible parameters available in this section, see Creating accelerator.yaml.

```
accelerator:
  displayName: Simple Accelerator
  description: Contains just a README
  iconUrl: https://blogs.vmware.com/wp-content/uploads/2022/02/tap.png
  tags:
    - simple
    - getting-started
```

3. Add the configuration parameters using the following code snippet. This configures what parameters are displayed in the accelerator form during project creation.

   In this example snippet, the field `firstConfigurableParameter` takes in text the user provides. The `secondConfigurableParameter` does the same, except it is only displayed if the user checks `secondConfigurableParameterCheckbox` because of the `dependsOn` parameter.

   For more information about possible options, see Creating accelerator.yaml.

```
# Place this after the 'tags' section from the previous step
  options:
    - name: firstConfigurableParameter
      inputType: text
      label: The text used to replace the first placeholder text in the README.
md. Converted to lowercase.
      defaultValue: Configurable Parameter 1
      required: true
    - name: secondConfigurableParameterCheckbox
      inputType: checkbox
      dataType: boolean
      label: Enable to configure the second configurable parameter, otherwise u
se the default value.
    - name: secondConfigurableParameter
      inputType: text
      label: The text used to replace the second placeholder text in the READM
E.md. Converted to lowercase.
      defaultValue: Configurable Parameter 2
      dependsOn:
        name: secondConfigurableParameterCheckbox
```

4. Add the `engine` configuration by using the following code snippet and save the file.

The `engine` configuration tells the `accelerator engine` behind the scenes what must be done to the project files during project creation. In this example, this instructs the engine to replace `CONFIGURABLE_PARAMETER_1` and, if the check box is checked, `CONFIGURABLE_PARAMETER_2` with the parameters that the user passes in during project creation.

This also leverages Spring Expression Language (SpEL) syntax to convert the text input to all lowercase.

For more information about the possible parameters for use within the `engine` section, see Creating accelerator.yaml.

```
# Place this after the `options` section from the previous step
engine:
  merge:
    - include: [ "README.md" ]
      chain:
        - type: ReplaceText
          substitutions:
            - text: "CONFIGURABLE_PARAMETER_1"
              with: "#firstConfigurableParameter.toLowerCase()"
        - condition: "#secondConfigurableParameterCheckbox"
          chain:
          - type: ReplaceText
            substitutions:
              - text: "CONFIGURABLE_PARAMETER_2"
                with: "#secondConfigurableParameter.toLowerCase()"
```

Test the accelerator

It is important to quickly test and iterate on accelerators as they are being developed to ensure that the resulting project is generated as expected.

1. Using the terminal of your choice with access to the `tanzu` command, run the following command to test the accelerator created earlier.

   This step takes the local `accelerator.yaml` and project files, configures the project using the parameters passed in through the `--options` field, and outputs the project to a specified directory.

   Important

   This step requires that the `TANZU-APPLICATION-ACCELERATOR-URL` endpoint is exposed and accessible. For more information, see Server API connections for operators and developers.

   ```
   tanzu accelerator generate-from-local \
       --accelerator-path simple-accelerator="$(pwd)" `# The path to new accelerat
   or` \
       --server-url TANZU-APPLICATION-ACCELERATOR-URL `# Example: https://accelera
   tor.mytapcluster.myorg.com` \
       --options '{"firstConfigurableParameter": "Parameter 1", "secondConfigurabl
   eParameterCheckbox": true, "secondConfigurableParameter":"Parameter 2"}' \
       -o "${HOME}/simple-accelerator/" `# Change this path to change where the pr
   oject folder gets generated`
   ```

2. After the project is generated, a status message is displayed.

   ```
   generated project simple-accelerator
   ```

3. Navigate to the output directory and verify that the `README.md` is updated based on the `--options` specified in the preceding `generate-from-local` command.

```
## Tanzu Application Accelerator Sample Project

This is some very important placeholder text that should describe what this pro
ject can do and how to use it.

Here are some configurable parameters:

- parameter 1
- parameter 2
```

Upload the project to a Git repository

The Application Accelerator system and Tanzu Developer Portal depend on an accelerator project residing inside a Git repository. For this example, GitHub is used.

1. Create a new repository in GitHub and ensure that **Visibility** is set to **Public**. Click **Create Repository**.
2. To push your accelerator project (**not** the generated project from `generate-from-local`) to GitHub, follow the instructions that GitHub provides for the *…or create a new repository on the command line* that is shown after clicking **Create Repository**. Instructions can also be found in the GitHub documentation.
3. Verify that the project is pushed to the target repository.

Register the accelerator to the Tanzu Application Platform and verify project generation output

Now that the accelerator is committed to its own repository, you can register the accelerator to Tanzu Developer Portal for developers to generate projects from the newly created accelerator.

To do so, use the URL of the Git repository and branch name created earlier and run the following command using the Tanzu CLI to register the accelerator to Tanzu Developer Portal.

Note

`tanzu accelerator create` works with monorepos as well. Add the `--git-sub-path` parameter with the desired subpath to fetch the accelerator project in that directory. For more information, see the [Tanzu CLI Command Reference] (https://docs.vmware.> com/en/VMware-Tanzu-CLI/1.3/tanzu-cli/command-ref.html) documentation.

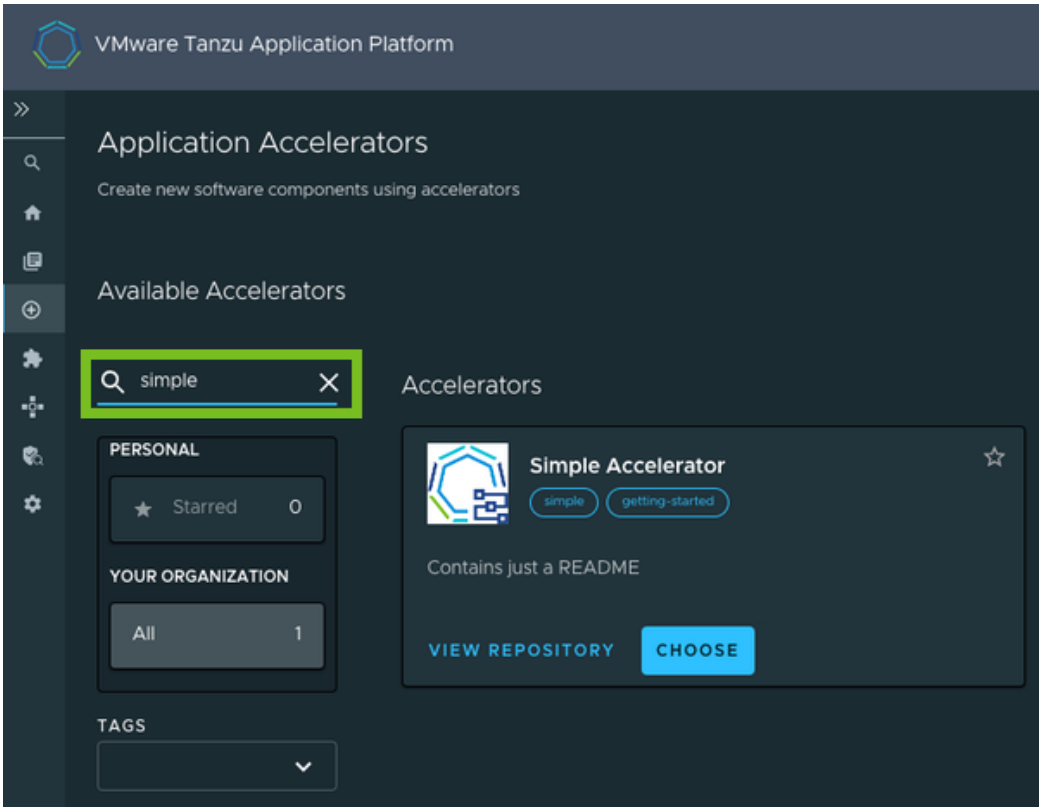
```
tanzu accelerator create simple-accelerator --git-repository https://github.com/myuser
name/myprojectrepository --git-branch main
```

The accelerator can take time to reconcile. After it has reconciled, it is available for use in Tanzu Developer Portal and the Application Accelerator extension for Visual Studio Code.

Verify project generation output by using Tanzu Developer Portal

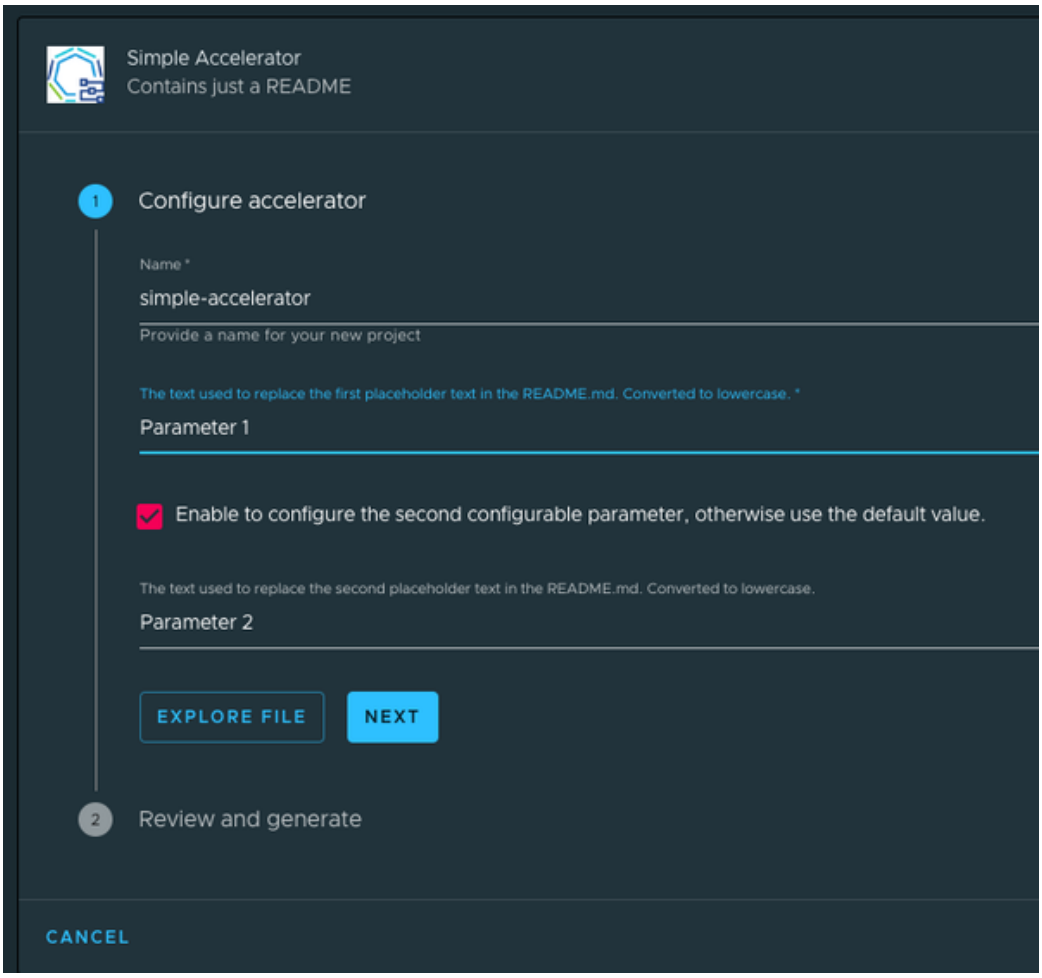
1. Navigate to your organization's instance of Tanzu Developer Portal.

2. On the left navigation pane, click **Create**.
3. Using the search bar near the left side of the page, search for `simple accelerator`. After you've found it, click **Choose** on the accelerator card.



4. Configure the project by filling in the parameters in the form.

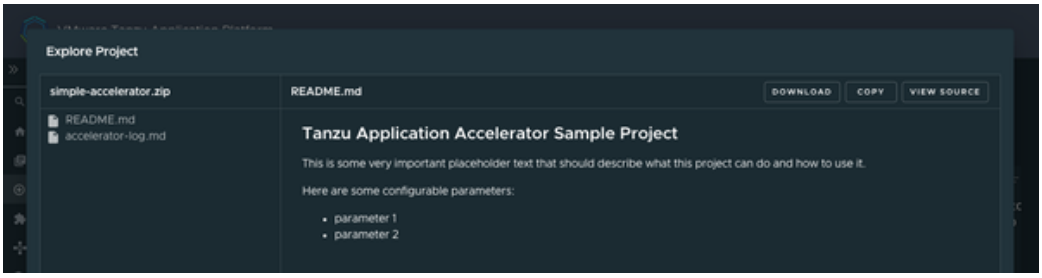
   The options you defined in `accelerator.yaml` are now displayed for you to configure. The `secondConfigurableParameter dependsOn secondConfigurableParameterCheckbox` might be hidden depending on whether the check box is selected.



5. After configuration is complete, click **Next**.

> **Note**
>
> Depending on your organization's Tanzu Application Platform configuration, you might be presented with an option to create a Git repository. In this guide, this is skipped and is covered in Deploy an app on Tanzu Application Platform.

6. On the **Review and generate** step, review the parameters and click **Generate Accelerator**.
7. Explore the ZIP file of the configured project and verify that the project is generated with the parameters you provided during configuration.



Learn more about Application Accelerator

- For advanced functionality when creating accelerators, such as accelerator best practices, accelerator fragments, engine transforms, and more, see the Application Accelerator documentation.
- For more information about Application Accelerator configurations, see the Configure Application Accelerator documentation.
- For information about installing the Application Accelerator extension for Visual Studio Code, see the Application Accelerator Visual Studio Code extension documentation.
- For general accelerator troubleshooting, see Troubleshooting Application Accelerator for VMware Tanzu.

Learn about Tanzu Application Platform

The topics in this section explain concepts important to getting started with Tanzu Application Platform (commonly known as TAP).

In this section:

- Application Accelerator
- Supply chains on Tanzu Application Platform
- Vulnerability scanning and metadata storage for your supply chain
- Consume services on Tanzu Application Platform

Application accelerators on Tanzu Application Platform

This topic describes the key concepts you need to know about application accelerators on Tanzu Application Platform (commonly known as TAP).

What are application accelerators

Application accelerators are templates that not only codify best practices but also provide important configuration and structures ready and available for use. Developers can create applications and get started with feature development immediately with the help of application accelerators.

Enterprise Architects use Application Accelerator to create application accelerators, which provide developers and admins in their organization with ready-made, enterprise-conforming code and configurations. Accelerators contain complete and runnable application code and deployment configurations. They also contain metadata for altering the code and deployment configurations based on input values provided for specific options defined in the accelerator metadata.

Working with accelerators

The Application Accelerator plug-in for Tanzu Developer Portal helps you to discover accelerators and to enter extra information used for processing the files before downloading. As of Tanzu Application Platform v1.2, developers can also discover and work on accelerators right in Visual Studio Code with the Tanzu Application Accelerator for VS Code extension. Developers can use the `list`, `get`, and `generate` commands to use accelerators available in an Application Accelerator server.

Admins use the `create`, `update`, and `delete` commands for managing accelerators in a Kubernetes context. When admins want to use the `get` and `list` commands, they can specify the `--from-context` flag to access accelerators in a Kubernetes context.

Apply what you have learned:

Developers:

- Deploy an app on Tanzu Application Platform

Operators:

- Create an application accelerator

Supply chains on Tanzu Application Platform

This topic describes the key concepts you need to know about supply chains and Continuous Integration/Continuous Delivery (CI/CD) on Tanzu Application Platform (commonly known as TAP).

What are supply chains

Supply chains provide a way of codifying all of the steps of your path to production, more commonly known as CI/CD. CI/CD is a method to frequently deliver applications by introducing automation into the stages of application development. The main concepts attributed to CI/CD are continuous integration, continuous delivery, and continuous deployment.

CI/CD is the method used by supply chains to deliver applications through automation. Tanzu Application Platform supply chains allow you to use CI/CD and add any other steps necessary for an application to reach production or a different environment, such as staging.

A path to production

A path to production allows you to create a unified access point for all of the tools required for your applications to reach a customer-facing environment. Instead of having four tools that are loosely coupled to each other, a path to production defines all four tools in a single, unified layer of abstraction. The path to production can be automated and repeatable between teams for applications at scale.

Typically tools cannot integrate with one another without scripting or webhooks. Whereas with a path to production, there is a unified automation tool to codify all the interactions between each of the tools. Supply chains that are used to codify the path to production for an organization are configurable. This allows their authors to add all of the steps of the path to production for their applications.

Available supply chains

Tanzu Application Platform provides three out of the box (OOTB) supply chains to work with the Tanzu Application Platform components. They include:

- OOTB Supply Chain Basic (default)
- OOTB Supply Chain with Testing (optional)
- OOTB Supply Chain with Testing+Scanning (optional)

1: OOTB Basic (default)

The default **OOTB Basic** supply chain and its dependencies were installed on your cluster during the Tanzu Application Platform install. The following diagram and table provide a description of the supply chain and dependencies provided with Tanzu Application Platform.

Name	Package Name	Description	Dependencies
Out of the Box Basic (Default - Installed during Installing Part 2)	`ootb-supply-chain-basic.tanzu.vmware.com`	This supply chain monitors a repository that is identified in the developer's `workload.yaml` file. When any new commits are made to the application, the supply chain: • Creates a new image. • Applies any predefined conventions. • Deploys the application to the cluster.	• Flux/Source Controller • Tanzu Build Service • Cartographer Conventions • Tekton • Cloud Native Runtimes • If using Service References: ◦ Service Bindings ◦ Services Toolkit

2: OOTB Testing

OOTB Testing supply chain runs a Tekton pipeline within the supply chain. The following diagram and table provide a description of the supply chain and dependencies provided with Tanzu Application Platform.

Name	Package Name	Description	Dependencies
Out of the Box Testing	`ootb-supply-chain-testing.tanzu.vmware.com`	Out of the Box Testing contains all of the same elements as the Source to URL. It allows developers to specify a Tekton pipeline that runs as part of the CI step of the supply chain. • The application tests using the Tekton pipeline. • A new image is created. • Any predefined conventions are applied. • The application is deployed to the cluster.	All of the Source to URL dependencies

3: OOTB Testing+Scanning

OOTB Testing+Scanning supply chain includes integrations for secure scanning tools. The following diagram and table provide a description of the supply chain and dependencies provided with Tanzu Application Platform.

Name	Package Name	Description	Dependencies
Out of the Box Testing and Scanning	`ootb-supply-chain-testing-scanning.tanzu.vmware.com`	Out of the Box Testing and Scanning contains all of the same elements as the Out of the Box Testing supply chain, and it also includes integrations with the secure scanning components of Tanzu Application Platform. • The application is tested using the provided Tekton pipeline. • (Optional) The application source code is scanned for vulnerabilities. For how to opt in, see Adding Source Scan to the Test and Scan Supply Chain. • A new image is created. • The image is scanned for vulnerabilities. • Any predefined conventions are applied. • The application deploys to the cluster.	All of the Source to URL dependencies, and: • The secure scanning components included with Tanzu Application Platform

Apply what you have learned:

- Add testing and scanning to your application

Or learn about:

- Vulnerability scanning and metadata storage for your supply chain

Vulnerability scanning, storing, and viewing for your supply chain

This topic describes the vulnerability scanning features you can use with Tanzu Application Platform (commonly known as TAP).

This feature set allows an application operator to introduce source code and image vulnerability scanning, storing, and viewing to their Tanzu Application Platform supply chain. It also allows for the creation of scan-time rules that prevent critical vulnerabilities from flowing to the supply chain unresolved.

Features

Features include:

- Scan source code repositories and images for known common vulnerabilities and exposures (CVEs) before deploying to a cluster.
- Identify CVEs by scanning continuously on each new code commit or each new image built.
- Analyze scan results against user-defined policies by using Open Policy Agent. Create scan policy to prevent vulnerable components from going into production.
- Produce vulnerability scan results and post them to the SCST - Store where they can be queried.
- Query the store for such use cases as:
    - What images and packages are affected by a specific vulnerability?
    - What source code repositories are affected by a specific vulnerability?
    - What packages and vulnerabilities does a particular image have?

- Visualize the supply chain and its packages and vulnerabilities of your supply chain.

Components

- Supply Chain Security Tools (SCST) - Scan scans source code and images for their packages and vulnerabilities.
- SCST - Store takes the vulnerability scanning results and stores them.
- Tanzu Insight plug-in provides a CLI to query for packages and vulnerabilities.
- Supply Chain Choreographer in Tanzu Developer Portal visualizes the supply chain, including scans, packages, and vulnerabilities.

About consuming services on Tanzu Application Platform

This topic describes the key concepts and terms you need to know about consuming services on Tanzu Application Platform (commonly known as TAP).

As part of Tanzu Application Platform, you can work with backing services such as RabbitMQ, PostgreSQL, and MySQL among others. The most common use of services is binding an application workload to a service instance.

Key concepts

When working with services on Tanzu Application Platform, you must be familiar with service instances, service bindings, and resource claims. This section provides a brief overview of each of these key concepts.

Service instances

A **service instance** is a logical grouping of one or more Kubernetes resources that together expose a known capability through a well-defined interface. For example, a theoretical MySQL service instance might consist of a `MySQLDatabase` and a `MySQLUser` resource. When considering compatibility of service instances for Tanzu Application Platform, one of the resources of a service instance must adhere to the Service Binding for Kubernetes specification.

Service bindings

Service binding refers to a mechanism in which connectivity information, such as service instance credentials, and connectivity information, such as host and port, are automatically communicated to application workloads. Tanzu Application Platform uses a standard named Service Binding for Kubernetes to implement this mechanism. See this standard to fully understand the services aspect of Tanzu Application Platform.

Resource claims

Resource claims are inspired in part by Persistent Volume Claims. For more information, see the Kubernetes documentation. Resource claims provide a mechanism for users to claim service instances on a cluster, while also decoupling the life cycle of application workloads and service instances.

Services you can use with Tanzu Application Platform

The following list of Kubernetes operators expose APIs that integrate well with Tanzu Application Platform:

1. VMware RabbitMQ for Kubernetes.
2. VMware SQL with Postgres for Kubernetes.
3. VMware SQL with MySQL for Kubernetes.

Compatibility of a service with Tanzu Application Platform ranges on a scale between fully compatible and incompatible. The minimum requirement for compatibility is that there must be a declarative, Kubernetes-based API on which at least one API resource type adheres to the Provisioned Service duck type defined by the Service Binding Specification for Kubernetes in GitHub. This duck type includes any resource type with the following schema:

```
status:
  binding:
    name: # string
```

The value of `.status.binding.name` must point to a `Secret` in the same namespace. The `Secret` contains required credentials and connectivity information for the resource.

Typically, APIs that include these resource types are installed onto the Tanzu Application Platform cluster as Kubernetes operators. These Kubernetes operators provide custom resource definitions (CRDs) and corresponding controllers to reconcile the resources of the CRDs, as is the case with the three Kubernetes operators listed earlier.

For services that do not provide a resource adhering to the Service Binding Specification for Kubernetes, you might still be able to provide configurations allowing such services to integrate with Tanzu Application Platform. For an example of how to do this for Amazon AWS RDS, see the tutorial Integrating cloud services into Tanzu Application Platform.

User roles and responsibilities

It is important to understand the user roles for services on Tanzu Application Platform and the responsibilities assumed by each. The following table describes each user role.

User role	Exists as a default role in Tanzu Application Platform?	Responsibilities
Service operator	Yes - service-operator	• Life cycle management (CRUD) of service instances • Life cycle management (CRUD) of service instance classes • Life cycle management (CRUD) of resource claim policies • View and query for resource claims across namespaces
Application operator	Yes - app-operator	Life cycle management (CRUD) of resource claims
Application developer	Yes - app-editor and app-viewer	Binding service instances to application workloads

Next steps

Apply what you've learned:

- Claim services on Tanzu Application Platform
- Consume services on Tanzu Application Platform

Migrate applications from Tanzu Application Service

The topics in this section tell you how to migrate applications from Tanzu Application Service (commonly known as TAS) to Tanzu Application Platform (commonly known as TAP).

In this section:

Migrate applications from Tanzu Application Service

The topics in this section tell you how to migrate applications from Tanzu Application Service (commonly known as TAS) to Tanzu Application Platform (commonly known as TAP).

In this section:

Compare service management on Tanzu Application Platform and Tanzu Application Service

This topic compares how you manage services on Tanzu Application Platform (commonly known as TAP) with how you manage services on Tanzu Application Service (commonly known as TAS).

Overview

Tanzu Application Service and Tanzu Application Platform both provide service binding capabilities to declaratively connect applications to their backing services. However, the catalog of available services, the user experience, and the mechanics of this capability differ.

For Tanzu Application Platform, the enabling package for services is called Services Toolkit. Tanzu Application Platform is usually installed using package profiles. Services Toolkit is installed by default in the Run and Iterate profiles. For more information, see Components and installation profiles for Tanzu Application Platform.

In Tanzu Application Platform, services are deployed alongside workloads in the same Kubernetes cluster. By contrast, Tanzu Application Service registers service brokers with the Cloud Foundry Marketplace which can run anywhere, but are commonly run as BOSH or Cloud Foundry deployments.

Service offerings

The following table compares the services offering capabilities in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Deploy an API for service instance CRUD	Services are packaged in a Tile which provision an OSBAPI-compliant API (“service broker”)	Services are packaged as Crossplane Composition and XRD, and Services Toolkit ClusterInstanceClass.
Publish a service offering	When a tile is installed, it can then be registered in the Services Marketplace. Service brokers include catalog metadata that is used by services Marketplace.	A ClusterInstanceClass Kubernetes resource is created to reference a Crossplane Composition.
List available service offerings	CLI: `cf marketplace`	CLI: `tanzu service class list`
Service Plans	Defined in the service broker implementation	There is no concept of plans. Parameters can be exposed to the user and wired through Crossplane composition, XRD, and ClusterInstanceClass. Multiple compositions can be created to offer different variants of a service, for example `{small, large}`
Get Service offering details	CLI: `cf marketplace -s SERVICE_NAME`	CLI: `tanzu service class get SERVICE_NAME`

Available out-of-the-box services

Services offered out of the box are very similar to offerings in `cf marketplace`. The following services are available on Tanzu Application Platform out of the box as provisioner-based classes that and require little to no configuration for a user to self-provision:

- Dev Backing Services by Bitnami: Redis, RabbitMQ, MySQL, PostgreSQL, Kafka, MongoDB
- AWS Services: RDS (PostgreSQL and MySQL) and AWS MQ (RabbitMQ)

For services not offered out of the box, Tanzu Application Platform also has a workflow for user-provided service instances called Direct Secret Reference.

Service compatibility and creating new service offerings

You can integrate most services with Tanzu Application Platform workloads. There are four levels of services consumption on Tanzu Application Platform. On one end of the spectrum, Tanzu Application Platform has a concept similar to Tanzu Application Service’s user provided service instances called direct secret references. User-provided service instances and direct secret

references allow you to use services that are not available in the Marketplace by providing the credentials and network endpoint. On the other end of the spectrum, a platform operator can write Crossplane compositions to offer a provisioner-based class. With each level comes more complexity but provides a more integrated self-service offering. Use the highest-level abstraction you can to make life cycle management of the services as easy to use as possible.

A key difference between Tanzu Application Service and Tanzu Application Platform is that Tanzu Application Service requires a much more rigid implementation that requires the build and release of a new versioned Tile. Whereas on Tanzu Application Platform the approach is much more modular and can be updated by modifying YAML to change settings or exposed parameters.

Tanzu Application Platform also offers a layer of abstraction called pooled classes where pre-provisioned services can be grouped together by service type, for example, MySQL, and those instances can be claimed without having to specify a particular service instance. This is a great option for still being able to offer developer self-service in organizations that have advanced service configuration requirements managed by a central services team

- Using Direct Secret references (Level 1): See Using direct secret references
- Create a Tanzu RabbitMQ service offering (Level 4): See Set up dynamic provisioning of service instances
- Create a Tanzu PostgreSQL service offering (Level 4): See Configure dynamic provisioning of VMware SQL with Postgres for Kubernetes service instances
- Create a service offering for a cloud service (Level 4): See Integrating cloud services into Tanzu Application Platform

Service binding workflow

This section compares the service binding workflow for Tanzu Application Service to Tanzu Application Platform.

Out of the box services

The following table compares the binding workflow for out of the box services.

Feature	Tanzu Application Service	Tanzu Application Platform
List available service offerings	`cf marketplace`	`tanzu service class list`
Provision a service instance	`cf create-service SERVICE-CLASS PLAN SERVICE-INSTANCE`	`tanzu service class-claim create SERVICE-INSTANCE -class SERVICE-CLASS`
Bind a service to app	`cf bind-service APP-NAME SERVICE-INSTANCE`	`tanzu apps workload update APP-NAME --service-ref SERVICE-INSTANCE`
Unbind a service to app	`cf unbind-service APP-NAME SERVICE-INSTANCE`	`tanzu apps workload update my-app --service-ref=SERVICE-INSTANCE:-`
Delete a service instance	`cf delete-service SERVICE-INSTANCE`	`tanzu service class-claim delete SERVICE-INSTANCE`

User-provided services

The following table compares the binding workflow for for user provided services.

Feature	Tanzu Application Service	Tanzu Application Platform
Create service credentials	`cf cups SERVICE-INSTANCE -p '{"username":"USERNAME", "password":"PASSWORD"}'`	Create a Kubernetes secret containing key/value pairs
Bind a service to app	`cf bind-service APP-NAME SERVICE-INSTANCE`	`tanzu apps workload update APP-NAME --service-ref SERVICE-INSTANCE`
Unbind a service to app	`cf unbind-service APP-NAME SERVICE-INSTANCE`	`tanzu apps workload update my-app --service-ref=SERVICE-INSTANCE:-`

Common operations

This section compares how Tanzu Application Service and Tanzu Application Platform meets the needs of different roles.

Service author perspective

The following table compares Tanzu Application Service and Tanzu Application Platform for service authors.

Feature	Tanzu Application Service	Tanzu Application Platform
Integrate a backing service with the platform	• Develop and maintain an OSBAPI Service Broker • Develop and maintain a Tanzu Application Service Tile	• Develop and maintain a Kubernetes Operator • Develop and maintain a set of Crossplane and Services Toolkit configurations (XRD, Composition, ClusterInstanceClass)

Service operator perspective

The following table compares Tanzu Application Service and Tanzu Application Platform for service operators.

Feature	Tanzu Application Service	Tanzu Application Platform
Offer a backing service for self-serve consumption to application developers on the platform	Install the Tanzu Application Service Tile	Install the Kubernetes operator
Ensure that all service instances on the platform meet all compliance and security requirements	Configure settings in the Tile using Ops Manager	Configure the Crossplane XRD or Composition and Services Toolkit ClusterInstanceClass accordingly

Application developer perspective

The following table compares Tanzu Application Service and Tanzu Application Platform for app developers.

Feature	Tanzu Application Service	Tanzu Application Platform
Discover the list of backing services that are available	CLI: `cf marketplace`	CLI: `tanzu service class list`
See detailed information about a particular backing service	CLI: `cf marketplace`	CLI: `tanzu service class get CLASS-NAME`

Feature	Tanzu Application Service	Tanzu Application Platform
Create a new service instance of one of the available backing services	CLI: `cf create-service SERVICE-CLASS PLAN SERVICE-INSTANCE`	CLI: `tanzu service class-claim create INSTANCE-NAME --class CLASS-NAME --parameter foo=bar`
Bind a service instance to an application workload	CLI: `cf bind-service APP-NAME SERVICE-INSTANCE`	CLI: `tanzu apps workload update my-app --service-ref CLASS-CLAIM-REF`
Bind a User Provided Service to an application workload	CLI: `cf cups SERVICE-INSTANCE -p '{"username":"admin","password":"pa55woRD"}` then run `cf bind-service`	Create a Kubernetes Secret containing the required credentials then run `tanzu apps workload update my-app --service-ref KUBERNETES-SECRET-REF`
Bind two application workloads to the same service instance in the same Tanzu Application Service space or Tanzu Application Platform namespace	Run the `cf bind-service` command twice, once for each app	Run the `tanzu apps workload update` command twice, once for each app
Share a service instance with another Tanzu Application Service space or Tanzu Application Platform namespace	CLI: `cf share-service SERVICE-INSTANCE -s OTHER_SPACE [-o OTHER_ORG]`	Not currently supported

Key differences

- Tanzu Application Platform does not use OSBAPI to provide backing service integrations. Tanzu Application Platform uses the Service Binding Specification for Kubernetes instead.
- Tanzu Application Platform does not have a concept of Service Plans. However, you can configure the ClusterInstanceClass in Tanzu Application Platform to expose zero or more properties that enable developers to configure parameters for service instances to meet their needs. You can also set defaults for those parameters.

  This approach is arguably more flexible because service operators can configure or update these properties when needed without requiring code changes and version updates to the corresponding OSBAPI brokers.
- Tanzu Application Platform does not currently have a GUI element for services.
- In Tanzu Application Service when you bind a service instance to an application workload, each separate binding is guaranteed to receive a unique set of credentials for access to the service instance. This is not guaranteed in Tanzu Application Platform.

  The behavior in Tanzu Application Platform depends on the backing Kubernetes operator.

End-to-end example deploying an app

for a step-by-step workflow of deploying an app with a service, see Migrate Spring Data Services apps to Tanzu Application Platform.

Migrate from Single Sign-On for VMware Tanzu Application Service

This topic tells you how to migrate single-sign on services from Tanzu Application Service (TAS) to Tanzu Application Platform (TAP).

Application Single Sign-On for VMware Tanzu provides single sign-on services for VMware Tanzu Application Platform. There is a comparable offering available for VMwate Tanzu Application

Service. For more information, see the Single Sign-On for VMware Tanzu Application Service documentation.

Concept comparison

The following table outlines the essential concepts, highlighting the key differences between Single Sign-On for VMware Tanzu Application Service (SSO for TAS) and Application Single Sign-On for VMware Tanzu Application Platform (AppSSO for TAP).

SSO for TAS	AppSSO for TAP	Notes
Service Plan	`AuthServer` and `ClusterWorkloadRegistrationClass`	In TAS User Account and Authentication (UAA), this corresponds to an Identity Zone. For more information, see Curate a service offering.
System Plan	n/a	This represents the special tenant in the UAA for platform access.
Internal user store	n/a	AppSSO does not support internal users. For more information, see Unsupported features. `AuthServer.spec.identityProviders.internalUnsafe` is for testing purposes.
External Identity Provider	`AuthServer.spec.identityProviders`	For more information, see Identity providers for AppSSO.
Operator dashboard	`AuthServer` Custom Resource	Operators or Service Operators interact with AppSSO by using the `AuthServer` custom resource.
Developer dashboard	`ClientRegistration` Custom Resource	Developers or App Operators interact with AppSSO by using the `ClientRegistration` resource. For more information, see ClientRegistration API for AppSSO.
Resources	n/a	Resources map to OAuth2 scopes and are tied to a Cloud Foundry space. AppSSO does not support the concept of resource. For more information, see Unsupported features.
Application	Workload	This is not AppSSO specific but applicable to both Tanzu Application Service and Tanzu Application Platform.
Service Instance	n/a	In SSO for TAS, this is the way of making a Service Plan visible in a Cloud Foundry Space. There are no direct equivalents in AppSSO.
Service Binding	Service Claim by using the `ClassClaim` resource	Service Binding binds an app to a service, creating credentials for this app and injecting those credentials. In Tanzu Application Service, this is done by using the `VCAP_SERVICES` environment variable. In Tanzu Application Platform, this is done by using Kubernetes Service Bindings. AppSSO creates a `ClientRegistration` in the background and a `Secret` holding the credentials.
Service Key	`ClientRegistration` resource	AppSSO generates a `Secret` for the given `ClientRegistration`.
UAA (one per Cloud Foundry foundation)	The running `AuthServer` Deployment. One per `AuthServer` resource means one per “Service Plan” or one per Identity Zone.	The UAA is multi-tenant. The `AuthServer` is single-tenant, and one `AuthServer` is used per UAA tenant.

Unsupported features

The following features available in Single Sign-On for VMware Tanzu Application Service (SSO for TAS) are not supported in Application Single Sign-On for VMware Tanzu Application Platform

(AppSSO for TAP):

- **UAA Internal user store:** AppSSO does not support creating and managing users in an internal user database.
- **Security Assertion Markup Language (SAML) identity providers:** AppSSO does not support SAML external identity providers. It only supports OpenID Connect and Lightweight Directory Access Protocol (LDAP).
- **User management:** AppSSO does not support managing individual users. In SSO for TAS, users from an external Identity Provider are synchronized to the user database when they first log in. Permissions or scopes can be assigned to each user. This is not supported in AppSSO, all scopes come from roles to scopes mapping. For more information, see Mapping individual roles into authorization scopes.

  Important: Users cannot manage their own accounts in AppSSO. When allowed, they can manage their accounts in the External Identity Provider.
- **Single logout:** AppSSO does not support single logout.
- **OAuth2 grant types:** According to OAuth 2 Security best practices, AppSSO does not support the `password` or `implicit` grant types. You can migrate your application to the `authorization_code` grant type.
- **Selective auto-approval of scopes:** Consent is optional for all scopes except `openid`.
- **Resource management:** AppSSO operates solely on OAuth2 scopes, without using the concepts of permissions or resources.
  - In SSO for TAS, Operators control the availability of scopes for a specific Service Plan in a space using the Developer Dashboard. For more information, see the Single Sign-On for VMware Tanzu Application Service documentation.

    When an app is bound by using a Service Binding, an OAuth2 Client is created for that app in User Account and Authentication (UAA). The client can only request scopes that match the permissions pre-configured by operators.
  - In AppSSO, Developers can specify OAuth2 scopes when creating a `ClientRegistration` or a `ClassClaim`, with role management aggregated in the well-known roles of the Tanzu Application Platform. For more information, see RBAC for AppSSO.
- **Unsecured Lightweight Directory Access Protocol (LDAP):** LDAP traffic must be secured with TLS by using the `ldaps://` protocol.

Migration prerequisites

The migration scripts use:

- ytt for templating Kubernetes resources.
- uaac for extracting data from the UAA.
- python v3.9 and later for migrating data.
- several utilities, such as kubectl and jq.

If you do not already have an admin client for your UAA Identity Zone, you must create an UAA Admin client first. For more information, see the Single Sign-On for VMware Tanzu Application Service documentation

Migrate Service Plans to AuthServer custom resources

List all service plans by subdomain:

```
uaac curl "/identity-zones" -b | jq -r ".[].subdomain"
export SUBDOMAIN=<your-subdomain>
```

Identity-zone level configuration

The `AuthServer` specification only includes equivalents for the following configurable entries:

- Token expiration times.
- Cross-origin resource sharing (CORS) configuration.

By default, they are configured in the UAA Service Plan, and can be overridden in each individual plan.

The AuthServer definition includes default values. You can skip this section if you don't want to replicate the exact settings.

Cross-origin resource sharing (CORS) configuration

Cross-origin resource sharing (CORS) configuration is available under `config.corsPolicy` in the UAA as follows:

```
uaac curl "/identity-zones" -b | jq ".[] | select(.subdomain == \"$SUBDOMAIN\") | .con
fig.corsPolicy"
```

You can port the values into AppSSO's `AuthServer` by using `AuthServer.spec.cors`. For more information, see Public clients and CORS for AppSSO, or the `kubectl explain AuthServer.spec.cors` API documentation.

Token configuration

Token configuration is available under `config.tokenPolicy` in the UAA as follows:

```
uaac curl "/identity-zones" -b | jq ".[] | select(.subdomain == \"$SUBDOMAIN\") | .con
fig.tokenPolicy"
```

Fields can be `null` or equal to `-1`, indicating configuration at the UAA level. In such cases, you can retrieve the configuration by using:

```
uaac curl "/identity-zones" -b | jq ".[] | select(.subdomain == \"\") | .config.tokenP
olicy"
```

You can port the values into AppSSO's `AuthServer` by using `AuthServer.spec.token`. For more information, see Token settings for Application Single Sign-On, or the `kubectl explain AuthServer.spec.token` API documentation.

Migrate Identity Providers

Most of the configuration for OpenID Connect (OIDC) or LDAP-type identity providers can be ported automatically.

1. Log into the UAA and get a token for the admin client by using `uaac`.
2. Copy the UAA URL and the access token from `uaac context`:

   ```
   $ uaac context

   [1]*[➡ UAA_URL]
   ```

```
  [0]*[...]
      client_id: ...
      access_token: ➡ ACCESS_TOKEN
      token_type: ...
      expires_in: ...
      scope: ...
      jti: ...
```

3. Save the following script as `migration.py`.

```
#!/usr/bin/env python3

import getopt
import json
import sys
from urllib.request import Request, urlopen

def transform_ldap_providers(providers, external_group_mappings=[]):
    def to_ldap(provider):
        config = provider["config"]
        result = {
            "name": "ldap",
            "ldap": {
                "url": config["baseUrl"],
                "bind": {
                    "dn": config["bindUserDn"],
                    "passwordRef": {"name": "ldap-password"},
                },
                "user": {
                    "searchBase": config["userSearchBase"],
                    "searchFilter": config["userSearchFilter"],
                },
            },
        }

        roles_config = __extract_ldap_roles_config(config)
        if roles_config:
            result["ldap"]["roles"] = roles_config

        id_token_config = __extract_id_token_config(config)
        if id_token_config:
            result["ldap"]["idToken"] = id_token_config

    url = None
    try:
        opts, _ = getopt.getopt(argv[1:], "hu:s:t:", ["url=", "subdomain=", "to
ken="])
    except getopt.GetoptError:
        print("idzone-to-authserver.py -u <uaa url> -t <uaa token> -s <subdomai
n>")
        sys.exit(2)
    for opt, arg in opts:
        if opt == "-h":
            print("idzone-to-authserver.py -u <uaa url> -t <uaa token> -s <subd
omain>")
            sys.exit()
        elif opt in ("-s", "--subdomain"):
            subdomain = arg
        elif opt in ("-t", "--token"):
            token = arg
        elif opt in ("-u", "--url"):
            url = arg
    return url, token, subdomain

if __name__ == "__main__":
    uaa = UaaClient(*extract_cli_args(sys.argv))
    uaa_idps = uaa.get_idp()
    uaa_groups = uaa.get_groups()
    idps = [
        *transform_openid_providers(uaa_idps, uaa_groups),
        *transform_ldap_providers(uaa_idps, uaa_groups),
```

```
    ]
    print(json.dumps(idps))
```

4. Run the script with the UAA URL, access token, and the previously captured `SUBDOMAIN`.

```
python3 migration.py -u $UAA_URL -t $TOKEN -s $SUBDOMAIN
```

The following JSON output can be templated into an `AuthServer` by using tools such as YTT. This structure is nearly complete for establishing a functioning authorization server with migrated identity providers.

```
#@ load("@ytt:data", "data")
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  name: MY-AUTH-SERVER
  namespace: MY-NAMESPACE
  labels:
    name: MY-AUTH-SERVER
spec:
  #! Token signature keys are managed in the UAA Config and not accessible thro
ugh
  #! the API. These are UAA-level, not id-zone level config options.
  #! The signing key is required.
  tokenSignature:
    signAndVerifyKeyRef:
      name: my-token-signing-key
  identityProviders: #@ data.values.identityProviders

  #! All other properties are omitted, because they are optional. You can updat
e them as needed.

---
apiVersion: secretgen.k14s.io/v1alpha1
kind: RSAKey
metadata:
  name: my-token-signing-key
  namespace: MY-NAMESPACE
spec:
  secretTemplate:
    type: Opaque
    stringData:
      key.pem: $(privateKey)
      pub.pem: $(publicKey)
```

5. Chain the migration script into YTT and obtain an `AuthServer` configuration.

```
ytt \
  --data-value-yaml identityProviders="$(python3 migration.py -u "$UAA_URL" -s
"$SUBDOMAIN" -t "$ACCESS_TOKEN")" \
  --file authserver-template.yaml
```

You must manually input the credentials for connecting to the upstream identity providers, including the bind password for LDAP and the client secret for OIDC, because the UAA does not expose such secrets. You can either create new OIDC clients or edit existing ones to include the `AuthServer` redirect URIs. For more information about configuring properties for AppSSO identity providers, see Identity providers for AppSSO. The secrets adhere to the following format:

```
#! For LDAP-type identity provider:
---
```

```
apiVersion: v1
kind: Secret
metadata:
  name: ldap-password
  namespace: MY-NAMESPACE
stringData:
  password: MY-PASSWORD

#! One secret per openID identity provider and it must match clientSecretRef.na
me:
---
apiVersion: v1
kind: Secret
metadata:
  name: MY-OIDC-IDENTITY-PROVIDER
  namespace: MY-NAMESPACE
stringData:
  clientSecret: MY-CLIENT-SECRET
```

Migrate OAuth2 Clients

Migrating OAuth2 Clients, including Service Bindings, Service Keys, Applications created in the SSO dashboard, are more difficult to automate, because the configuration model is very different. It is likely that the domains in the clients `redirect_uri`s differ from platform to platform.

The recommended approach to use Service Bindings in Tanzu Application Platform is to use an AppSSO `ClassClaim`. For more information, see Claim credentials for an Application Single Sign-On service offering. The `ClassClaim` is bound to a workload, but a UAA client lacks a direct binding to the UAA. The connection is established solely through a layer in Cloud Foundry.

For Service Keys or Applications created in the dashboard, the common use case is to copy the credentials returned in the create service key call, and then use them either in Cloud Foundry apps or off-platform. For those use cases, you can use a `ClientRegistration` instead of a `ClassClaim`. For more information, see ClientRegistration API for AppSSO.

Automation is possible to a certain extent, but manual intervention is required. The following script retrieves a list of all clients for your Identity Zone. You can save the script as `get-clients.sh`:

```
uaac curl "/oauth/clients" -H"X-Identity-Zone-Subdomain: $SUBDOMAIN" -b |
  jq ".resources | map(
{
  apiVersion: \"services.apps.tanzu.vmware.com/v1alpha1\",
  kind: \"ClientRegistration\",
  metadata: {
    name: .name,
    namespace: \"PLACEHOLDER\",
  },
  spec: {
    authServerSelector: {
      matchLabels: {
        PLACEHOLDER: \"PLACEHOLDER\",
      },
    },
    redirectUris: .redirect_uri,
    scopes: .scope | map({name: .}),
    authorization_grant_types: .authorized_grant_types,
  }
})
"
```

Store the following content in `client-registration-template.yaml`:

```
#@ load("@ytt:data", "data")
#@ load("@ytt:template", "template")

#@ for client in data.values.clients:
---
_: #@ template.replace(client)
#@ end
```

Use YTT to convert clients into placeholders for `ClientRegistration`s:

```
ytt -f client-registration-template.yaml --data-value-yaml clients="$(./get-clients.s
h)"
```

Service-to-Service flows

In SSO for TAS, you can register some applications to use a Service-to-Service flow. This corresponds to the OAuth2 `client_credentials` grant, where no human interaction is required to obtain tokens.

In this case, you must use a `ClientRegistration` described in Migrate OAuth2 Clients, with `ClientRegistration.spec.authorizationGrantTypes=["client_credentials"]`. You can use the resulting client id and client secret such as a Service-to-Service app uses them in Tanzu Application Platform.

When creating a `ClientRegistration` name “example-cr”, a corresponding Kubernetes `Secret` is created in the same namespace, with the name “example-cr”. The credentials are available in this secret under the fields `client-id` and `client-secret`.

Spring Boot application

You have the option to deploy your Spring Boot application with or without Spring Cloud Bindings

With Spring Cloud Bindings
Spring Boot applications deployed to Tanzu Application Service likely use the java-cfenv library to read service bindings data from `VCAP_SERVICES`. In Tanzu Application Platform, `java-cfenv` is not applicable. You can remove it from your dependencies.

If you build your Spring Boot app by using buildpacks, such as Tanzu Build Service, Tanzu Application Platform Supply Chains, Spring Boot maven, or gradle plugins, Spring Cloud Bindings are added to your path and perform the binding automatically. For more information, see Secure a Spring Boot workload. VMware recommends that your application uses Spring Boot v2.7, so that `ClientRegistration.spec.client_authentication_method` maps to a value known to Spring Boot, such as `client_secret_basic` or `client_secret_post`. Older versions of Spring Boot expect the value to be either `basic` or `post`.

Spring Cloud Bindings is not intended to work with existing configuration values in `spring.security.oauth2.client`. Instead, it serves as an alternative mechanism for automatic population of these values. The recommended approach is to create a `local` or similar profile for local development, tailored to the authorization server used in the development environment. In your standard application.yaml, refrain from populating `spring.security.oauth2.client`. Including default values in your `application.yaml` might cause inconsistent behavior, because Spring Cloud Bindings can override some of the values. For more information, see the appsso-starter-java accelerator documentation in GitHub.

Without Spring Cloud Bindings
If you are unable or prefer not to depend on Spring Cloud Bindings, see Secure a workload with Application Single Sign-On, which explains how credentials are exposed to the underlying application.

To use multiple `ClientRegistration`s in a single app, or a `ClientRegistration` with multiple grant types, such as `authorization_code` and `client_credentials`, you can turn off the Spring Cloud Bindings integration by setting the following configuration property: `org.springframework.cloud.bindings.boot.oauth2.enable=false`. To access the bindings, you can either load the Secret values in environment variables, or read the files populated by the Secret in the pod. You can still use the Spring Cloud Bindings library to access the files as follows:

```
class Example {

   public void exampleMethod() {
       // ...
       var binding = new Bindings().findBinding("MY-BINDING-NAME");
       String issuerUri = binding.get("issuer-uri");
       String clientId = binding.get("client-id");

       // or
       var binding = new Bindings().filterBindings("oauth2");
       // ...
   }

}
```

Migrate Spring Cloud Gateway apps to Tanzu Application Platform

This topic tells you how to migrate to Spring Cloud Gateway (SCG) for Kubernetes from a Tanzu Application Service (commonly known as TAS) offering of SCG or an open-source implementation of SCG. An example `animal-rescue` app is used to illustrate the high-level steps.

Deploy the `animal-rescue` app to Tanzu Application Service

This section describes, at a high level, the steps for deploying an example `animal-rescue` app and configuring SCG on TAS. For more detailed instructions, see the SCG documentation.

Create an SCG instance

Create an instance of SCG from Marketplace by running `cf create-service`.

```
cf create-service  p.gateway standard GATEWAY-NAME -c GATEWAY-CONFIG-FILE
```

Where:

- `GATEWAY-NAME` is the name of the SCG instance
- `GATEWAY-CONFIG-FILE` is the SCG instance configuration file

For more information, see app-gateway-config.json on GitHub.

Bind the SCG service to your app

You can directly bind the SCG service to the app or you can update the route configurations with the Service Broker API. For more information about configuring routes, see the SCG documentation.

Binding

To directly bind the SCG service to your app:

1. Bind the SCG service to your app by running:

   ```
   cf bind-service APP-NAME GATEWAY-NAME -c ROUTE-CONFIG-FILE
   ```

   Where:

   - `APP-NAME` is the app name.
   - `GATEWAY-NAME` is the name of the SCG instance created in the previous step
   - `ROUTE-CONFIG-FILE` is the route configuration file used for configuring routes of the app

2. Restart your app by running:

   ```
   cf restart $APP_NAME
   ```

For reference here and here are the configuration files used for configuring front-end and back-end routes with SCG service in the `animal-rescue` app.

Update the route config

To use curl to dynamically update route configurations with the Service Broker API:

1. Retrieve the GUID representing the `animal-rescue` app by running:

   ```
   cf app animals --guid
   6e41a492-a17c-4b27-83b0-78635baa54b4
   ```

2. Obtain the URL of a service instance's backing app for `my-gateway` by running:

   ```
   cf service my-gateway
   ```

   Example:

   ```
   $ cf service my-gateway
   Showing info of service my-gateway in org myorg / space dev as user...

   name:             my-gateway
   service:          p.gateway
   tags:
   plan:             standard
   description:      Spring Cloud Gateway for VMware Tanzu
   documentation:
   dashboard:        https://my-gateway.apps.example.com/scg-dashboard
   ```

3. Copy the URL given for the dashboard and remove the `/scg-dashboard` path. This is the URL of the service instance's backing app. For example, `https://my-gateway.apps.example.com`.

4. Update route configuration for the `animal-rescue` app through the routes actuator endpoint on the `my-gateway` service instance by running:

   ```
   curl -k -X PUT https://my-gateway.apps.example.com/actuator/bound-apps/6e41a4
   92-a17c-4b27-83b0-78635baa54b4/routes \
   -d "@./gateway-route-config.json" -H "Authorization: $(cf oauth-token)" -H "C
   ontent-Type: application/json"
   ...
   < HTTP/1.1 204 No Content
   ...
   ```

Deploy the `animal-rescue` app to Tanzu Application Platform

This section describes, at a high level, the steps for deploying an `animal-rescue` app and configuring the SCG on Tanzu Application Platform. For detailed instructions, see the `animal-rescue` app README file in GitHub.

Create an SCG instance

To create an SCG instance:

1. Create a file called `gateway-config.yaml` containing the following YAML definition:

```
---
apiVersion: "tanzu.vmware.com/v1"
kind: SpringCloudGateway
metadata:
  name: my-gateway
spec:
  count: 1
```

2. Apply this definition to your Kubernetes cluster by running:

```
kubectl apply --filename gateway-config.yaml
```

Example:

```
$ kubectl get springcloudgateway my-gateway
NAME               READY   REASON
my-gateway         True    Created
```

Create a route configuration

The SCG tile service has a JSON-based API route configuration approach. There are many similarities in terms of the configuration options available to those in Spring Cloud Gateway for Kubernetes.

1. Create a file called `animal-rescue-backend-route-config.yaml` with the following definition:

```
---
apiVersion: "tanzu.vmware.com/v1"
kind: SpringCloudGatewayRouteConfig
metadata:
  name: animal-rescue-backend-route-config
spec:
  service:
    name: animal-rescue-backend
  routes:
    - predicates:
        - Path=/api/**
      filters:
        - StripPrefix=1
```

2. Apply this definition to your Kubernetes cluster by running:

```
kubectl apply --filename animal-rescue-backend-route-config.yaml
```

Create an SCG mapping

In TAS, the SCG tile services use the Service Broker API and service-binding approach for apps to set up container-network routing of requests to a service instance.

Spring Cloud Gateway for Kubernetes provides a `SpringCloudGatewayMapping` resource definition to expose API routes on to an API SCG instance. For more information, see the Spring Cloud Gateway for Kubernetes documentation.

To create an SCG mapping:

1. Create another file called `animal-rescue-backend-mapping.yaml` with the following definition:

   ```
   ---
   apiVersion: "tanzu.vmware.com/v1"
   kind: SpringCloudGatewayMapping
   metadata:
     name: animal-rescue-backend-mapping
   spec:
     gatewayRef:
       name: my-gateway
     routeConfigRef:
       name: animal-rescue-backend-route-config
   ```

2. Apply `animal-rescue-backend-mapping.yaml` to your Kubernetes cluster by running:

   ```
   kubectl apply --filename animal-rescue-backend-mapping.yaml
   ```

   If your cluster has an ingress configured then, if `my-gateway` is accessible through the ingress with a fully-qualified domain name of `my-gateway.my-example-domain.com`, the `animal-rescue` back-end API is available in the path `my-gateway.my-example-domain.com/api/...`.

   One of the endpoints available in the sample app is `GET /api/animals`, which lists all of the animals available for adoption.

3. From curl, verify that this endpoint is accessible by running:

   ```
   curl my-gateway.my-example-domain.com/api/animals
   ```

Migrate Spring Config Server apps to Tanzu Application Platform

Tanzu Application Service (commonly known as TAS) and Tanzu Application Platform (commonly known as TAP) both enable you to load Java properties into an app from a configuration repository.

You can migrate an app running on TAS with Spring Configuration Service (SCS) to Tanzu Application Platform with Application Configuration Service (ACS).

This migration does not require changes to the app code or the configuration repository where properties are stored. However, the mechanism for loading properties into a Tanzu Application Platform workload is quite different and requires a substantially different setup.

At a high level SCS and ACS operate as follows:

- SCS instances run as web apps serving configuration by using REST requests. TAS apps bound to SCS instances fetch configuration using an autowired `ConfigServerConfigDataLoader` bean and add it to the app properties.
- ACS `ConfigurationServer` instances are Kubernetes custom resources, reconciled by a controller manager. These resources are wired into Tanzu Application Platform workloads using a `ConfigurationSlice` object. Each `ConfigurationSlice` creates a bindable secret

object containing properties, which is mounted to the app file system and loaded into the Spring app from there.

This topic uses the cook sample app to demonstrate how to migrate.

Deploy the `cook` app to Tanzu Application Service

This section describes, at a high level, the steps for deploying an example `cook` app on Tanzu Application Service.

To deploy the app:

1. Create an SCS instance that points to the cook-config GitHub repository by running:

```
cf create-service -c '{ "git": { "uri": "https://github.com/spring-cloud-servic
es-samples/cook-config", \
"label": "main"  } }' ${service_name} standard cook-config-server
```

2. Run `cf push` to push the app to TAS with an app manifest that binds to the service instance:

```
---
applications:
  - name: cook
    host: cookie
    instances: 1
    memory: 1G
    services:
      - cook-config-server
    env:
      SPRING_PROFILES_ACTIVE: development
      JBP_CONFIG_OPEN_JDK_JRE: '{ jre: { version: 17.+ }}'
```

For more detailed instructions, see the README file.

Migrate from TAS to Tanzu Application Platform

This section describes the areas to translate when creating a Tanzu Application Platform workload that will deploy the same app.

Create a Config Server instance

TAS/SCS

Create a service instance by running `cf create-service`, specifying the URI and label (branch) of the `cook-config` repository in the configuration JSON:

```
cf create-service -c '{ "git": { "uri": "https://github.com/spring-cloud-services-sa
mples/cook-config", \
"label": "main"  } }' p.config-server standard cook-config-server
```

Tanzu Application Platform/ACS

Create a `ConfigurationSource` resource, specifying the location of the `cook-config` repository in the `spec.backends` property. For detailed options, see the ACS documentation.

Specify the app name and Spring profiles

TAS/SCS

To specify the app name and Spring profiles:

1. Specify the app name is specified in the `spring.application.name` property. For the `cook` app this is found in application.yml.
2. Set the `SPRING_PROFILES_ACTIVE` environment variable in the `env` key in the app manifest to designate profiles. Multiple entries must be comma-separated.

Tanzu Application Platform/ACS

To specify the app name and Spring profiles:

1. Create a `ConfigurationSlice` resource, specifying the name of the `ConfigurationSource` resource in the `spec.configurationSource` property.
2. Create one or more entries in the `spec.content` array property of the `ConfigurationSlice` resource with the format `APP-NAME/PROFILE-NAME/OPTIONAL-LABEL` where:
    - `APP-NAME` is the app name.
    - `PROFILE-NAME` is the profile name.
    - `OPTIONAL-LABEL` is an optional comma-separated list of labels from which to retrieve properties.

For more information, see the ACS documentation.

Bind the Config Server to the app

TAS/SCS

To bind the Config Server to the app, either add the service-instance name in the services key in the app manifest, or run `cf bind-service` to bind the service to the app.

Tanzu Application Platform/ACS

To bind the Config Server to the app:

1. Create a `ResourceClaim` resource, specifying the details of the `ConfigurationSlice` resource in the `spec.ref` section of the configuration.
2. Specify the `ResourceClaim` resource in the `spec.serviceClaims` section of the workload. This mounts the properties to the running pod's file system.
3. Specify a `SPRING_CONFIG_IMPORT` property in the `spec.env` section of the workload with the value `optional:configtree:${SERVICE_BINDING_ROOT}/CLAIM-NAME/`, where `CLAIM-NAME` is the name you specified in the `spec.serviceClaims` list.

    This environment variable tells the Spring runtime to pull properties from the file system at the path where the `serviceClaims` mechanism mounted them. For more information, see ACS documentation.

Deploy the `cook` app to Tanzu Application Platform

Apply the following resources to Tanzu Application Platform to run the `cook` sample:

```
apiVersion: "config.apps.tanzu.vmware.com/v1alpha4"
kind: ConfigurationSource
metadata:
  name: cook-config-source
spec:
  backends:
    - type: git
      uri: https://github.com/spring-cloud-services-samples/cook-config
---
```

```
apiVersion: "config.apps.tanzu.vmware.com/v1alpha4"
kind: ConfigurationSlice
metadata:
  name: cook-config-slice
spec:
  configurationSource: cook-config-source
  content:
  - cook/production/tap
  - cook/default
---
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ResourceClaim
metadata:
  name: cook-config-claim
spec:
  ref:
    apiVersion: config.apps.tanzu.vmware.com/v1alpha4
    kind: ConfigurationSlice
    name: cook-config-slice
---
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: cook
  labels:
    app.kubernetes.io/part-of: cook-app
    apps.tanzu.vmware.com/has-tests: "true"
    apps.tanzu.vmware.com/workload-type: web
spec:
  serviceClaims:
  - name: spring-properties
    ref:
      apiVersion: services.apps.tanzu.vmware.com/v1alpha1
      kind: ResourceClaim
      name: cook-config
  build:
    env:
      - name: BP_JVM_VERSION
        value: "17"
  env:
    - name: SPRING_CONFIG_IMPORT
      value: "optional:configtree:${SERVICE_BINDING_ROOT}/spring-properties/"
    - name: SPRING_CLOUD_CONFIG_ENABLED
      value: "false"
    - name: SPRING_PROFILES_ACTIVE
      value: "development"
  source:
    git:
      url: https://github.com/spring-cloud-services-samples/cook.git
      ref:
        branch: tap
```

Configuration samples for deploying the `cook` app on Tanzu Application Platform are in the tap directory in GitHub.

Migrate Spring Service Registry apps to Tanzu Application Platform

This topic tells you how to migrate Spring Service Registry apps from Tanzu Application Service (commonly known as TAS) to Tanzu Application Platform (commonly known as TAP). This topic uses the sample Greeter app in the procedures to illustrate how migration works.

Tanzu Application Service and Tanzu Application Platform can both provide apps with an implementation of the Service Discovery pattern. You can migrate an app running on TAS with Spring Service Registry (SSR) to Tanzu Application Platform without changing the app code.

At a high level, SSR on Tanzu Application Service and SSR on Tanzu Application Platform operate as follows:

- **For Tanzu Application Service:**

  Creating a `service-registry` instance in a TAS space creates a `cf` app running a Eureka server.

  TAS apps bound to this service instance are autowired with a Spring Cloud Netflix Eureka client configuration bean. The presence of the `VCAP_APPLICATION` environment variable triggers the bean to examine the `VCAP_SERVICES` environment variable to inject `eureka.client.*` properties into the app by using connection information in `VCAP_SERVICES`.

- **For Tanzu Application Platform:**

  `EurekaServer` instances are Kubernetes custom resources. Each `EurekaServer` instance is reconciled into a Kubernetes deployment running a Eureka server with a bindable `Secret` object containing connection information for that Eureka server.

  When a `EurekaServer` is wired into Tanzu Application Platform workloads using a `ResourceClaim` object, it mounts the bindable `Secret` object into the application container's file system at a standard location.

  The spring-cloud-bindings library in GitHub finds any service bindings in this standard location and verifies that the binding is a Eureka server, based on a binding `type` key in the binding secret, and injects `eureka.client.*` properties into the app by using connection information in the mounted secret.

Deploy the `greeter` app to Tanzu Application Service

This section describes, at a high level, the steps for deploying an example `greeter` app on Tanzu Application Service.

To deploy the app:

1. Create an instance of the service registry product from Marketplace by running:

   ```
   cf create-service p.service-registry standard greeter-service-registry
   ```

2. Run `cf push` to push the apps to TAS with an app manifest that binds the service instance. Example:

   ```
   ---
   applications:
   - name: greeter-cs
     instances: 1
     memory: 1G
     services:
     - greeter-service-registry
     env:
       SPRING_PROFILES_ACTIVE: development
       JBP_CONFIG_OPEN_JDK_JRE: '{ jre: { version: 17.+ }}'

   - name: greeter-messages-cs
     instances: 1
     memory: 1G
     services:
     - greeter-service-registry
     env:
   ```

```
    SPRING_PROFILES_ACTIVE: development
    JBP_CONFIG_OPEN_JDK_JRE: '{ jre: { version: 17.+ }}'
```

For more information about the Greeter app, see its README file in GitHub.

For more information about Service Registry, see the TAS documentation.

Migrate from Tanzu Application Service to Tanzu Application Platform

This section describes the areas to translate when creating a Tanzu Application Platform workload that deploys the same app.

Create a database instance

Tanzu Application Service
Create a service instance by running:

```
cf create-service
```

Tanzu Application Platform
For Tanzu Application Platform, you must create a `EurekaServer` resource.

Bind the database instance to the app

Tanzu Application Service
Include the name of the service instance in the `services` key in the app manifest. Alternatively, use `cf bind-service` to bind the service to the app.

Tanzu Application Platform
Create a `ResourceClaim` resource, specifying the details of the `EurekaServer` resource in the `spec.ref` section of the configuration. Specify the `ResourceClaim` resource in the `spec.serviceClaims` section of the `Workload` resource.

Deploy the `greeter` app to Tanzu Application Platform

This section describes, at a high level, the steps for deploying an example `greeter` app on Tanzu Application Platform. For more information about how to deploy a service registry instance and configure workloads, see Overview of Service Registry.

To deploy the app:

1. Install the Eureka Service Registry package by running:

   ```
   tanzu package available list service-registry.spring.apps.tanzu.vmware.com --na
   mespace tap-install

   tanzu package install service-registry \
   --package service-registry.spring.apps.tanzu.vmware.com \
   --version VERSION -n tap-install

   tanzu package installed get service-registry -n tap-install
   ```

2. Create a `EurekaServer` resource by applying the following YAML to your Kubernetes cluster:

```
---
apiVersion: service-registry.spring.apps.tanzu.vmware.com/v1alpha1
kind: EurekaServer
metadata:
  name: eurekaserver-sample
  namespace: my-apps
spec:
  replicas: 2
```

A successful `EurekaServer` resource has a `Ready` condition set to `true` and a `status.binding.name` field pointing to a secret containing connection information.

3. Claim credentials by using `ResourceClaim`.

```
---
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ResourceClaim
metadata:
  name: eurekaserver-sample
  namespace: my-apps
spec:
  ref:
    apiVersion: service-registry.spring.apps.tanzu.vmware.com/v1alpha1
    kind: EurekaServer
    name: eurekaserver-sample
    namespace: my-apps
```

4. Configure workloads. The greeting app is a sample workload in GitHub. Deploy both `greeter` and `greeter-messages` by using the following YAML. The YAML claims `EurekaServer` credentials by adding a `spec.serviceClaims` section to each workload.

```
---
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: greeter-messages
  namespace: my-apps
  labels:
    apps.tanzu.vmware.com/workload-type: server
    apps.tanzu.vmware.com/has-tests: "true"
    app.kubernetes.io/part-of: greeter
spec:
  build:
    env:
      - name: BP_JVM_VERSION
        value: "17"
      - name: BP_GRADLE_BUILT_MODULE
        value: "greeter-messages"
      - name: BP_GRADLE_BUILD_ARGUMENTS
        value: "--no-daemon clean bootJar"
  env:
    - name: SPRING_PROFILES_ACTIVE
      value: "development"
  serviceClaims:
    - name: eureka
      ref:
        apiVersion: services.apps.tanzu.vmware.com/v1alpha1
        kind: ResourceClaim
        name: eurekaserver-sample
  source:
    git:
      url: https://github.com/spring-cloud-services-samples/greeting
      ref:
        branch: main
```

```
---
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: greeter
  namespace: my-apps
  labels:
    apps.tanzu.vmware.com/workload-type: web
    apps.tanzu.vmware.com/has-tests: "true"
    app.kubernetes.io/part-of: greeter
spec:
  build:
    env:
      - name: BP_JVM_VERSION
        value: "17"
      - name: BP_GRADLE_BUILT_MODULE
        value: "greeter"
      - name: BP_GRADLE_BUILD_ARGUMENTS
        value: "--no-daemon clean bootJar"
  env:
    - name: SPRING_PROFILES_ACTIVE
      value: "development"
  serviceClaims:
    - name: eureka
      ref:
        apiVersion: services.apps.tanzu.vmware.com/v1alpha1
        kind: ResourceClaim
        name: eurekaserver-sample
  source:
    git:
      url: https://github.com/spring-cloud-services-samples/greeting
      ref:
        branch: main
```

Use Service Registry with an executable JAR file app

In the `greeting` app example, `BP_GRADLE_BUILD_ARGUMENTS` is set to include the `bootJar` task in addition to the default Gradle build arguments. This setting is necessary for this example base because the `build.gradle` file contains a `jar` section and the Spring Boot buildpack does not inject the `spring-cloud-bindings` library into the app if it is an executable JAR file.

`spring-cloud-bindings` is required to process the `serviceClaim` into properties that tell the discovery client how to find the Eureka server.

To use Service Registry with an executable JAR file app, explicitly include spring-cloud-bindings v1.13.0 or later and set the `org.springframework.cloud.bindings.boot.enable=true` system property as described in the library README file in GitHub.

Migrate Spring Data Services apps to Tanzu Application Platform

This topic tells you how to migrate apps bound to Spring Data Services from Tanzu Application Service (commonly known as TAS) to Tanzu Application Platform (commonly known as TAP).

Both Tanzu Application Service and Tanzu Application Platform support applications with an implementation of the Service Discovery pattern. You can migrate an application using Spring Data Services from Tanzu Application Service to Tanzu Application Platform without changing the application code.

Deploy the `fortune-teller` app to Tanzu Application Service

This section describes, at a high level, the steps for deploying the example `fortune-teller` app on Tanzu Application Service. For more detailed instructions, see the fortune-teller README in GitHub.

To deploy the app:

1. Create an instance of MySQL database from the Marketplace by running:

   ```
   cf create-service  p.mysql db-small fortunes-db
   ```

2. Create an instance of Spring Config Server that points to the config JSON by running:

   ```
   cf create-service -c '{ "git": { "uri": "https://github.com/spring-cloud-servic
   es-samples/fortune-teller", "searchPaths": "configuration"  } }'p.config-server
   standard config-server
   ```

3. Create an instance of the Service Registry product from the Marketplace by running:

   ```
   cf create-service s p.service-registry standard service-registry
   ```

4. Push the applications to Tanzu Application Service using `cf push` with an application manifest that binds the service instance:

   ```
   ---
   applications:
   - name: fortune-service
     memory: 1024M
     host: fortunes
     path: fortune-teller-fortune-service/target/fortune-teller-fortune-service-0.
   0.1-SNAPSHOT.jar
     services:
     - fortunes-db
     - config-server
     - service-registry
     env:
       # JBP adds deprecated connectors when using mysql service
       JBP_CONFIG_SPRING_AUTO_RECONFIGURATION: '{"enabled":false}'
       # Replace with API URI of target PCF environment
       #CF_TARGET: https://api.yourpcfenvironment.local
   - name: fortune-ui
     memory: 1024M
     host: fortunes-ui
     path: fortune-teller-ui/target/fortune-teller-ui-0.0.1-SNAPSHOT.jar
     services:
     - config-server
     - service-registry
     env:
       # Replace with API URI of target PCF environment
       #CF_TARGET: https://api.yourpcfenvironment.local
   ```

Migrate from Tanzu Application Service to Tanzu Application Platform

This section describes the areas to translate when creating a Tanzu Application Platform workload that deploys the same app.

Create a database instance

Tanzu Application Service
Create a service instance using `cf create-service`.

Tanzu Application Platform
There are multiple options to create an instance. For more information, see Services Toolkit.

The easiest way to get started is to create a service instance using Bitnami Services. For more information, see Working with Bitnami Services.

Bind the database instance to the app

Tanzu Application Service

- Include the name of the service instance in the `services` key in the application manifest.
- Alternatively, use `cf bind-service` to bind the service to the application.

Tanzu Application Platform
If you are using Bitnami Services, Specify the `ClassClaim` resource in the `spec.serviceClaims` section of the `Workload`.

Deploy the `fortune-teller` application to Tanzu Application Platform

This section describes, at a high level, the steps for deploying an example `fortune-teller` app on Tanzu Application Platform.

For information about installing and configuring data services on Tanzu Application Platform, see the Services Toolkit documentation.

Prerequisites: To follow this example, you must first deploy Service Registry and Spring Config Server instances. To do so, apply the following YAML files in the fortune-teller repo:

- Install Service Registry: Apply the file eureka-server.yaml.
- Install Spring Config Server: Apply the file configuration-source.yaml.
- ConfigureSpring Config Server: Apply the file configuration-slice.yaml.
- Setup the `forture-teller` app to use Service Registry and Spring Config Server: Apply the file resource-claim.yaml.

Note

This prerequisite is not required for all Spring Data Services apps.

To deploy the app:

1. Claim MySQL service from Bitnami services by running:

```
tanzu service class-claim create fortune-database --class mysql-unmanaged -n my
-apps
tanzu services class-claims get fortune-database --namespace my-apps
```

2. Bind the service to your workload. Bind the MySQL service by adding `ClassClaim` under the `spec.serviceClaims` section as follows:

```
---
apiVersion: carto.run/v1alpha1
```

```
kind: Workload
metadata:
name: fortune-teller-fortune-service
namespace: my-apps
labels:
  apps.tanzu.vmware.com/workload-type: web
  apps.tanzu.vmware.com/has-tests: "true"
  app.kubernetes.io/part-of: fortune
spec:
params:
  - name: annotations
    value:
      autoscaling.knative.dev/minScale: "1"
build:
  env:
  - name: BP_JVM_VERSION
    value: "8"
  - name: BP_MAVEN_BUILT_MODULE
    value: "fortune-teller-fortune-service"
env:
  - name: SPRING_CONFIG_IMPORT
    value: "optional:configtree:${SERVICE_BINDING_ROOT}/spring-properties/"
serviceClaims:
  - name: eureka
    ref:
    apiVersion: services.apps.tanzu.vmware.com/v1alpha1
    kind: ResourceClaim
    name: eurekaserver-sample
  - name: db
    ref:
    apiVersion: services.apps.tanzu.vmware.com/v1alpha1
    kind: ClassClaim
    name: fortune-database
  - name: spring-properties
    ref:
    apiVersion: services.apps.tanzu.vmware.com/v1alpha1
    kind: ResourceClaim
    name: fortune-config
source:
  git:
  url: https://github.com/akrishna90/fortune-teller
  ref:
    branch: main
```

For more information about claiming an instance of MySQL using Bitnami services, see the tutorial Working with Bitnami Services.

Using Gradle for building Spring applications

By default, when the `bootJar` task is configured, the `jar` task is also configured and uses `plain` as the convention for its archive classifier. This ensures that `bootJar` and `jar` are executed and causes the executable archive and the plain archive to be built at the same time. For more information, see the Spring documentation.

Spring Boot buildpack behavior

The gradle buildpack produces both `<ARTIFACT_NAME>.jar` and `<ARTIFACT_NAME>-plain.jar`. The presence of a second JAR file in the build output means that the Gradle buildpack leaves both JAR files in compressed form instead of unpacking the `<ARTIFACT_NAME>.jar` file into the application directory. As a result, the spring-boot buildpack will fail to find a `<APPLICATION_ROOT>/META-INF/MANIFEST.MF` file and will fail to contribute the `spring-cloud-bindings` JAR file to the application. You will be able to run the application, but service bindings will not be processed.

To avoid this, deactivate the `jar` task in your `build.gradle` file to prevent the plain JAR from being created.

```
jar {
  enabled = false
}
```

Alternatively you can set `BP_GRADLE_ADDITIONAL_BUILD_ARGUMENTS="-x jar"` to prevent generating the plain JAR without modifying the `build.gradle` file.

Using Maven for building Spring applications

- No changes are required.
- When both Maven and Gradle builds are available, for example, in the case of the greeting repo, the Paketo Java buildpack checks Maven first and uses Maven to build the application.

Migrate to Cloud Native Buildpacks

This section tells you how to migrate from using Cloud Foundry buildpacks for Tanzu Application Service (commonly known as TAS for VMs) to using Cloud Native buildpacks for Tanzu Application Platform (commonly known as TAP).

In this section:

- Migrate to the .NET Core Cloud Native Buildpack
- Migrate from the Binary CF Buildpack to the Procfile Cloud Native Buildpack
- Migrate to the Go Cloud Native Buildpack
- Migrate to the Java Cloud Native Buildpack
- Migrate from the NGINX and Staticfile CF buildpack to the Web Server Cloud Native Buildpack
- Migrate to the Node.js Cloud Native Buildpack
- Migrate to the PHP Cloud Native Buildpack
- Migrate to the Python Cloud Native Buildpack
- Migrate to the Ruby Cloud Native Buildpack

Migrate to the .NET Core Cloud Native Buildpack

This topic tells you how to migrate your .NET Core app from using a Cloud Foundry buildpack for Tanzu Application Service (commonly known as TAS for VMs) to using a Cloud Native Buildpack for Tanzu Application Platform (commonly known as TAP).

Install specific .NET runtime and ASP.NET versions

The following table compares how Tanzu Application Service and Tanzu Application Platform handle installing specific versions.

Feature	Tanzu Application Service	Tanzu Application Platform
Detects version from `.csproj` `<RuntimeFrameworkVersion>` or `<TargetFramework>`		

Feature	Tanzu Application Service	Tanzu Application Platform
Detects version from `runtimeconfig.json` `runtimeOptions.framework.version`		
Detects versions from `.fsproj` and `.vbproj`.		
Override app-based version detection.	Use `builpack.yml`	Use `$BP_DOTNET_FRAMEWORK_VERSION`

Tanzu Application Service: Override version detection

Tanzu Application Service buildpacks allows you to specify a .NET Core SDK version using a `buildpack.yml`.

Example `buildpack.yml`:

```
dotnet-core:
  sdk: 7.0.x
```

Tanzu Application Platform: Override version detection

In Tanzu Application Platform, users set the `$BP_DOTNET_FRAMEWORK_VERSION` environment variable to specify which version of the .NET Core runtime to install. The buildpack automatically installs an SDK version that is compatible with the runtime version .NET Core runtime you selected.

The Tanzu Application Platform buildpack requires you to provide an exact version unlike in the Tanzu Application Service `buildpack.yml` where you can provide version patterns such as `7.x.x`.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: BP_DOTNET_FRAMEWORK_VERSION
       value: 7.0.10
  source:
    git:
      ref:
        branch: master
      url: https://github.com/cloudfoundry/dotnet-core-buildpack
    subPath: fixtures/source_apps/source-app-7
```

Configure multiple projects in an app

The following table compares how Tanzu Application Service and Tanzu Application Platform handle multiple projects in an app.

Feature	Tanzu Application Service	Tanzu Application Platform
Configure multiple projects in one app	Use a `.deployment` file	Use `$BP_DOTNET_PROJECT_PATH`
Projects referenced by the configured main project are also built		

Tanzu Application Service: Configure multiple projects

In Tanzu Application Service, users create a `.deployment` file in your app's root folder to designate the main project's path.

For example:

```
[config]
project = src/MyApp.Web/MyApp.Web.csproj
```

Tanzu Application Platform: Configure multiple projects

In Tanzu Application Platform, you configure the main project's path with `$BP_DOTNET_PROJECT_PATH` as the `spec` shown in this Tanzu Application Platform workload example. In Tanzu Application Platform, you point to the root of the project not the project file.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: BP_DOTNET_PROJECT_PATH
       value: ./src/asp_web_app
  source:
    git:
      ref:
        branch: master
      url: https://github.com/cloudfoundry/dotnet-core-buildpack
    subPath: fixtures/source_apps/multiple_projects_msbuild
```

Configure the publish command

The following table compares how you configure the publish command in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Configure the publish command	Not supported	Use `$BP_DOTNET_PUBLISH_FLAGS`

Configure the publish command in Tanzu Application Platform

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: BP_DOTNET_PUBLISH_FLAGS
       value: "--verbosity=normal"
```

Provide a NuGet configuration

The following table compares how you provide a NuGet configuration in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Provide a NuGet.Config with the app		

Feature	Tanzu Application Service	Tanzu Application Platform
Provide a NuGet.Config through service bindings	Not supported	Use a binding of type `nugetconfig` that contains the `nuget.config`

Provide a NuGet configuration with sensitive data

In Tanzu Application Platform, if your NuGet config contains credentials or other sensitive data, you can provide it to the build without explicitly including the file in the application directory.

To provide your NuGet config without including it in the directory:

1. Create the service binding as a secret. For example:

```
---
apiVersion: v1
kind: Secret
metadata:
  name: nuget-config
  namespace: my-apps
type: service.binding/nugetconfig
stringData:
  type: nugetconfig
  nuget.config: |
    <?xml version="1.0" encoding="utf-8"?>
    <configuration>
      <packageSources>
        <clear />
        <add key="NuGet.org" value="https://api.nuget.org/v3/index.json" />
      </packageSources>
    </configuration>
```

2. Use the binding in the workload. For example:

```
---
kind: Workload
apiVersion: carto.run/v1alpha1
metadata:
name: dotnet-app
spec:
# ...
  params:
  - name: buildServiceBindings
    value:
      - name: nuget-config
        kind: Secret
        apiVersion: v1
```

For more information about service bindings, see Configure Tanzu Build Service properties on a workload.

Migrate from the Binary Cloud Foundry Buildpack to the Procfile Cloud Native Buildpack

This topic tells you how to migrate your binary app from using a Cloud Foundry buildpack for Tanzu Application Service (commonly known as TAS for VMs) to using a Cloud Native Buildpack for Tanzu Application Platform (commonly known as TAP).

The Tanzu Application Platform Procfile buildpack provides the capability corresponding to the Tanzu Application Service Binary buildpack.

In Tanzu Application Service, Procfile capability is built into the platform. For more information, see the Cloud Foundry documentation. However, due to the nature of the Cloud Foundry API, a no-op/null buildpack was required, and this null buildpack was named Binary buildpack.

A Procfile follows the same format in Tanzu Application Service and Tanzu Application Platform. If your app contains an executable file or a preceding buildpack generates an executable file in the build process, you can use the Tanzu Application Platform Procfile buildpack to run your app in the same way as the Tanzu Application Service Binary buildpack.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  source:
    git:
      ref:
        branch: master
      url: https://github.com/cloudfoundry/binary-buildpack
    subPath: fixtures/default_app
```

Migrate to the Go Cloud Native Buildpack

This topic tells you how to migrate your Go app from using a Cloud Foundry buildpack for Tanzu Application Service (commonly known as TAS for VMs) to using a Cloud Native Buildpack for Tanzu Application Platform (commonly known as TAP).

Install a specific Go version

The following table compares how Tanzu Application Service and Tanzu Application Platform handle installing specific versions.

Feature	Tanzu Application Service	Tanzu Application Platform
Detects version from `go.mod`		
Override app-based version detection	Using `$GOVERSION`	Using `$BP_GO_VERSION`

Tanzu Application Service: Override version detection

To instruct the buildpack to select a specific version, set the environment variable `$GOVERSION`. For example, `$GOVERSION="go1.22"`.

Tanzu Application Platform: Override version detection

To configure the version, set the environment variable `$BP_GO_VERSION` in your `workload.yaml` file.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: BP_GO_VERSION
       value: "1.22.*"
```

Set LDFLAGS

The following table compares how you set LDFLAGS in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Set any LDFLAG		`$BP_GO_BUILD_LDFLAGS`
Set the -X LDFLAG	Using `buidpack.yml` OR `{$GO_LINKER_SYMBOL, $GO_LINKER_VALUE}`	`$BP_GO_BUILD_LDFLAGS`

Tanzu Application Service: Set LDFLAGS

In the Tanzu Application Service Go buildpack, you can only set the value of a variable when setting linker flags, that is, the `-X` flag.

Example Tanzu Application Service `buildpack.yml`:

```
---
go:
  ldflags:
    main.var1: val1
    main.var2: val2
```

Tanzu Application Platform: Set LDFLAGS

In Tanzu Application Platform Go buildpack, you can set any arbitrary LDFLAG.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: BP_GO_BUILD_LDFLAGS
       value: "-X 'main.var1=val1' -X 'main.var2=val2'"
```

Note

The Tanzu Application Service buildpack provided a special environment variable combination to set one variable value, `$GO_LINKER_SYMBOL` and `$GO_LINKER_VALUE`. If you used this combination, use the generic Tanzu Application Platform format shown in the preceding snippet for migration.

Custom build flags

The Tanzu Application Service buildpack did not allow users to set custom build flags other than the `-X ldflag`. A build flag of `"-tags cloudfoundry -buildmode pie"` is always added to the build in Tanzu Application Service.

In Tanzu Application Platform, you can set your own build flags with `$BP_GO_BUILD_FLAGS`, for example:

```
---
spec:
  build:
    env:
    - name: BP_GO_BUILD_FLAGS
       value: "-buildmode=default -tags=ilovetanzu"
```

For Static Stack in Tanzu Application Platform, unless you provide a `-buildmode` flag through `$BP_GO_BUILD_FLAGS`, the buildpack sets `CGO_ENABLED=0` and `-buildmode=default` build flag to enable support for the static stack by default.

Build non-default packages

The following table compares how Tanzu Application Service and Tanzu Application Platform handle building non-default packages.

Feature	Tanzu Application Service	Tanzu Application Platform
Set locations or targets of the Go programs to be compiled	`$GO_INSTALL_PACKAGE_SPEC`	`$BP_GO_TARGETS`

Tanzu Application Service: Build non-default packages

Example Tanzu Application Service `manifest.yml`:

```
---
applications:
- name: myapp
  env:
    GO_INSTALL_PACKAGE_SPEC: "./app1 ./app2"
```

Tanzu Application Platform: Build non-default packages

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: BP_GO_TARGETS
       value: "./app1:./app2"
```

Pre-vendored apps based on Go mod

In Tanzu Application Service, you must set the `$GOPACKAGENAME` for go-mod based apps with dependencies vendored into a vendor directory. For more information, see the Cloud Foundry documentation.

In Tanzu Application Platform, this is not required because the Tanzu Application Platform Go buildpack can auto-detect your vendor directory, and use it if it exists.

Glide and Dep based apps

The Tanzu Application Platform Go buildpack does not support programs based on Glide and Go Dep dependency management tools. This is because the Go community has moved towards go modules. You must update your apps to use go modules.

Migrate to the Java Cloud Native Buildpack

This topic tells you how to migrate your Java app from using a Cloud Foundry buildpack for Tanzu Application Service (commonly known as TAS for VMs) to using a Cloud Native Buildpack for Tanzu Application Platform (commonly known as TAP).

Use a specific Java version

The following table compares how Tanzu Application Service and Tanzu Application Platform handle installing specific versions.

Feature (lowest to highest priority)	Tanzu Application Service	Tanzu Application Platform
Buildpack Default	8	11
Maven MANIFEST.MF property	Not supported	
Detects version from `.sdkmanrc` file	Not supported	
Override app-based version detection	Use `cf set-env`: `JBP_CONFIG_OPEN_JDK_JRE`	Use `$BP_JVM_VERSION`

Tanzu Application Service: Override version detection

In Tanzu Application Service, changing from the default JVM v8 requires you to configure the following app environment variable key and value:

```
JBP_CONFIG_OPEN_JDK_JRE '{ jre: { version: 17.+ }}'
```

This builds the app with the version of Java v17 that was bundled with the buildpack. Currently Java v8, v11, v17, and v21 are supported.

Tanzu Application Platform: Override version detection

In Tanzu Application Platform, set the `$BP_JVM_VERSION` build-time environment variable to specify which version of the JVM to install. The value can be the major version of one of the LTS Java releases included in the buildpack, currently 8, 11, 17, and 21. Patches for these majors are released quarterly along with OpenJDK release schedules. For the buildpack's exact versions, see the Java Buildpack Release Notes.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: BP_JVM_VERSION
       value: "17"
```

Configure Maven repository settings

The following table compares configuring Maven repository settings in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Connect to a private Maven repository	Not supported	Use a binding of type `maven` with key `settings.xml`

Configure Maven repository settings with sensitive data

In Tanzu Application Platform, if your Maven settings contain sensitive data, you can provide your own `settings.xml` to the build without explicitly including the file in the application directory.

To provide your `settings.xml` without including it in the directory:

1. Create the service binding as a secret. For example:

```
---
apiVersion: v1
kind: Secret
metadata:
  name: settings-xml
  namespace: my-apps
type: service.binding/maven
stringData:
  type: maven
  settings.xml: |
    <settings xmlns="http://maven.apache.org/SETTINGS/1.0.0" xmlns:xsi="http://
www.w3.org/2001/XMLSchema-instance"
      xsi:schemaLocation="http://maven.apache.org/SETTINGS/1.0.0 https://maven.
apache.org/xsd/settings-1.0.0.xsd">
      <servers>
        <server>
          <id>myrepo</id>
          <username>admin</username>
          <password>changeme</password>
        </server>
      </servers>

      <mirrors>
        <mirror>
          <id>myrepo</id>
          <name>myrepo</name>
          <url>http://myrepo/</url>
          <mirrorOf>*</mirrorOf>
        </mirror>
      </mirrors>
    </settings>
```

2. Apply the binding in the workload by running:

```
tanzu apps workload apply APP-NAME \
  --param-yaml buildServiceBindings='[{"name": "settings-xml", "kind": "Secre
t"}]'
```

   Where `APP-NAME` is the name of your app.

For more information about service bindings, see Configure Tanzu Build Service properties on a workload.

Service bindings

The following table compares service bindings in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Connect an app to a bound service		

Tanzu Application Service: Service bindings

In Tanzu Application Service, the Java Buildpack supplies Spring Boot v3 apps with the Java CF Env Library. This library parses the `VCAP_SERVICES` variable and allows the auto-configuration for Spring Boot to set properties and connect to the bound service.

Tanzu Application Platform: Service bindings

In Tanzu Application Platform, Tanzu Buildpacks supply a similar library, named Spring Cloud Bindings, which supports the Kubernetes-style service bindings. This does the following:

- Adds a PropertySource with a flattened representation, `k8s.bindings.{name}.*`, of the bindings.
- Adds a PropertySource with binding-specific Spring Boot configuration properties.

The auto-configuration for Spring Boot configures application properties appropriate for the type of binding encountered.

After you have applied a service binding, for example to a PostgreSQL database, Spring Cloud Bindings automatically uses the properties from the binding to set the relevant Spring Boot properties.

Example command to apply a service binding:

```
tanzu apps workload apply APP-NAME \
  --service-ref "psql=services.apps.tanzu.vmware.com/v1alpha1:ClassClaim:psql"
```

For more information about service bindings, see Configure Tanzu Build Service properties on a workload.

Deploy with Tomcat

The following table compares deploying with Tomcat for Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Configure Tomcat Version	Not possible without creating a custom (unsupported) buildpack	Use `BP_TOMCAT_VERSION`
Use External Tomcat		

In Tanzu Application Platform, the Apache Tomcat buildpack includes versions 8, 9, and 10.1. The detection criteria to deploy with the buildpack-provided Tomcat remains the same as in Tanzu Application Service, which is the presence of a WEB-INF directory and no Main-Class entry in the manifest.

You can configure an external Tomcat instance by using environment variables. For more information about configuration options, see the Tanzu Java Buildpacks documentation.

Choose Java distribution

The following table compares deploying choosing a Java distribution for Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Use an alternative JVM provider	Not possible without creating a custom (unsupported) buildpack	

Compare third-party integrations

The following table compares third-party integrations available for Tanzu Application Service and Tanzu Application Platform.

Partner	Tanzu Application Service	Tanzu Application Platform
Apache Skywalking		

Partner	Tanzu Application Service	Tanzu Application Platform
AppDynamics		
AppInternals (Aternity/Riverbed)		
AspectJ		
Azure App Insights		
Checkmarx		
Contrast Security		
Datadog		
Elastic APM		
Dynatrace		
Google Stackdriver		
Introscope (Broadcom)		?
JaCoCo		
Java Memory Assistant		
JProfiler		
JRebel		
Luna Sec Provider		
MariaDB Client PostgreSQL Client		See Notes
Metric Writer		See Notes
New Relic		
OpenTelemetry Agent		
ProtectApp (Thales)		
Sealights		
Seeker Security/Synopsys		
Spring Insight	See Notes	See Notes
Takipi		
YourKit		

Note

The following integrations do not have a Tanzu Application Platform equivalent:

- **MariaDB and PostgreSQL Client Libraries:** The recommended way to include these libraries is as an application dependency rather than supplied by the buildpack. Therefore in Tanzu Application Platform, included in the app, for example, using a `pom.xml` entry.
- **Metrics Writer:** This integration library provides Cloud Foundry-specific tags for micrometer enabled apps, and so does not have a Tanzu Application Platform equivalent.

- **Spring Insight:** This is no longer supported and is no longer available in Tanzu Application Service or Tanzu Application Platform.

Most of the third-party integrations that are supported in Tanzu Application Service are also supported in Tanzu Application Platform. The detection criteria to trigger enabling the integration, for example, adding a Java Agent to the JVM, is as follows:

- **Tanzu Application Service:** Bind a Tanzu Application Service service of the relevant type, or set an environment variable.
- **Tanzu Application Platform:** Provide a Tanzu Application Platform binding of the relevant type, or setting an environment variable.

Tanzu Application Platform only integrations

The following integrations are only available in Tanzu Application Platform through Cloud Native Buildpacks:

- **Checkmarx:** Contributes the Checkmarx CxIAST agent.
- **Snyk:** Contributes Snyk scanning and configures it to connect to the service.
- **Synopsys:** Contributes Synopsys scanning and configures it to connect to the service.

Configure debugging for your application

The following table compares configuring debugging for your app in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Enable Remote Debugging	`$JBP_CONFIG_DEBUG`	`$BPL_DEBUG_ENABLED`

Enabling remote debugging for Java apps in Tanzu Application Platform is similar to Tanzu Application Service. Specify a runtime environment variable in your `workload.yaml` as follows:

```
spec:
  env:
  - name: BPL_DEBUG_ENABLED
    value: "true"
```

This adds the JVM argument:

```
-agentlib:jdwp=transport=dt_socket,server=y,address=*:8000,suspend=n
```

(Optional) You can specify `BPL_DEBUG_PORT` and `BPL_DEBUG_SUSPEND` to change the defaults for these options.

Enable Application Performance Monitoring (APM) with Datadog

To enable Datadog, you must first install the Datadog Agent on your platform. After installing Datadog, the environment variable allows the buildpack to contribute the Datadaog Tracing library to the app classpath. To install the Datadog agent for Tanzu Application Platform, follow the instructions in Use Datadog as your observability tool.

Note

> Your Tanzu Application Platform environment might be restricted to the baseline pod security standard For more information about the baseline pod security standard, see the Kubernetes documentation. In that case, you must remove the restriction before you can install the Datadog Agent DaemonSet.

The following table compares enabling APM in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Enable Datadog	`$DD_API_KEY=XXX`	`$BP_DATADOG_ENABLED=true`

Example Datadog configuration

If you previously deployed the following `workload.yaml` to Tanzu Application Platform:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
 labels:
   app.kubernetes.io/part-of: petclinic
   apps.tanzu.vmware.com/has-tests: "true"
   apps.tanzu.vmware.com/workload-type: web
 name: petclinic
 namespace: apps
spec:
 build:
   env:
   - name: BP_JVM_VERSION
     value: "17"
 params:
 - name: annotations
   value:
     autoscaling.knative.dev/minScale: "1"
 source:
   git:
     ref:
       branch: main
     url: https://github.com/spring-projects/spring-petclinic
```

To enable Datadog, change the `workload.yaml` as follows:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
 labels:
   app.kubernetes.io/part-of: petclinic
   apps.tanzu.vmware.com/has-tests: "true"
   apps.tanzu.vmware.com/workload-type: web
   tags.datadoghq.com/env: "dev"
   tags.datadoghq.com/service: "petclinic"
   tags.datadoghq.com/version: "0.0.1"
 name: petclinic
 namespace: apps
spec:
 build:
   env:
   - name: BP_JVM_VERSION
     value: "17"
   - name: BP_DATADOG_ENABLED
     value: "true"
 env:
```

```
    - name: DD_AGENT_HOST
      value: "datadog-agent"
    - name: DD_ENV
      value: "dev"
    - name: DD_SERVICE
      value: "petclinic"
    - name: DD_VERSION
      value: "0.0.1"
  params:
  - name: annotations
    value:
      autoscaling.knative.dev/minScale: "1"
  source:
    git:
      ref:
        branch: main
      url: https://github.com/spring-projects/spring-petclinic
```

Configure the log level for buildpacks

The following table compares configuring the log level in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Enable Debug Logging	`$JBP_LOG_LEVEL=DEBUG`	`$BP_LOG_LEVEL=DEBUG`

In Tanzu Application Platform, changing the log level to DEBUG is similar to Tanzu Application Service. Set the environment variable in your `workload.yaml` as follows:

```
spec:
 build:
  env:
  - name: BP_LOG_LEVEL
    value: "DEBUG"
```

This shows debug level output for buildpacks during the build phase.

Migrate from the NGINX and Staticfile CF buildpack to the Web Server Cloud Native Buildpack

This topic tells you how to migrate your NGINX or Staticfile app from using a Cloud Foundry buildpack for Tanzu Application Service (commonly known as TAS for VMs) to using a Cloud Native Buildpack for Tanzu Application Platform (commonly known as TAP).

The Tanzu Application Platform Web Server buildpack provides the capability corresponding to the Tanzu Application Service NGINX buildpack and Tanzu Application Service Staticfile Buildpack.

Install a specific NGINX version

The following table compares how Tanzu Application Service and Tanzu Application Platform handle installing specific versions.

Feature	Tanzu Application Service	Tanzu Application Platform
Override app-based version detection.	Using `builpack.yml`	Using `$BP_NGINX_VERSION`

Tanzu Application Service: Override version detection

Tanzu Application Service buildpacks allows you to specify an NGINX version or version line, such as mainline or stable, using a `buildpack.yml` file.

Example `buildpack.yml`:

```
nginx:
  version: mainline
```

Tanzu Application Platform: Override version detection

In Tanzu Application Platform, set the `$BP_NGINX_VERSION` environment variable to specify which version or version line to install.

Example `spec` section from a `workload.yaml`:

```
spec:
  build:
    env:
    - name: BP_NGINX_VERSION
       value: mainline
```

Templating in the NGINX configuration file

The Tanzu Application Platform Web Servers buildpack supports templating in the `nginx.conf` file, such as `{{port}}`, `{{env "YOUR-VARIABLE"}}`, `{{module "module_name"}}`, similar to Tanzu Application Service.

Tanzu Application Platform does not support the template `{{nameservers}}` because it was intended only for the Cloud Foundry platform.

Static web apps

The Tanzu Application Platform Web Server buildpack can automatically generate an `nginx.conf` for your app when built with the environment `$BP_WEB_SERVER=nginx`. This is useful for apps that run in Tanzu Application Service using the Staticfile Buildpack.

You can configure the generated `nginx.conf` in combination with other environment variables, for example:

- `$BP_WEB_SERVER_ROOT`
- `$BP_WEB_SERVER_LOCATION_PATH`
- `$BP_WEB_SERVER_ENABLE_PUSH_STATE`
- `$BP_WEB_SERVER_FORCE_HTTPS`
- `$BP_NGINX_STUB_STATUS_PORT`

For more information about how to use these environment variables, see the Paketo documentation for NGINX.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: BP_WEB_SERVER
      value: nginx
    - name: BP_WEB_SERVER_ROOT
      value: build
```

```
  - name: BP_WEB_SERVER_ENABLE_PUSH_STATE
    value: "true"
```

Configure basic authentication

The following table compares how you set up basic authentication in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Provide HTTP basic authentication	Use a `Staticfile.auth`	Use a binding of type `htpasswd` containing `.htpasswd`

Tanzu Application Service: Set up basic authentication

In Tanzu Application Service Staticfile buildpack applications you use a file at the root of the app.

Tanzu Application Platform: Set up basic authentication

For the Tanzu Application Platform Web Server buildpack you provide basic authentication credentials by using a service binding as follows:

1. Create the service binding as a secret. For example:

```
---
apiVersion: v1
kind: Secret
metadata:
name: basic-auth-config
namespace: my-apps
type: service.binding/htpasswd
stringData:
type: htpasswd
.htpasswd: |
  user1:$foooo.oooo
  user2:$baaaaaaa.ar
```

2. Use the binding in the `workload.yaml`. For example:

```
---
kind: Workload
apiVersion: carto.run/v1alpha1
metadata:
name: nginx-app
spec:
# ...
  params:
  - name: buildServiceBindings
    value:
      - name: basic-auth-config
        kind: Secret
        apiVersion: v1
```

For more information about service bindings, see Configure Tanzu Build Service properties on a workload.

Migrate to the Node.js Cloud Native Buildpack

This topic tells you how to migrate your Node.js app from using a Cloud Foundry buildpack for Tanzu Application Service (commonly known as TAS for VMs) to using a Cloud Native Buildpack for

Tanzu Application Platform (commonly known as TAP).

Install a specific Node Engine version

The following table compares how Tanzu Application Service and Tanzu Application Platform handle installing specific versions.

Feature	Tanzu Application Service	Tanzu Application Platform
Detects version from `package.json` Detects version from `.nvmrc`		
Detects version from `.node-version`		
Override app-based version detection		Use `$BP_NODE_VERSION`

Tanzu Application Service: Override version detection

Specifying the version to install is not supported.

Tanzu Application Platform: Override version detection

In Tanzu Application Platform, users can set the `$BP_NODE_VERSION` environment variable to specify which version of the Node Engine to installed.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: BP_NODE_VERSION
       value: "20.*.*"
```

Heap memory optimization

The following table compares how to configure heap memory optimization in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Enable Heap Memory Optimization	Use `$OPTIMIZE_MEMORY=true`	Use `$BP_NODE_OPTIMIZE_MEMORY=true`

Provide npm configuration files

The following table compares how to provide npm configuration files in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Provide a `.npmrc` with the app		
Provide a `.npmrc` by using service bindings	Not supported	Use a binding of type npmrc containing `.npmrc`

Configure npm settings with sensitive data

In Tanzu Application Platform, if your npm configuration contains sensitive data, you can provide the npm configuration to the build without explicitly including the file in the application directory.

To provide your npm configuration file without including it in the directory:

1. Create the service binding as a secret. For example:

```
---
apiVersion: v1
kind: Secret
metadata:
  name: npmrc-binding
  namespace: my-apps
type: service.binding/npmrc
stringData:
  type: npmrc
  .npmrc: |
    registry=https://registry.npmjs.org/
    loglevel=warn
    save-exact=true
```

2. Use the binding in the `workload.yaml`. For example:

```
---
kind: Workload
apiVersion: carto.run/v1alpha1
metadata:
name: nodejs-app
spec:
# ...
  params:
  - name: buildServiceBindings
    value:
      - name: npmrc-binding
        kind: Secret
        apiVersion: v1
```

For more information about service bindings, see Configure Tanzu Build Service properties on a workload.

Provide yarn configuration files

The following table compares how to provide yarn configuration files in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Provide a `.yarnrc` with the app		
Provide a `.yarnrc` by using service bindings	Not supported	Use a binding of type yarnrc containing `.yarnrc`

Configure yarn settings with sensitive data

In Tanzu Application Platform, if your yarn configuration contains sensitive data, you can provide the yarn configuration to the build without explicitly including the file in the application directory.

To provide your yarn configuration file without including it in the directory:

1. Create the service binding as a secret. For example:

```
---
apiVersion: v1
kind: Secret
metadata:
```

```
  name: yarnrc-binding
  namespace: my-apps
type: service.binding/yarnrc
stringData:
  type: yarnrc
  .yarnrc: |
    registry "https://registry.yarnpkg.com"
    flat "true"
```

2. Use the binding in the workload. For example:

```
---
kind: Workload
apiVersion: carto.run/v1alpha1
metadata:
name: nodejs-app
spec:
# ...
  params:
  - name: buildServiceBindings
    value:
      - name: yarnc-binding
        kind: Secret
        apiVersion: v1
```

For more information about service bindings, see Configure Tanzu Build Service properties on a workload.

Build and serve a front end framework app

The Tanzu Application Platform Node.js buildpack is designed exclusively for building back end server node applications. If your app is using a front end framework that generates static content from JavaScript source code, such as React, Vue, Angular, you must use the Tanzu Application Platform Web Servers buildpack instead of the Tanzu Application Platform Node.js buildpack.

To build a front end app, set the environment variable `$BP_NODE_RUN_SCRIPTS` to instruct the Tanzu Application Platform Web Servers buildpack to run a specific npm or yarn script event during the build. For popular frameworks such as Angular and React, this is generally the build script.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
  - name: BP_NODE_RUN_SCRIPTS
    value: build
  - name: BP_WEB_SERVER
    value: nginx
  - name: BP_WEB_SERVER_ROOT
    value: build
```

For more information about using the Tanzu Application Platform Web Server buildpack, see Use the Tanzu Web Servers Buildpack in the Tanzu Buildpacks documentation.

Migrate to the PHP Cloud Native Buildpack

This topic tells you how to migrate your PHP app from using a Cloud Foundry buildpack for Tanzu Application Service (commonly known as TAS for VMs) to using a Cloud Native Buildpack for Tanzu Application Platform (commonly known as TAP).

PHP configuration

This section describes how you change PHP configurations when migrating from Tanzu Application Service to Tanzu Application Platform.

Install specific PHP versions

The following table compares how Tanzu Application Service and Tanzu Application Platform handle installing specific versions.

Feature	Tanzu Application Service	Tanzu Application Platform
Detects version from `composer.lock`		
Detects version from `composer.json`: `"require": { "php": ">=8.0" }`		
Override app-based version detection	Use `options.json`	Use `$BP_PHP_VERSION`

Tanzu Application Service: Override version detection

Tanzu Application Service buildpacks allows you to specify a PHP version using a `options.json` file.

Example `options.json`:

```
{
    "PHP_VERSION": "7.34.5"
}
```

The Tanzu Application Service `options.json` supports providing the exact version to use, or specifying a more general minor version line to use such as `PHP_80_LATEST` instead of `8.0.1`.

Tanzu Application Platform: Override version detection

In Tanzu Application Platform, set the `$BP_PHP_VERSION` environment variable to specify which version of the PHP distribution to install.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: BP_PHP_VERSION
      value: 8.0.0
```

Configure the PHP library directory

The following table compares how you configure the PHP library directory for Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Set PHP library directory	Use `options.json`	Use `$BP_PHP_LIB_DIR`

Tanzu Application Service: Configure the PHP library directory

Tanzu Application Service buildpacks allow you to specify the PHP library directory using a `options.json` file.

Example `options.json`:

```
{
    "LIBDIR": "lib"
}
```

Tanzu Application Platform: Configure the PHP library directory

In Tanzu Application Platform, specify the PHP library directory by using the `$BP_PHP_LIB_DIR` environment variable.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: BP_PHP_LIB_DIR
      value: lib
```

Configure a custom `.ini` file

In Tanzu Application Service and Tanzu Application Platform, you can configure custom `.ini` files in addition to the default `php.ini` provided.

The following table compares how you configure a custom `.ini` file for Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Custom `.ini` file in the application	Enabled by file in `.bp-config/php/php.ini.d/*.ini`	Enabled by file in `.php.ini.d/*.ini`

Create an `.ini` file under `.bp-config/php/php.ini.d/FILENAME.ini` in Tanzu Application Service, and under `.php.ini.d/FILENAME.ini` in Tanzu Application Platform.

Enable PHP extensions

In Tanzu Application Platform, the only extensions available to use at this time are the ones that come with the distribution of PHP.

The following table compares how you enable PHP extensions for Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Enable PHP extensions by custom `.ini` snippet	Located in `.bp-config/php/php.ini.d/FILENAME.ini`	Located in `APP-ROOT/.php.ini.d/*.ini`
Enable PHP extensions by `composer.json`		
Enable additional custom extensions through `.extensions` directory. For more information, see the (php-buildpack README) in GitHub.		

Tanzu Application Service: Enable PHP extensions by custom `.ini` file

In Tanzu Application Service, you can specify extensions in a custom `.ini` file under `.bp-config/php/php.ini.d/FILENAME.ini` in the application. If an extension is already present and enabled in the compiled PHP, explicitly enabling the extension is not required in Tanzu Application Service.

For example:

```
extension=bz2.so
extension=curl.so
zend_extension=opcache.so
```

Tanzu Application Platform: Enable PHP extensions by custom `.ini` file

In Tanzu Application Platform, you can enable extensions by using a custom `.ini` file snippet. An `.ini` snippet is a valid PHP configuration file. The buildpacks look for any user-provided snippets under `APP-ROOT/.php.ini.d/*.ini`.

For example:

```
extension=bz2.so
extension=curl.so
```

Alternatively, in both Tanzu Application Service and Tanzu Application Platform, if you are using Composer as a package manager, you can specify extensions through the `composer.json` file.

For example:

```
{
    "require": {
        "php": ">=7.1",
        "ext-bz2": "*",
        "ext-curl": "*",
    },
}
```

Profile scripts

The following table compares enabling launch-time scripts for Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Enable launch-time scripts (link for more info)	Located in `.profile.d` directory	

A `.profile.d` directory containing scripts to be run just before application launch is not currently supported in Tanzu Application Platform. These scripts are ignored during launch.

Server configuration

This section describes how you change server configurations when migrating from Tanzu Application Service to Tanzu Application Platform.

Select a web server

The following table compares how you select a web server in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Select a web server to use	Use `options.json`	Use `$BP_WEB_SERVER`

Tanzu Application Service: Select a web server

Tanzu Application Service buildpacks allow you to specify which web server to use by using an `options.json` file.

Example `options.json`:

```
{
    "WEB_SERVER": "httpd"
}
```

Tanzu Application Platform: Select a web server

In Tanzu Application Platform, you specify the web server by using the `$BP_WEB_SERVER` environment variable. For more information about the web servers you can, see Select a Web Server in the Tanzu Buildpacks documentation.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: BP_WEB_SERVER
      value: httpd
```

Set server configuration

The following table compares how you set server configuration in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
HTTPD configuration	`.bp-config/httpd/*.conf`	`APP-DIRECTORY/.httpd.conf.d/*.conf`
NGINX configuration	`.bp-config/nginx/*.conf`	`APP-DIRECTORY/.nginx.conf.d/*-server.conf` OR `APP-DIRECTORY/.nginx.conf.d/*-http.conf`
FPM configuration	`.bp-config/php/fpm.d`	`APP-DIRECTORY/.php.fpm.d/*.conf.`

Tanzu Application Service: Set server configuration

For Tanzu Application Service buildpacks, you can add server configuration files under the `.bp-config` directory to override the buildpack-set configuration options. For more information, see the Cloud Foundry documentation.

Put these files under `.bp-config` in directories named for the relevant component, such as `httpd` for HTTPD, `nginx` for NGINX, and `fpm.d` for FPM configuration.

Tanzu Application Platform: Set server configuration

Tanzu Application Platform buildpacks also support providing custom settings for HTTPD, NGINX and FPM that are not supported through the buildpack environment variables using specially-

named directories:

- **HTTPD:** `APP-DIRECTORY/.httpd.conf.d/*.conf`
- **NGINX:** `APP-DIRECTORY/.nginx.conf.d/*-server.conf` OR `APP-DIRECTORY/.nginx.conf.d/*-http.conf`
- **FPM:** `APP-DIRECTORY/.php.fpm.d/*.conf.`

For more information, see Set Server Configuration.

Configure the web directory

The following table compares how you set the web directory in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Set the web directory	Use `options.json`	Use `$BP_WEB_SERVER`

Tanzu Application Service: Configure the web directory

Tanzu Application Service buildpacks allow you to specify the root directory of the files served by the web server, relative to the root of the app, through an `options.json`, for example:

```
{
    "WEBDIR": "htdocs"
}
```

Tanzu Application Platform: Configure the web directory

In Tanzu Application Platform you specify the web directory by using the `$BP_PHP_WEB_DIR` environment variable. For more information, see Configure Web Directory in the Tanzu Buildpacks documentation.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: BP_PHP_WEB_DIR
      value: htdocs
```

Set the app start command

The following table compares how you set the app start command in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Set a custom app start command	Use `options.json`	Use Procfile

Tanzu Application Service: Set the app start command

Tanzu Application Service buildpacks allow you to specify the start command for your app through an `options.json` file.

Example `options.json`:

```
{
    "APP_START_CMD": "app.php"
}
```

Tanzu Application Platform: Set the app start command

In Tanzu Application Platform buildpacks support setting a custom start command for your app by using a Procfile located at the root of the application. For more information, see Additional Configuration in the Tanzu Buildpacks documentation.

Example Procfile:

```
web: php -S 0.0.0.0:"${PORT:-80}" -t htdocs && echo hi
```

Activate or deactivate HTTPS redirect

The following table compares how you activate or deactivate the HTTPS redirect in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Activate or deactivate HTTPS redirect		Use Procfile

HTTPS redirect is enabled by default for NGINX and HTTPD. In Tanzu Application Platform, you can deactivate this by setting the `$BP_PHP_ENABLE_HTTPS_REDIRECT` environment variable to `false` at build time.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: BP_PHP_ENABLE_HTTPS_REDIRECT
      value: false
```

Composer configuration

This section describes how you change the Composer configurations when migrating from Tanzu Application Service to Tanzu Application Platform.

Install specific Composer versions

The following table compares how Tanzu Application Service and Tanzu Application Platform handle installing specific Composer versions.

Feature	Tanzu Application Service	Tanzu Application Platform
Override app-based version detection	Use `options.json`	Use `$BP_COMPOSER_VERSION`

Tanzu Application Service: Override Composer version detection

Tanzu Application Service buildpacks allow you to specify a Composer version using an `options.json` file.

Example `options.json`:

```
{
    "COMPOSER_VERSION": "2.6.6"
```

```
}
```

Tanzu Application Service: Override Composer version detection

Tanzu Application Platform buildpacks allow you to specify Composer version by using the `$BP_COMPOSER_VERSION` environment variable. For more information, see Set Composer Version in the Tanzu Buildpacks documentation.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: BP_COMPOSER_VERSION
      value: 2.6.6
```

Set Composer install options

The following table compares how you set install options for Composer in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Set a list of options to be passed to Composer install	Use `options.json`	Use `$BP_COMPOSER_INSTALL_OPTIONS`

Tanzu Application Service: Set Composer install options

Tanzu Application Service buildpacks allow you to specify Composer install options by using an `options.json` file.

Example `options.json`:

```
{
    "COMPOSER_INSTALL_OPTIONS": ["--no-interaction","--no-dev","--no-progress"]
}
```

Tanzu Application Platform: Set Composer install options

Tanzu Application Platform buildpacks allow you to specify composer install options by using the `$BP_COMPOSER_INSTALL_OPTIONS` environment variable. For more information, see Set Composer Install Options in the Tanzu Buildpacks documentation.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: BP_COMPOSER_INSTALL_OPTIONS
      value: "--no-dev --prefer-install=auto"
```

Set the `composer.json` path

The following table compares how you set the `composer.json` path in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Set a custom composer.json path	Use `$COMPOSER_PATH`	Use `$COMPOSER`

Tanzu Application Service: Set `composer.json` path

Tanzu Application Service buildpacks allow you to specify a `composer.json` path, relative to the project root, using the `$COMPOSER_PATH` environment variable either through the `manifest.yml` or the cf CLI, for example:

```
cf set-env YOUR_APP_NAME COMPOSER_PATH "PATH_TO_COMPOSER_JSON"
```

For more information, see the Cloud Foundry documentation.

Tanzu Application Platform: Set `composer.json` path

Tanzu Application Platform buildpacks allow you to specify the `composer.json` path, relative to the project root, by using the native `$COMPOSER` environment variable. For more information, see Set the composer.json Path. in the Tanzu Buildpacks documentation.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: COMPOSER
      value: some-other-composer-json
```

Set Composer-native environment variables

The following table compares how you set Composer-native environment variables Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Override buildpack-set Composer environment variables	Use `options.json`	Use `$COMPOSER_ENV-VAR-NAME`. For example: `COMPOSER_VENDOR_DIR`

Tanzu Application Service: Set Composer-native environment variables

Tanzu Application Service buildpacks allow you to specify various Composer-native extensions using an `options.json`, which is passed through to Composer to override the buildpack-set defaults.

Example `options.json`:

```
{
    "COMPOSER_VENDOR_DIR": "vendor",
}
```

Tanzu Application Platform: Set Composer-native environment variables

Tanzu Application Platform buildpacks respect any Composer-native environment variables set at build-time.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: COMPOSER_VENDOR_DIR
      value: vendor
    - name: COMPOSER_BIN_DIR
      value: some-bin-dir
    - name: COMPOSER_CACHE_DIR
      value: some-cache-dir
```

Supply Composer authentication

The following table compares how you supply Composer authentication in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Supply Composer authentication (for example, GitHub token)	Use `$COMPOSER_GIHTUB_OAUTH_TOKEN`	Use `$COMPOSER_AUTH`

Tanzu Application Service: Supply Composer authentication

Tanzu Application Service buildpacks allow you to supply Composer authentication, mainly in the form of a Github token to bypass rate-limiting, by using an environment variable, for example:

```
cf set-env YOUR-APP-NAME COMPOSER_GITHUB_OAUTH_TOKEN "OAUTH-TOKEN-VALUE"
```

Where:

- `YOUR-APP-NAME` is the name of your app.
- `OAUTH-TOKEN-VALUE` is the token.

For more information, see the Cloud Foundry documentation.

Tanzu Application Platform: Supply Composer authentication

Tanzu Application Platform buildpacks respect any Composer-native environment variables set at build-time. You can supply a GitHub token, or any other authentication supported by Composer, through the native `COMPOSER_AUTH` environment variable. For more information, see Set Composer Authentication. in the Tanzu Buildpacks documentation.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: COMPOSER_AUTH
      value: '{"github-oauth": {"github.com": "<oauthtoken>"}}'
```

Session Handlers

This section describes how you change session handlers when migrating from Tanzu Application Service to Tanzu Application Platform.

Enable Redis or Memcached session handler

The following table compares how you enable a Redis or Memcached session handler in Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Bind session handler service to application	Use `cf create-service`	Use Service Bindings

Tanzu Application Service: Enable session handler

In Tanzu Application Service, you can bind a Redis or Memcached instance to a PHP app using the cf CLI, for example:

```
$ cf create-service redis some-plan app-redis-sessions
$ cf bind-service app app-redis-sessions
$ cf restage app
```

For more information, see the Cloud Foundry documentation.

Tanzu Application Platform: Enable session handler

In Tanzu Application Platform, you can configure session handlers for Redis or Memcached by using Service Bindings:

1. Create the service binding as a secret. For example:

   ```
   ---
   apiVersion: v1
   kind: Secret
   metadata:
     name: php-redis-session
     namespace: my-apps
   type: service.binding/php-redis-session
   stringData:
     type: php-redis-session
     host: HOST # default: 127.0.0.1
   port: PORT # default: 6379
   password: PASSWORD # omitted if unset
   ```

2. Use the binding in the workload. For example:

   ```
   ---
   kind: Workload
   apiVersion: carto.run/v1alpha1
   metadata:
   name: php-app
   spec:
   # ...
     params:
     - name: buildServiceBindings
       value:
         - name: php-redis-session
           kind: Secret
           apiVersion: v1
   ```

For more information on using Service Bindings in Tanzu Application Platform, see Configure build-time service bindings.

New Relic

This section describes how you configure New Relic when migrating from Tanzu Application Service to Tanzu Application Platform.

Configure New Relic

Feature	Tanzu Application Service	Tanzu Application Platform
Bind session handler service to application	Use `$VCAP_SERVICES` or `$NEWRELIC_LICENSE`	Use Service Bindings

Tanzu Application Service: Configure New Relic

In Tanzu Application Service, you can configure New Relic for the PHP buildpack either by:

- Using a Cloud Foundry service: Your `VCAP_SERVICES` environment variable must contain a service named `newrelic`. The `newrelic` service must contain a key named `credentials` and the `credentials` key must contain a `licenseKey`.
- Obtaining a license key and setting the value of the environment variable `NEWRELIC_LICENSE` to your New Relic license key in the `manifest.yml` or through the cf CLI, for example:

  ```
  cf set-env NEWRELIC_LICENSE NEW-RELIC-LICENSE-KEY
  ```

  Where `NEW-RELIC-LICENSE-KEY` is you New Relic license key.

Tanzu Application Platform: Configure New Relic

In Tanzu Application Platform, the PHP language family buildpack includes the New Relic buildpack, which participates in a build when there is a service binding of type `NewRelic`.

To configure New Relic:

1. Create the service binding as a secret. For example:

   ```
   ---
   apiVersion: v1
   kind: Secret
   metadata:
     name: new-relic
     namespace: my-apps
   type: service.binding/NewRelic
   stringData:
     type: NewRelic
   ```

2. Use the binding in the workload. For example:

   ```
   ---
   kind: Workload
   apiVersion: carto.run/v1alpha1
   metadata:
   name: php-app
   spec:
   # ...
     params:
     - name: buildServiceBindings
       value:
         - name: new-relic
           kind: Secret
           apiVersion: v1
   ```

Migrate to the Python Cloud Native Buildpack

This topic tells you how to migrate your Python app from using a Cloud Foundry buildpack for Tanzu Application Service (commonly known as TAS for VMs) to using a Cloud Native Buildpack for Tanzu Application Platform (commonly known as TAP).

Install a specific Python version

The following table compares how Tanzu Application Service and Tanzu Application Platform handle installing specific versions.

Feature	Tanzu Application Service	Tanzu Application Platform
Detects version from `runtime.txt`		
Override app-based version detection.		Use `$BP_CPYTHON_VERSION`

Tanzu Application Platform: Specify version

In Tanzu Application Platform, set the `$BP_CPYTHON_VERSION` environment variable to specify which version of CPython 3 to install.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: BP_CPYTHON_VERSION
       value: "3.12.1"
```

Install a specific pip version

Both Tanzu Application Service and Tanzu Application Platform Python buildpacks provide an extra pip dependency. You can configure this dependency using the `$BP_PIP_VERSION` environment variable in the same way you configure `$BP_CPYTHON_VERSION` in Tanzu Application Platform: Specify version above.

Install a specific Pipenv version

Tanzu Application Service buildpack does not support selecting a version. However, for the Tanzu Application Platform Python buildpack, you con configure the Pipenv version using the `$BP_PIPENV_VERSION` environment variable.

Start command

The Tanzu Application Service buildpack does not generate a default start command for your apps. However, the Tanzu Application Platform Python buildpack sets the default start command to run the Python read-eval-print loop (REPL) at launch.

For production apps, use a Procfile to specify the start command for both Tanzu Application Service and Tanzu Application Platform. For more information about Procfile on Tanzu Application Platform, see the Tanzu Buildpacks documentation.

Migrate to the Ruby Cloud Native Buildpack

This topic tells you how to migrate your Ruby app from using a Cloud Foundry buildpack for Tanzu Application Service (commonly known as TAS for VMs) to using a Cloud Native Buildpack for Tanzu

Application Platform (commonly known as TAP).

Specifying the Ruby version to install

The following table compares how Tanzu Application Service and Tanzu Application Platform handle installing specific Ruby versions.

Feature	Tanzu Application Service	Tanzu Application Platform
Detects version from `Gemfile` `ruby '~> <version>'`		
Detects version from `$BP_MRI_VERSION` env var		

Tanzu Application Service: Override version detection

Specifying the version to install is not supported.

Tanzu Application Platform: Override version detection

In Tanzu Application Platform, set the `$BP_MRI_VERSION` environment variable to specify which version of Ruby MRI to install. You can set the version to any valid semver version or version constraint, for example, `2.7.4` or `2.7.*`. The buildpack automatically installs an Ruby MRI version that is compatible with the selected version.

Example `spec` section from a `workload.yaml`:

```
---
spec:
  build:
    env:
    - name: BP_MRI_VERSION
      value: 3.2.*
  source:
    git:
      ref:
        branch: master
      url: https://github.com/cloudfoundry/ruby-buildpack
    subPath: fixtures/bundler_2
```

Specifying the Bundler version to install

The following table compares how Tanzu Application Service and Tanzu Application Platform handle installing specific Bundler versions.

Feature	Tanzu Application Service	Tanzu Application Platform
Detects version from Gemfile.lock `BUNDLED_WITH <version>'`		
Detects version from `$BP_BUNDLER_VERSION` env var		

Specifying the Jruby version to install

Specifying the Jruby version is not supported in Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Detects version from Gemfile		

Vendor in app dependencies before a build

The following table compares vendoring app dependencies before a build for Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Packages in the default cache location `bundle package --all`		
Packages in a non-default cache location		

Migration to vendoring gems in a non-default cache location

In Tanzu Application Platform, you can vendor in your app dependencies before a build. To do this, put all `.gem` files into the custom path inside the app source code, for example, `custom_dir/custom_cache`. Then, create a `.bundle/config` file with the `BUNDLE_CACHE_PATH` setting configured:

```
---
BUNDLE_CACHE_PATH: "custom_dir/custom_cache"
```

Configure Rake tasks

The following table compares how to configure rake tasks with Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Non-default Rake task support		
Default Rake task support		

Tanzu Application Service: Invoke Rake tasks

In Tanzu Application Service, you can automatically invoke a Rake task as follows:

1. Include a `.rake` file containing a Rake task in `lib/tasks`. For example:

   ```
   namespace :cf do
       desc "Only run on the first application instance"
       task :on_first_instance do
           instance_index = JSON.parse(ENV["VCAP_APPLICATION"])["instance_index"]
   rescue nil
       exit(0) unless instance_index == 0
       end
   end
   ```

2. Add the task to the `manifest.yml` with the command attribute to use this as the start command. For example:

   ```
   applications:
   - name: my-app
     command: bundle exec rake cf:on_first_instance db:migrate
   ```

Tanzu Application Platform: Invoke Rake tasks

In Tanzu Application Platform, you still specify a Rake task, but it goes in a Rakefile in the root of the application directory. Then, the buildpacks automatically set the default Rake task as the start

command.

- If you specify a default Rake task, this is the task executed by the buildpack.
- If you specify a non-default Rake task, use the Procfile Buildpack by including the start command for the non-default task in a Procfile file. Set as the web process, for example:

```
web: bundle exec rake non_default
```

Building a Rails application

The following table compares building a rails app on Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Building a Rails application		

Building Rails applications is supported on both Tanzu Application Service and Tanzu Application Platform. In both cases, you must specify the rails gem in the Gemfile.

In Tanzu Application Platform, one of the following asset directories must also be present in the application source code:

- `app/assets`
- `lib/assets`
- `vendor/assets`
- `app/javascript`

Supported web servers

The following table compares supported web servers for Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Rake		
Thin		
Rackup		
Rails Server		
Puma		
Unicorn	requires custom start command through the `manifest.yml`	
Passenger		

Supported dependencies

The following table compares supported dependencies for Tanzu Application Service and Tanzu Application Platform.

Feature	Tanzu Application Service	Tanzu Application Platform
Bundler		
Ruby		

Feature	Tanzu Application Service	Tanzu Application Platform
Node		
Yarn		
Jruby		
OpenJDK		
Ruby Gems		

Set up Tanzu Service Mesh

This topic tells you how to set up a Tanzu Application Platform application deployed on Kubernetes with Tanzu Service Mesh (commonly called TSM).

Sample applications are used to demonstrate how a global namespace can provide a network for Kubernetes workloads that are connected and secured within and across clusters, and across clouds.

Note

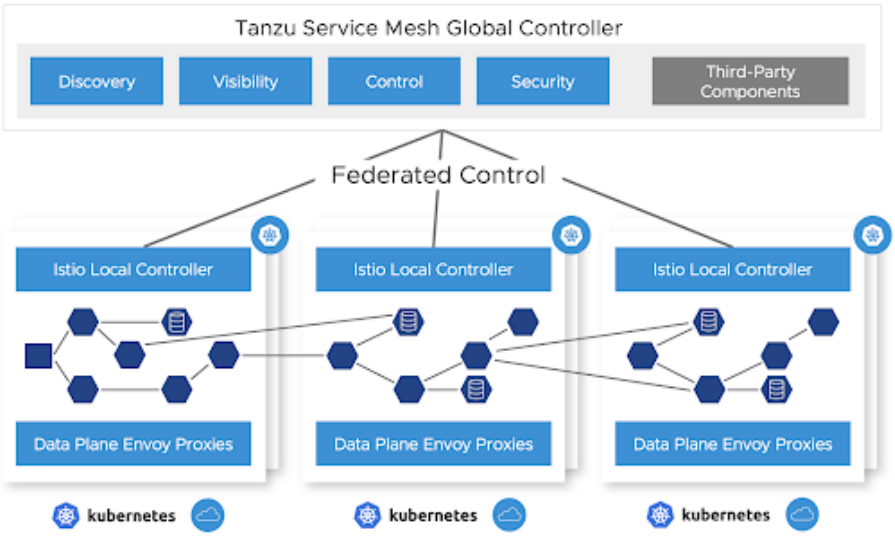
You can also use Tanzu Mission Control (commonly called TMC) to install Tanzu Application Platform (commonly called TAP) on a managed cluster. For more information, see the Tanzu Mission Control documentation.

Prerequisites

Meet the prerequisites, which includes having

- A supported Kubernetes platform
- The correct resource configuration (number of nodes, CPUs, RAM, and so on)
- The required connectivity requirements

Connectivity is only required from your local clusters out to Tanzu Service Mesh and not inwards. This can traverse a corporate proxy as well. In addition, connectivity in the data plane is required between the clusters that must communicate, specifically egress to ingress gateways. No data plane traffic needs to reach the Tanzu Service Mesh software as a service (SaaS) management plane.



Activate your Tanzu Service Mesh subscription

Activate your Tanzu Service Mesh subscription at cloud.vmware.com. After purchasing your Tanzu Service Mesh subscription, the VMware Cloud team sends you instructions. If you don't receive them, you can follow these instructions.

Onboard your clusters to Tanzu Service Mesh as described later in this topic. This deploys the Tanzu Service Mesh local control plane and OSS Istio on your Kubernetes cluster and connects the local control plane to your Tanzu Service Mesh tenant.

Set up Tanzu Application Platform

To enable Tanzu Service Mesh support in Tanzu Application Platform Build clusters:

1. Add the following key to `tap-values.yaml` under the `buildservice` top-level key:

   ```
   buildservice:
    injected_sidecar_support: true
   ```

2. Install Tanzu Application Platform on the run cluster.

End-to-end workload build and deployment scenario

The following sections describe how to build and deploy a workload.

Apply a workload resource to a build cluster

Workloads can be built by using a Tanzu Application Platform supply chain by applying a workload resource to a build cluster. At this time, Tanzu Service Mesh and Tanzu Application Platform cannot use the Knative resources that are the default runtime target when using the `web` resource type.

In Tanzu Application Platform v1.4 and later, two workload types support a Tanzu Service Mesh and Tanzu Application Platform integration: **server** and **worker**.

To work with Tanzu Service Mesh, web workloads must be converted to the `server` or `worker` workload type. Server workloads cause a Kubernetes `Deployment` resource to be created with a `Service` resource that uses port 8080 by default.

1. If the service port that you want is 80 or some other port, add port information to `workload.yaml`. The following example YAML snippets show the changes to make from the `web` to `server` workload type. This is an example before applying the changes:

   ```
   apiVersion: carto.run/v1alpha1
   kind: Workload
   metadata:
    name: where-for-dinner
    labels:
      apps.tanzu.vmware.com/workload-type: web
      app.kubernetes.io/part-of: where-for-dinner-api-gateway
   spec:
    params:
    - name: annotations
   value:
   autoscaling.knative.dev/minScale: "1"
    source:
      git:
        url: https://github.com/vmware-tanzu/application-accelerator-samples.git
      ref:
        branch: tap-1.6.x
      subPath: where-for-dinner/where-for-dinner-api-gateway
   ```

   This is an example modified for Tanzu Service Mesh, which includes the removal of the autoscaling annotation:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
 name: where-for-dinner
 labels:
 apps.tanzu.vmware.com/workload-type: server # modification
 app.kubernetes.io/part-of: where-for-dinner-api-gateway
spec:
 params:
 - name: ports # modification
 value:
 - port: 80 # modification
   containerPort: 8080 # modification
   name: http # modification
 source:
 git:
     url: https://github.com/vmware-tanzu/application-accelerator-samples.git
   ref:
       branch: tap-1.6.x
 subPath: where-for-dinner/where-for-dinner-api-gateway
```

This results in a deployment and a service that listens on port 80 and forwards traffic to port 8080 on the pod's workload container.

2. Submit the modified YAML to your build cluster by running:

```
tanzu apps NAMESPACE apply --file WORKLOAD-YAML-FILE
```

Where:

- `NAMESPACE` is the namespace that the build cluster uses for building.
- `WORKLOAD-YAML-FILE` is the name of your workload YAML file, such as `workload.yaml`.

After your workload is built a `Deliverable` resource is created.

Configure egress for Tanzu Build Service

For Tanzu Build Service to properly work, provide egress to access the registry where Tanzu Build Service writes application images, and define the registry in the `kp_default_repository` key and the Tanzu Application Platform install registry.

Additionally, configure egress for buildpack builds to download any required dependencies. This configuration varies with different buildpacks and language environments. For example, Java builds might need to download dependencies from Maven central.

Create a global namespace

Using the Tanzu Service Mesh portal or API, create a global namespace (GNS) that includes the namespaces where your application components are deployed. For more information, see Global Namespaces

Whether in a single cluster or multiple clusters, or within the same site or across clouds, after you add a namespace selection to the GNS, the services that Tanzu Application Platform deploys are connected based on the GNS configuration for service discovery and connectivity policies.

If a service must be accessible through the ingress from the outside, it can be configured through the public service option in Tanzu Service Mesh or directly through Istio on the clusters where that service resides. It's best practice to configure the service's accessibility through the GNS.

Run cluster deployment

Before deploying a workload to a run cluster, ensure that any prerequisite resources have already been created on the run cluster. This includes concepts such as data, messaging, routing, security services, RBAC, ResourceClaims, and so on.

After a successful build in a build cluster, workloads can be deployed to the run cluster by applying resulting deliverable resources to the run cluster as described in Getting Started with Multicluster Tanzu Application Platform.

Another option is to create a kapp application that references a GitOps repository to include all deliverable resources for a given cluster. See the following example of a kapp definition that points to a GitOps repository:

```
apiVersion: kappctrl.k14s.io/v1alpha1
kind: App
metadata:
  name: deliverable-gitops
  namespace: where-for-dinner
spec:
  serviceAccountName: default
  fetch:
  - git:
    url: https://github.com/gm2552/tap-play-gitops
    ref: origin/deliverables-tap-east01
    subPath: config
  template:
  - ytt: {}
  deploy:
  - kapp: {}
```

The advantage of this model is that applications can be deployed or uninstalled from a cluster by managing the contents of the deliverable resources from within the GitOps repository and enabling a GitOps workflow for application and service change control.

Deployment use case: Where For Dinner

The following instructions describe an end-to-end process for configuring, building, and deploying the Where For Dinner application into a Tanzu Service Mesh global namespace.

These instructions use the default configuration of Where For Dinner, which consists of only needing a single-node RabbitMQ cluster, an in-memory database, and no security. The application is deployed across two Tanzu Application Platform run clusters. It requires the `ytt` command to execute the build and deployment commands.

The configuration resources referenced in this scenario are located in the where-for-dinner-tap-tsm GitHub repository.

Create an initial set of configuration files from the accelerator

This use case deployment includes a pre-built set of configuration files in a Git repository. However, they were created from a set of configuration files by using a bootstrapped process that uses the Where For Dinner accelerator, and were later modified.

For reference, you can create an initial set of configuration files from the Where For Dinner accelerator, which is available in Tanzu Application Platform v1.3 and later.

This section does not include instructions for modifying the configuration files from the accelerator into configuration files used in a later section.

From the accelerator, accept all of the default options with the following exceptions:

- **Workload namespace:** Update this field with the name of the namespace you will use to build the application in your build cluster
- **Service namespace:** Update this field with the name of the namespace you will use to deploy a RabbitMQ cluster on your Tanzu Application Platform run cluster

Apply the workload resources to your build cluster

To build the application services, run the following command to apply the workload resources to your build cluster. You can also clone or fork the repository in this command to either use the YAML files locally or point to your own Git repository.

```
ytt -f workloads.yaml -v workloadNamespace=WORKLOAD-NAMESPACE | kubectl apply -f-
```

Where `WORKLOAD-NAMESPACE` is the name of your build namespace

For example:

```
ytt -f https://raw.githubusercontent.com/gm2552/where-for-dinner-tap-tsm/main/workload
s.yaml \
-v workloadNamespace=workloads | kubectl apply -f-
```

If you are using a GitOps workflow with your build cluster, after the workloads are built the deployment information is pushed to your GitOps repository.

If you follow these instructions without pull requests in the GitOps workflow, the config-writer pods that commit deployment information to the GtiOps repository might fail because of concurrency conflicts. A workaround for this is to delete the failed workloads from the build cluster and re-run the command provided in the instructions.

Install service claim resources on the cluster

Where For Dinner requires a RabbitMQ cluster installed on your run cluster. You must install RabbitMQ on the same run cluster that is named `RunCluster01` in the following deployment section. Additionally, you must install service claim resources on this cluster.

1. If you haven't already done so, install the RabbitMQ Cluster Operator on the run cluster by running:

   ```
   kubectl apply -f "https://github.com/rabbitmq/cluster-operator/releases/downloa
   d/v1.13.1/cluster-operator.yml"
   ```

2. Spin up an instance of a RabbitMQ cluster by running:

   ```
   kubectl create ns SERVICE-NAMESPACE

   ytt -f rmqCluster.yaml -v serviceNamespace=SERVICE-NAMESPACE | kubectl apply -f
   -
   ```

   Where `SERVICE-NAMESPACE` is the namespace of where you want to deploy your RabbitMQ cluster

   For example:

   ```
   kubectl create ns service-instances

   ytt -f https://raw.githubusercontent.com/gm2552/where-for-dinner-tap-tsm/main/r
   mqCluster.yaml -v \
   serviceNamespace=service-instances | kubectl apply -f-
   ```

3. Create service toolkit resources for the RabbitMQ class and resource claim by running:

```
ytt -f rmqResourceClaim.yaml -v serviceNamespace=SERVICE-NAMESPACE -v \
workloadNamespace=WORKLOAD-NAMESPACE | kubectl apply -f-
```

Where `SERVICE-NAMESPACE` and `WORKLOAD-NAMESPACE` are the namespaces where you deployed your RabbitMQ cluster and the namespace where the application service will run.

For example:

```
ytt -f https://raw.githubusercontent.com/gm2552/where-for-dinner-tap-tsm/main/r
mqResourceClaim.yaml \
-v serviceNamespace=service-instances -v workloadNamespace=where-for-dinner | k
ubectl apply -f-
```

Run cluster deployment

Workloads are deployed to the run cluster using deliverable resources. This section applies the deliverable resources directly to the run clusters instead of using a kapp application.

This deployment assumes that two clusters are part of the Tanzu Service Mesh GNS Where For Dinner. These example clusters are named `RunCluster01` and `RunCluster02`. The majority of the workload is deployed to `RunCluster01` while the crawler workload is deployed to `RunCluster02`.

The deliverable objects reference the GitOps repository, where the build cluster has written deployment information, and needs to reference this repository in the following commands.

Deploy the workloads to the run clusters by running these commands against their respective clusters:

```
ytt -f cluster01Deliverables.yaml -v workloadNamespace=WORKLOAD-NAMESPACE -v \
gitOpsSecret=GIT-OPS-SECRET -v gitOpsRepo=GIT-OPS-REPO | kubectl apply -f-
```

Where:

- `WORKLOAD-NAMESPACE` is the namespace where the workloads are deployed
- `GIT-OPS-SECRET` is the GitOps secret used to access the GitOps repository
- `GIT-OPS-REPO` is the URL of the GitOps repository where the build cluster wrote out deployment configuration information

```
ytt -f cluster02Deliverables.yaml -v workloadNamespace=WORKLOAD-NAMESPACE -v \
gitOpsSecret=GIT-OPS-SECRET -v gitOpsRepo=GIT-OPS-REPO | kubectl apply -f-
```

Where:

- `WORKLOAD-NAMESPACE` is the namespace where the workloads are deployed
- `GIT-OPS-SECRET` is the GitOps secret used to access the GitOps repository
- `GIT-OPS-REPO` is the URL of the GitOps repository where the build cluster wrote out deployment configuration information

To run this deployment on cluster `RunCluster01`, for example, you run:

```
ytt -f https://raw.githubusercontent.com/gm2552/where-for-dinner-tap-tsm/main/cluster0
1Deliverables.yaml -v \
workloadNamespace=where-for-dinner -v gitOpsSecret=tap-play-gitops-secret -v \
gitOpsRepo=https://github.com/gm2552/tap-play-gitops.git | kubectl apply -f-
```

To run this deployment on cluster `RunCluster02`, for example, you run:

```
ytt -f https://raw.githubusercontent.com/gm2552/where-for-dinner-tap-tsm/main/cluster0
2Deliverables.yaml -v \
```

```
workloadNamespace=where-for-dinner -v gitOpsSecret=tap-play-gitops-secret -v \
gitOpsRepo=https://github.com/gm2552/tap-play-gitops.git | kubectl apply -f-
```

You can create an Istio ingress resource on `RunCluster01` if you do not plan on using the GNS capabilities to expose the application to external networks.

You must create a domain name system address (DNS A) record in your DNS provider's configuration tool to point to the Istio load-balanced IP address of `RunCluster01`. The DNS configuration is out of the scope of this topic.

Create the ingress by running:

```
ytt -f ingress.yaml -v workloadNamespace=WORKLOAD-NAMESPACE -v domainName=DOMAIN-NAME
| kubectl apply -f-
```

Where:

- `WORKLOAD-NAMESPACE` is the namespace where the workload is deployed
- `DOMAIN-NAME` is the public domain that will host your application

For example:

```
ytt -f https://raw.githubusercontent.com/gm2552/where-for-dinner-tap-tsm/main/ingress.
yaml -v \
workloadNamespace=where-for-dinner -v domainName=tsmdemo.perfect300rock.com | kubectl
apply -f-
```

Create a global namespace

The example clusters have the names `RunCluster01` and `RunCluster02`, and they assume the workload and service namespaces of where-for-dinner and service-instances, respectively.

1. Open the Tanzu Service Mesh console and create a new GNS.
2. Configure the following settings in each step:
    1. General details
        - **GNS Name:** where-for-dinner
        - **Domain:** where-for-dinner.lab
    2. Namespace mapping
        - Namespace mapping Rule 1
            - **Cluster name:** RunCluster01
            - **Namespace:** where-for-dinner
        - Namespace Mapping Rule 2
            - **Cluster name:** RunCluster02
            - **Namespace:** where-for-dinner
        - Namespace Mapping Rule 3
            - **Cluster name:** RunCluster01
            - **Namespace:** service-instances
    3. Autodiscovery. Use the default settings.
    4. Public services
        - **Service name:** where-for-dinner
        - **Service port:** 80

- **Public URL:** http where-for-dinner . Select a domain.

5. Global server load balancing and resiliency. Use the default settings.

You can now access the Where For Dinner application with the URL configured earlier.

Deployment use case: ACME Fitness Store

The following instructions describe an end-to-end process for configuring, building, and deploying the ACME Fitness Store application into a Tanzu Service Mesh GNS. In this use case, the application is deployed across two Tanzu Application Platform run clusters. ytt is used to run the build and deployment commands.

The configuration resources referenced in this scenario are in the acme-fitness-tap-tsm Git repository.

Deploy AppSSO

ACME requires the use of an AppSSO authorization server and client registration resource. Install these resources on the same run cluster that is named `RunCluster01` in the deployment section.

1. Deploy the authorization server instance by running:

   ```
   ytt -f appSSOInstance.yaml -v workloadNamespace=WORKLOAD-NAMESPACE \
   -v devDefaultAccountUsername=DEV-DEFAULT-ACCOUNT-USERNAME -v \
   devDefaultAccountPassword=DEV-DEFAULT-ACCOUNT-PASSWORD | kubectl apply -f-
   ```

   Where:

   - `WORKLOAD-NAMESPACE` is the namespace where the workloads will be deployed
   - `DEV-DEFAULT-ACCOUNT-USERNAME` is the user name for the ACME application authentication
   - `DEV-DEFAULT-ACCOUNT-PASSWORD` is the password for the ACME application authentication

   For example:

   ```
   ytt -f https://raw.githubusercontent.com/gm2552/acme-fitness-tap-tsm/main/appSS
   OInstance.yaml -v \
   workloadNamespace=acme -v devDefaultAccountUsername=acme -v \
   devDefaultAccountPassword=fitness | kubectl apply -f-
   ```

2. Create a `ClientRegistration` resource by running:

   ```
   ytt -f appSSOInstance.yaml -v workloadNamespace=WORKLOAD-NAMESPACE -v \
   appSSORedirectURI=APP-SSO-REDIRECT-URI | kubectl apply -f-
   ```

   Where:

   - `WORKLOAD-NAMESPACE` is the namespace where the workloads will be deployed.
   - `APP-SSO-REDIRECT-URI` is the public URI that the authorization server redirects to after a login

   For example:

   ```
   ytt -f https://raw.githubusercontent.com/gm2552/acme-fitness-tap-tsm/main/clien
   tRegistrationResourceClaim.yaml \
   -v workloadNamespace=acme -v \
   appSSORedirectURI=http://acme-fitness.tsmdemo.perfect300rock.com/login/oauth2/c
   ode/sso | kubectl apply -f-
   ```

3. Obtain the appSSO Issuer URI by running:

   ```
   kubectl get authserver -n WORKLOAD-NAMESPACE
   ```

   Where `WORKLOAD-NAMESPACE` is the name of the namespace where the workloads will be deployed.

4. Record the Issuer URI because you need it for the next section.

Apply the workload resources to your build cluster

To build the application services, run the following command to apply the workload resources to your build cluster. You can also clone or fork the repository in the following command to either use the YAML files locally or point to your own Git repository.

```
ytt -f workloads.yaml -v workloadNamespace=WORKLOAD-NAMESPACE -v \
appSSOIssuerURI=APP-SSO-ISSUER-URL | kubectl apply -f-
```

Where:

- `WORKLOAD-NAMESPACE` is the name of your build namespace
- `APP-SSO-ISSUER-URL` is the URL of the AppSSO authorization server that you deployed earlier

For example:

```
ytt -f https://raw.githubusercontent.com/gm2552/acme-fitness-tap-tsm/main/workloads.ya
ml -v \
workloadNamespace=workloads -v \
appSSOIssuerURI=http://appsso-acme-fitness.acme.tsmdemo.perfect300rock.com | kubectl a
pply -f-
```

If you are using a GitOps workflow with your build cluster then, after building the workloads, the deployment information is pushed to your GitOps repository.

If you follow these instructions without pull requests in the GitOps workflow, the `config-writer` pods that commit deployment information to the GitOps repository might fail because of concurrency conflicts. A workaround for this is to delete the failed workloads from the build cluster and re-run the command provided in these instructions.

Create the Istio ingress resources

The authorization server requires a publicly accessible URL and must be available before the Spring Cloud Gateway can deploy properly. The authorization server is deployed at the URI authserver app domain.

You must create a domain name system address (DNS A) record in your DNS provider's configuration tool to point to the Istio load-balanced IP address of `RunCluster01`. The DNS configuration is out of the scope of this topic.

Create the Istio ingress resources by running:

```
ytt -f istioGateway.yaml -v workloadNamespace=WORKLOAD-NAMESPACE -v \
appDomainName=APP-DOMAIN | kubectl apply -f-
```

Where:

- `WORKLOAD-NAMESPACE` is the name of your build namespace
- `APP-DOMAIN` is the application's DNS domain

For example:

```
ytt -f https://raw.githubusercontent.com/gm2552/acme-fitness-tap-tsm/main/istioGatewa
y.yaml -v \
workloadNamespace=acme -v appDomainName=tsmdemo.perfect300rock.com | kubectl apply -f-
```

Deploy Redis

A Redis instance is needed for caching the ACME fitness store cart service. Deploy the Redis instance by running:

```
ytt -f https://raw.githubusercontent.com/gm2552/acme-fitness-tap-tsm/main/redis.yaml -
v \
workloadNamespace=WORKLOAD-NAMESPACE -v redisPassword=REDIS-PASSWORD | kb apply -f-
```

Where:

- `WORKLOAD-NAMESPACE` is the namespace where the workloads will be deployed
- `REDIS-PASSWORD` is your password

For example:

```
ytt -f https://raw.githubusercontent.com/gm2552/acme-fitness-tap-tsm/main/redis.yaml -
v \
workloadNamespace=acme -v redisPassword=fitness | kubectl apply -f-
```

Run cluster deployment

Workloads are deployed to the run cluster by using deliverable resources. In this section you apply the deliverable resources directly to the run clusters, instead of using a kapp application. This deployment assumes that two clusters are part of the Tanzu Service Mesh GNS ACME. In this example these clusters are named `RunCluster01` and `RunCluster02`.

The deliverable objects reference the GitOps repository, where the build cluster has written deployment information, and need to reference this repository in the following commands.

To deploy the workloads to the run clusters, run these commands against their respective clusters:

```
ytt -f cluster01Deliverables.yaml -v workloadNamespace=WORKLOAD-NAMESPACE -v \
gitOpsSecret=GIT-OPS-SECRET -v gitOpsRepo=GIT-OPS-REPO | kubectl apply -f-
```

Where:

- `WORKLOAD-NAMESPACE` is the namespace where the workloads will be deployed
- `GIT-OPS-SECRET` is the GitOps secret used to access the GitOps repository
- `GIT-OPS-REPO` is the URL of the GitOps repository where the build cluster wrote out deployment configuration information

```
ytt -f cluster02Deliverables.yaml -v workloadNamespace=WORKLOAD-NAMESPACE -v \
gitOpsSecret=GIT-OPS-SECRET -v gitOpsRepo=GIT-OPS-REPO | kubectl apply -f-
```

Where:

- `WORKLOAD-NAMESPACE` is the namespace where the workloads will be deployed
- `GIT-OPS-SECRET` is the GitOps secret used to access the GitOps repository
- `GIT-OPS-REPO` is the URL of the GitOps repository where the build cluster wrote out deployment configuration information

For the `RunCluster01` example, run:

```
ytt -f https://raw.githubusercontent.com/gm2552/acme-fitness-tap-tsm/main/cluster01Del
iverables.yaml \
-v workloadNamespace=acme -v gitOpsSecret=tap-play-gitops-secret -v \
gitOpsRepo=https://github.com/gm2552/tap-play-gitops.git | kubectl apply -f-
```

For the `RunCluster02` example, run:

```
ytt -f https://raw.githubusercontent.com/gm2552/acme-fitness-tap-tsm/main/cluster02Del
iverables.yaml \
-v workloadNamespace=acme -v gitOpsSecret=tap-play-gitops-secret -v \
gitOpsRepo=https://github.com/gm2552/tap-play-gitops.git | kubectl apply -f-
```

Deploy Spring Cloud Gateway

The following sections describe how to deploy Spring Cloud Gateway.

Install the Spring Cloud Gateway package

The section requires the Spring Cloud Gateway for Kubernetes package to be installed on `RunCluster01`. If Spring Cloud Gateway is already installed on the run cluster, skip these install steps.

In Tanzu Application Platform v1.5 and later, Spring Cloud Gateway is included as an optional package in the Tanzu Application Platform Carvel bundle. Install the Spring Cloud Gateway package with the default settings by using this Tanzu CLI template:

```
tanzu package install scg --package spring-cloud-gateway.tanzu.vmware.com \
-version VERSION-NUMBER -n TAP-INSTALL-NAMESPACE
```

For example:

```
tanzu package install scg --package spring-cloud-gateway.tanzu.vmware.com \
--version 2.0.0-tap.3 -n tap-install
```

Configure the Spring Cloud Gateway instance and route

The Tanzu Application Platform fork of the ACME fitness store uses Spring Cloud Gateway for routing API classes from the web front end to the microservices.

Caution

The Spring Cloud Gateway `spec.service.name` configuration was not built with multicluster or cross-cluster support. The configuration for the gateway routes currently implements a workaround, which is brittle in terms of where certain services are deployed. Future releases of the gateway might have better support for this use case.

Deploy the gateway and applicable routes by running:

```
ytt -f scgInstance.yaml -v workloadNamespace=WORKLOAD-NAMESPACE
```

Where `WORKLOAD-NAMESPACE` is the namespace where the workload is deployed.

```
ytt -f scgRoutes.yaml -v workloadNamespace=WORKLOAD-NAMESPACE
```

Where `WORKLOAD-NAMESPACE` is the namespace where the workload is deployed.

For example:

```
ytt -f https://raw.githubusercontent.com/gm2552/acme-fitness-tap-tsm/main/scgInstance.
yaml -v \
workloadNamespace=acme | kubectl apply -f-
```

```
ytt -f https://raw.githubusercontent.com/gm2552/acme-fitness-tap-tsm/main/scgRoutes.ya
ml -v \
workloadNamespace=acme | kubectl apply -f-
```

Create a global namespace

The example clusters are named `RunCluster01` and `RunCluster02`, and they assume a workload namespace of ACME.

1. Open the Tanzu Service Mesh console and create a new global namespace.
2. Configure the following settings in each step:
    1. General details
        - **GNS name:** acme-tap
        - **Domain:** acme-tap.lab
    2. Namespace mapping
        - Namespace mapping Rule 1
            - **Cluster name:** RunCluster01
            - **Namespace:** acme
        - Namespace Mapping Rule 2
            - **Cluster name:** RunCluster02
            - **Namespace:** acme
    3. Autodiscovery. Use the default settings.
    4. Public Services
        - No Public service
    5. Global server load-balancing and resiliency. Use the default settings.

You can access the application by going to the URL `http://acme-fitness`.

Set up Tanzu Service Mesh

This topic tells you how to set up a Tanzu Application Platform application deployed on Kubernetes with Tanzu Service Mesh (commonly called TSM).

Sample applications are used to demonstrate how a global namespace can provide a network for Kubernetes workloads that are connected and secured within and across clusters, and across clouds.

Note

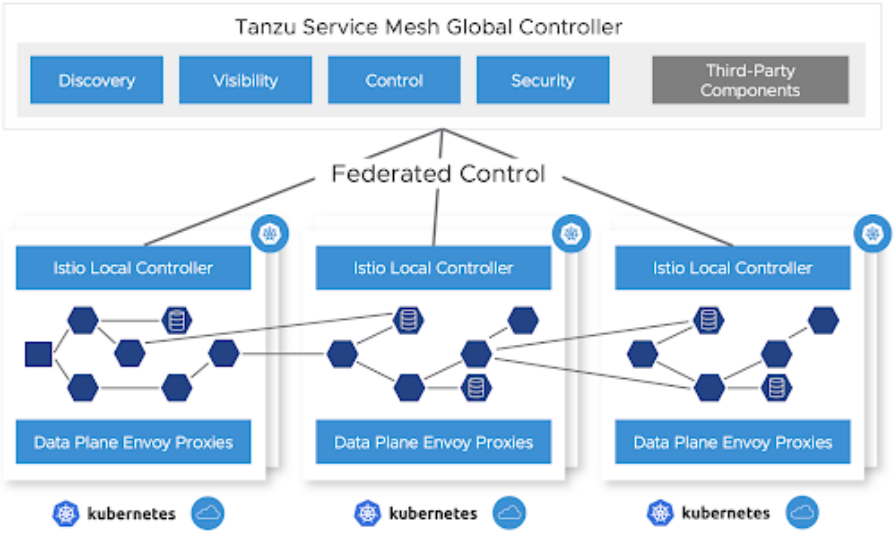
You can also use Tanzu Mission Control (commonly called TMC) to install Tanzu Application Platform (commonly called TAP) on a managed cluster. For more information, see the Tanzu Mission Control documentation.

Prerequisites

Meet the prerequisites, which includes having

- A supported Kubernetes platform
- The correct resource configuration (number of nodes, CPUs, RAM, and so on)
- The required connectivity requirements

Connectivity is only required from your local clusters out to Tanzu Service Mesh and not inwards. This can traverse a corporate proxy as well. In addition, connectivity in the data plane is required between the clusters that must communicate, specifically egress to ingress gateways. No data plane traffic needs to reach the Tanzu Service Mesh software as a service (SaaS) management plane.



Activate your Tanzu Service Mesh subscription

Activate your Tanzu Service Mesh subscription at cloud.vmware.com. After purchasing your Tanzu Service Mesh subscription, the VMware Cloud team sends you instructions. If you don't receive them, you can follow these instructions.

Onboard your clusters to Tanzu Service Mesh as described later in this topic. This deploys the Tanzu Service Mesh local control plane and OSS Istio on your Kubernetes cluster and connects the local control plane to your Tanzu Service Mesh tenant.

Set up Tanzu Application Platform

To enable Tanzu Service Mesh support in Tanzu Application Platform Build clusters:

1. Add the following key to `tap-values.yaml` under the `buildservice` top-level key:

   ```
   buildservice:
    injected_sidecar_support: true
   ```

2. Install Tanzu Application Platform on the run cluster.

End-to-end workload build and deployment scenario

The following sections describe how to build and deploy a workload.

Apply a workload resource to a build cluster

Workloads can be built by using a Tanzu Application Platform supply chain by applying a workload resource to a build cluster. At this time, Tanzu Service Mesh and Tanzu Application Platform cannot use the Knative resources that are the default runtime target when using the `web` resource type.

In Tanzu Application Platform v1.4 and later, two workload types support a Tanzu Service Mesh and Tanzu Application Platform integration: **server** and **worker**.

To work with Tanzu Service Mesh, web workloads must be converted to the `server` or `worker` workload type. Server workloads cause a Kubernetes `Deployment` resource to be created with a `Service` resource that uses port 8080 by default.

1. If the service port that you want is 80 or some other port, add port information to `workload.yaml`. The following example YAML snippets show the changes to make from the `web` to `server` workload type. This is an example before applying the changes:

   ```
   apiVersion: carto.run/v1alpha1
   kind: Workload
   metadata:
    name: where-for-dinner
    labels:
      apps.tanzu.vmware.com/workload-type: web
      app.kubernetes.io/part-of: where-for-dinner-api-gateway
   spec:
    params:
    - name: annotations
   value:
   autoscaling.knative.dev/minScale: "1"
    source:
      git:
        url: https://github.com/vmware-tanzu/application-accelerator-samples.git
      ref:
        branch: tap-1.6.x
      subPath: where-for-dinner/where-for-dinner-api-gateway
   ```

   This is an example modified for Tanzu Service Mesh, which includes the removal of the autoscaling annotation:

   ```
   apiVersion: carto.run/v1alpha1
   kind: Workload
   metadata:
    name: where-for-dinner
    labels:
    apps.tanzu.vmware.com/workload-type: server # modification
    app.kubernetes.io/part-of: where-for-dinner-api-gateway
   spec:
    params:
    - name: ports # modification
    value:
    - port: 80 # modification
      containerPort: 8080 # modification
      name: http # modification
    source:
    git:
        url: https://github.com/vmware-tanzu/application-accelerator-samples.git
      ref:
         branch: tap-1.6.x
    subPath: where-for-dinner/where-for-dinner-api-gateway
   ```

   This results in a deployment and a service that listens on port 80 and forwards traffic to port 8080 on the pod's workload container.

2. Submit the modified YAML to your build cluster by running:

```
tanzu apps NAMESPACE apply --file WORKLOAD-YAML-FILE
```

Where:

- `NAMESPACE` is the namespace that the build cluster uses for building.
- `WORKLOAD-YAML-FILE` is the name of your workload YAML file, such as `workload.yaml`.

After your workload is built a `Deliverable` resource is created.

Configure egress for Tanzu Build Service

For Tanzu Build Service to properly work, provide egress to access the registry where Tanzu Build Service writes application images, and define the registry in the `kp_default_repository` key and the Tanzu Application Platform install registry.

Additionally, configure egress for buildpack builds to download any required dependencies. This configuration varies with different buildpacks and language environments. For example, Java builds might need to download dependencies from Maven central.

Create a global namespace

Using the Tanzu Service Mesh portal or API, create a global namespace (GNS) that includes the namespaces where your application components are deployed. For more information, see Global Namespaces

Whether in a single cluster or multiple clusters, or within the same site or across clouds, after you add a namespace selection to the GNS, the services that Tanzu Application Platform deploys are connected based on the GNS configuration for service discovery and connectivity policies.

If a service must be accessible through the ingress from the outside, it can be configured through the public service option in Tanzu Service Mesh or directly through Istio on the clusters where that service resides. It's best practice to configure the service's accessibility through the GNS.

Run cluster deployment

Before deploying a workload to a run cluster, ensure that any prerequisite resources have already been created on the run cluster. This includes concepts such as data, messaging, routing, security services, RBAC, ResourceClaims, and so on.

After a successful build in a build cluster, workloads can be deployed to the run cluster by applying resulting deliverable resources to the run cluster as described in Getting Started with Multicluster Tanzu Application Platform.

Another option is to create a kapp application that references a GitOps repository to include all deliverable resources for a given cluster. See the following example of a kapp definition that points to a GitOps repository:

```
apiVersion: kappctrl.k14s.io/v1alpha1
kind: App
metadata:
  name: deliverable-gitops
  namespace: where-for-dinner
spec:
  serviceAccountName: default
  fetch:
  - git:
    url: https://github.com/gm2552/tap-play-gitops
    ref: origin/deliverables-tap-east01
    subPath: config
  template:
```

```
  - ytt: {}
  deploy:
  - kapp: {}
```

The advantage of this model is that applications can be deployed or uninstalled from a cluster by managing the contents of the deliverable resources from within the GitOps repository and enabling a GitOps workflow for application and service change control.

Deployment use case: Where For Dinner

The following instructions describe an end-to-end process for configuring, building, and deploying the Where For Dinner application into a Tanzu Service Mesh global namespace.

These instructions use the default configuration of Where For Dinner, which consists of only needing a single-node RabbitMQ cluster, an in-memory database, and no security. The application is deployed across two Tanzu Application Platform run clusters. It requires the `ytt` command to execute the build and deployment commands.

The configuration resources referenced in this scenario are located in the where-for-dinner-tap-tsm GitHub repository.

Create an initial set of configuration files from the accelerator

This use case deployment includes a pre-built set of configuration files in a Git repository. However, they were created from a set of configuration files by using a bootstrapped process that uses the Where For Dinner accelerator, and were later modified.

For reference, you can create an initial set of configuration files from the Where For Dinner accelerator, which is available in Tanzu Application Platform v1.3 and later.

This section does not include instructions for modifying the configuration files from the accelerator into configuration files used in a later section.

From the accelerator, accept all of the default options with the following exceptions:

- **Workload namespace:** Update this field with the name of the namespace you will use to build the application in your build cluster
- **Service namespace:** Update this field with the name of the namespace you will use to deploy a RabbitMQ cluster on your Tanzu Application Platform run cluster

Apply the workload resources to your build cluster

To build the application services, run the following command to apply the workload resources to your build cluster. You can also clone or fork the repository in this command to either use the YAML files locally or point to your own Git repository.

```
ytt -f workloads.yaml -v workloadNamespace=WORKLOAD-NAMESPACE | kubectl apply -f-
```

Where `WORKLOAD-NAMESPACE` is the name of your build namespace

For example:

```
ytt -f https://raw.githubusercontent.com/gm2552/where-for-dinner-tap-tsm/main/workload
s.yaml \
-v workloadNamespace=workloads | kubectl apply -f-
```

If you are using a GitOps workflow with your build cluster, after the workloads are built the deployment information is pushed to your GitOps repository.

If you follow these instructions without pull requests in the GitOps workflow, the config-writer pods that commit deployment information to the GtiOps repository might fail because of concurrency conflicts. A workaround for this is to delete the failed workloads from the build cluster and re-run the command provided in the instructions.

Install service claim resources on the cluster

Where For Dinner requires a RabbitMQ cluster installed on your run cluster. You must install RabbitMQ on the same run cluster that is named `RunCluster01` in the following deployment section. Additionally, you must install service claim resources on this cluster.

1. If you haven't already done so, install the RabbitMQ Cluster Operator on the run cluster by running:

   ```
   kubectl apply -f "https://github.com/rabbitmq/cluster-operator/releases/downloa
   d/v1.13.1/cluster-operator.yml"
   ```

2. Spin up an instance of a RabbitMQ cluster by running:

   ```
   kubectl create ns SERVICE-NAMESPACE

   ytt -f rmqCluster.yaml -v serviceNamespace=SERVICE-NAMESPACE | kubectl apply -f
   -
   ```

   Where `SERVICE-NAMESPACE` is the namespace of where you want to deploy your RabbitMQ cluster

   For example:

   ```
   kubectl create ns service-instances

   ytt -f https://raw.githubusercontent.com/gm2552/where-for-dinner-tap-tsm/main/r
   mqCluster.yaml -v \
   serviceNamespace=service-instances | kubectl apply -f-
   ```

3. Create service toolkit resources for the RabbitMQ class and resource claim by running:

   ```
   ytt -f rmqResourceClaim.yaml -v serviceNamespace=SERVICE-NAMESPACE -v \
   workloadNamespace=WORKLOAD-NAMESPACE | kubectl apply -f-
   ```

   Where `SERVICE-NAMESPACE` and `WORKLOAD-NAMESPACE` are the namespaces where you deployed your RabbitMQ cluster and the namespace where the application service will run.

   For example:

   ```
   ytt -f https://raw.githubusercontent.com/gm2552/where-for-dinner-tap-tsm/main/r
   mqResourceClaim.yaml \
   -v serviceNamespace=service-instances -v workloadNamespace=where-for-dinner | k
   ubectl apply -f-
   ```

Run cluster deployment

Workloads are deployed to the run cluster using deliverable resources. This section applies the deliverable resources directly to the run clusters instead of using a kapp application.

This deployment assumes that two clusters are part of the Tanzu Service Mesh GNS Where For Dinner. These example clusters are named `RunCluster01` and `RunCluster02`. The majority of the workload is deployed to `RunCluster01` while the crawler workload is deployed to `RunCluster02`.

The deliverable objects reference the GitOps repository, where the build cluster has written deployment information, and needs to reference this repository in the following commands.

Deploy the workloads to the run clusters by running these commands against their respective clusters:

```
ytt -f cluster01Deliverables.yaml -v workloadNamespace=WORKLOAD-NAMESPACE -v \
gitOpsSecret=GIT-OPS-SECRET -v gitOpsRepo=GIT-OPS-REPO | kubectl apply -f-
```

Where:

- `WORKLOAD-NAMESPACE` is the namespace where the workloads are deployed
- `GIT-OPS-SECRET` is the GitOps secret used to access the GitOps repository
- `GIT-OPS-REPO` is the URL of the GitOps repository where the build cluster wrote out deployment configuration information

```
ytt -f cluster02Deliverables.yaml -v workloadNamespace=WORKLOAD-NAMESPACE -v \
gitOpsSecret=GIT-OPS-SECRET -v gitOpsRepo=GIT-OPS-REPO | kubectl apply -f-
```

Where:

- `WORKLOAD-NAMESPACE` is the namespace where the workloads are deployed
- `GIT-OPS-SECRET` is the GitOps secret used to access the GitOps repository
- `GIT-OPS-REPO` is the URL of the GitOps repository where the build cluster wrote out deployment configuration information

To run this deployment on cluster `RunCluster01`, for example, you run:

```
ytt -f https://raw.githubusercontent.com/gm2552/where-for-dinner-tap-tsm/main/cluster0
1Deliverables.yaml -v \
workloadNamespace=where-for-dinner -v gitOpsSecret=tap-play-gitops-secret -v \
gitOpsRepo=https://github.com/gm2552/tap-play-gitops.git | kubectl apply -f-
```

To run this deployment on cluster `RunCluster02`, for example, you run:

```
ytt -f https://raw.githubusercontent.com/gm2552/where-for-dinner-tap-tsm/main/cluster0
2Deliverables.yaml -v \
workloadNamespace=where-for-dinner -v gitOpsSecret=tap-play-gitops-secret -v \
gitOpsRepo=https://github.com/gm2552/tap-play-gitops.git | kubectl apply -f-
```

You can create an Istio ingress resource on `RunCluster01` if you do not plan on using the GNS capabilities to expose the application to external networks.

You must create a domain name system address (DNS A) record in your DNS provider's configuration tool to point to the Istio load-balanced IP address of `RunCluster01`. The DNS configuration is out of the scope of this topic.

Create the ingress by running:

```
ytt -f ingress.yaml -v workloadNamespace=WORKLOAD-NAMESPACE -v domainName=DOMAIN-NAME
| kubectl apply -f-
```

Where:

- `WORKLOAD-NAMESPACE` is the namespace where the workload is deployed
- `DOMAIN-NAME` is the public domain that will host your application

For example:

```
ytt -f https://raw.githubusercontent.com/gm2552/where-for-dinner-tap-tsm/main/ingress.
yaml -v \
workloadNamespace=where-for-dinner -v domainName=tsmdemo.perfect300rock.com | kubectl
apply -f-
```

Create a global namespace

The example clusters have the names `RunCluster01` and `RunCluster02`, and they assume the workload and service namespaces of where-for-dinner and service-instances, respectively.

1. Open the Tanzu Service Mesh console and create a new GNS.
2. Configure the following settings in each step:
    1. General details
        - **GNS Name:** where-for-dinner
        - **Domain:** where-for-dinner.lab
    2. Namespace mapping
        - Namespace mapping Rule 1
            - **Cluster name:** RunCluster01
            - **Namespace:** where-for-dinner
        - Namespace Mapping Rule 2
            - **Cluster name:** RunCluster02
            - **Namespace:** where-for-dinner
        - Namespace Mapping Rule 3
            - **Cluster name:** RunCluster01
            - **Namespace:** service-instances
    3. Autodiscovery. Use the default settings.
    4. Public services
        - **Service name:** where-for-dinner
        - **Service port:** 80
        - **Public URL:** http where-for-dinner . Select a domain.
    5. Global server load balancing and resiliency. Use the default settings.

You can now access the Where For Dinner application with the URL configured earlier.

Deployment use case: ACME Fitness Store

The following instructions describe an end-to-end process for configuring, building, and deploying the ACME Fitness Store application into a Tanzu Service Mesh GNS. In this use case, the application is deployed across two Tanzu Application Platform run clusters. ytt is used to run the build and deployment commands.

The configuration resources referenced in this scenario are in the acme-fitness-tap-tsm Git repository.

Deploy AppSSO

ACME requires the use of an AppSSO authorization server and client registration resource. Install these resources on the same run cluster that is named `RunCluster01` in the deployment section.

1. Deploy the authorization server instance by running:

```
ytt -f appSSOInstance.yaml -v workloadNamespace=WORKLOAD-NAMESPACE \
-v devDefaultAccountUsername=DEV-DEFAULT-ACCOUNT-USERNAME -v \
devDefaultAccountPassword=DEV-DEFAULT-ACCOUNT-PASSWORD | kubectl apply -f-
```

Where:

- `WORKLOAD-NAMESPACE` is the namespace where the workloads will be deployed
- `DEV-DEFAULT-ACCOUNT-USERNAME` is the user name for the ACME application authentication
- `DEV-DEFAULT-ACCOUNT-PASSWORD` is the password for the ACME application authentication

For example:

```
ytt -f https://raw.githubusercontent.com/gm2552/acme-fitness-tap-tsm/main/appSS
OInstance.yaml -v \
workloadNamespace=acme -v devDefaultAccountUsername=acme -v \
devDefaultAccountPassword=fitness | kubectl apply -f-
```

2. Create a `ClientRegistration` resource by running:

```
ytt -f appSSOInstance.yaml -v workloadNamespace=WORKLOAD-NAMESPACE -v \
appSSORedirectURI=APP-SSO-REDIRECT-URI | kubectl apply -f-
```

Where:

- `WORKLOAD-NAMESPACE` is the namespace where the workloads will be deployed.
- `APP-SSO-REDIRECT-URI` is the public URI that the authorization server redirects to after a login

For example:

```
ytt -f https://raw.githubusercontent.com/gm2552/acme-fitness-tap-tsm/main/clien
tRegistrationResourceClaim.yaml \
-v workloadNamespace=acme -v \
appSSORedirectURI=http://acme-fitness.tsmdemo.perfect300rock.com/login/oauth2/c
ode/sso | kubectl apply -f-
```

3. Obtain the appSSO Issuer URI by running:

```
kubectl get authserver -n WORKLOAD-NAMESPACE
```

Where `WORKLOAD-NAMESPACE` is the name of the namespace where the workloads will be deployed.

4. Record the Issuer URI because you need it for the next section.

Apply the workload resources to your build cluster

To build the application services, run the following command to apply the workload resources to your build cluster. You can also clone or fork the repository in the following command to either use the YAML files locally or point to your own Git repository.

```
ytt -f workloads.yaml -v workloadNamespace=WORKLOAD-NAMESPACE -v \
appSSOIssuerURI=APP-SSO-ISSUER-URL | kubectl apply -f-
```

Where:

- `WORKLOAD-NAMESPACE` is the name of your build namespace

- `APP-SSO-ISSUER-URL` is the URL of the AppSSO authorization server that you deployed earlier

For example:

```
ytt -f https://raw.githubusercontent.com/gm2552/acme-fitness-tap-tsm/main/workloads.ya
ml -v \
workloadNamespace=workloads -v \
appSSOIssuerURI=http://appsso-acme-fitness.acme.tsmdemo.perfect300rock.com | kubectl a
pply -f-
```

If you are using a GitOps workflow with your build cluster then, after building the workloads, the deployment information is pushed to your GitOps repository.

If you follow these instructions without pull requests in the GitOps workflow, the `config-writer` pods that commit deployment information to the GitOps repository might fail because of concurrency conflicts. A workaround for this is to delete the failed workloads from the build cluster and re-run the command provided in these instructions.

Create the Istio ingress resources

The authorization server requires a publicly accessible URL and must be available before the Spring Cloud Gateway can deploy properly. The authorization server is deployed at the URI authserver app domain.

You must create a domain name system address (DNS A) record in your DNS provider's configuration tool to point to the Istio load-balanced IP address of `RunCluster01`. The DNS configuration is out of the scope of this topic.

Create the Istio ingress resources by running:

```
ytt -f istioGateway.yaml -v workloadNamespace=WORKLOAD-NAMESPACE -v \
appDomainName=APP-DOMAIN | kubectl apply -f-
```

Where:

- `WORKLOAD-NAMESPACE` is the name of your build namespace
- `APP-DOMAIN` is the application's DNS domain

For example:

```
ytt -f https://raw.githubusercontent.com/gm2552/acme-fitness-tap-tsm/main/istioGatewa
y.yaml -v \
workloadNamespace=acme -v appDomainName=tsmdemo.perfect300rock.com | kubectl apply -f-
```

Deploy Redis

A Redis instance is needed for caching the ACME fitness store cart service. Deploy the Redis instance by running:

```
ytt -f https://raw.githubusercontent.com/gm2552/acme-fitness-tap-tsm/main/redis.yaml -
v \
workloadNamespace=WORKLOAD-NAMESPACE -v redisPassword=REDIS-PASSWORD | kb apply -f-
```

Where:

- `WORKLOAD-NAMESPACE` is the namespace where the workloads will be deployed
- `REDIS-PASSWORD` is your password

For example:

```
ytt -f https://raw.githubusercontent.com/gm2552/acme-fitness-tap-tsm/main/redis.yaml -
v \
workloadNamespace=acme -v redisPassword=fitness | kubectl apply -f-
```

Run cluster deployment

Workloads are deployed to the run cluster by using deliverable resources. In this section you apply the deliverable resources directly to the run clusters, instead of using a kapp application. This deployment assumes that two clusters are part of the Tanzu Service Mesh GNS ACME. In this example these clusters are named `RunCluster01` and `RunCluster02`.

The deliverable objects reference the GitOps repository, where the build cluster has written deployment information, and need to reference this repository in the following commands.

To deploy the workloads to the run clusters, run these commands against their respective clusters:

```
ytt -f cluster01Deliverables.yaml -v workloadNamespace=WORKLOAD-NAMESPACE -v \
gitOpsSecret=GIT-OPS-SECRET -v gitOpsRepo=GIT-OPS-REPO | kubectl apply -f-
```

Where:

- `WORKLOAD-NAMESPACE` is the namespace where the workloads will be deployed
- `GIT-OPS-SECRET` is the GitOps secret used to access the GitOps repository
- `GIT-OPS-REPO` is the URL of the GitOps repository where the build cluster wrote out deployment configuration information

```
ytt -f cluster02Deliverables.yaml -v workloadNamespace=WORKLOAD-NAMESPACE -v \
gitOpsSecret=GIT-OPS-SECRET -v gitOpsRepo=GIT-OPS-REPO | kubectl apply -f-
```

Where:

- `WORKLOAD-NAMESPACE` is the namespace where the workloads will be deployed
- `GIT-OPS-SECRET` is the GitOps secret used to access the GitOps repository
- `GIT-OPS-REPO` is the URL of the GitOps repository where the build cluster wrote out deployment configuration information

For the `RunCluster01` example, run:

```
ytt -f https://raw.githubusercontent.com/gm2552/acme-fitness-tap-tsm/main/cluster01Del
iverables.yaml \
-v workloadNamespace=acme -v gitOpsSecret=tap-play-gitops-secret -v \
gitOpsRepo=https://github.com/gm2552/tap-play-gitops.git | kubectl apply -f-
```

For the `RunCluster02` example, run:

```
ytt -f https://raw.githubusercontent.com/gm2552/acme-fitness-tap-tsm/main/cluster02Del
iverables.yaml \
-v workloadNamespace=acme -v gitOpsSecret=tap-play-gitops-secret -v \
gitOpsRepo=https://github.com/gm2552/tap-play-gitops.git | kubectl apply -f-
```

Deploy Spring Cloud Gateway

The following sections describe how to deploy Spring Cloud Gateway.

Install the Spring Cloud Gateway package

The section requires the Spring Cloud Gateway for Kubernetes package to be installed on `RunCluster01`. If Spring Cloud Gateway is already installed on the run cluster, skip these install

steps.

In Tanzu Application Platform v1.5 and later, Spring Cloud Gateway is included as an optional package in the Tanzu Application Platform Carvel bundle. Install the Spring Cloud Gateway package with the default settings by using this Tanzu CLI template:

```
tanzu package install scg --package spring-cloud-gateway.tanzu.vmware.com \
-version VERSION-NUMBER -n TAP-INSTALL-NAMESPACE
```

For example:

```
tanzu package install scg --package spring-cloud-gateway.tanzu.vmware.com \
--version 2.0.0-tap.3 -n tap-install
```

Configure the Spring Cloud Gateway instance and route

The Tanzu Application Platform fork of the ACME fitness store uses Spring Cloud Gateway for routing API classes from the web front end to the microservices.

> **Caution**
>
> The Spring Cloud Gateway `spec.service.name` configuration was not built with multicluster or cross-cluster support. The configuration for the gateway routes currently implements a workaround, which is brittle in terms of where certain services are deployed. Future releases of the gateway might have better support for this use case.

Deploy the gateway and applicable routes by running:

```
ytt -f scgInstance.yaml -v workloadNamespace=WORKLOAD-NAMESPACE
```

Where `WORKLOAD-NAMESPACE` is the namespace where the workload is deployed.

```
ytt -f scgRoutes.yaml -v workloadNamespace=WORKLOAD-NAMESPACE
```

Where `WORKLOAD-NAMESPACE` is the namespace where the workload is deployed.

For example:

```
ytt -f https://raw.githubusercontent.com/gm2552/acme-fitness-tap-tsm/main/scgInstance.
yaml -v \
workloadNamespace=acme | kubectl apply -f-
```

```
ytt -f https://raw.githubusercontent.com/gm2552/acme-fitness-tap-tsm/main/scgRoutes.ya
ml -v \
workloadNamespace=acme | kubectl apply -f-
```

Create a global namespace

The example clusters are named `RunCluster01` and `RunCluster02`, and they assume a workload namespace of ACME.

1. Open the Tanzu Service Mesh console and create a new global namespace.
2. Configure the following settings in each step:
    1. General details

        - **GNS name:** acme-tap
        - **Domain:** acme-tap.lab
    2. Namespace mapping
        - Namespace mapping Rule 1
            - **Cluster name:** RunCluster01
            - **Namespace:** acme
        - Namespace Mapping Rule 2
            - **Cluster name:** RunCluster02
            - **Namespace:** acme
    3. Autodiscovery. Use the default settings.
    4. Public Services
        - No Public service
    5. Global server load-balancing and resiliency. Use the default settings.

You can access the application by going to the URL `http://acme-fitness`.

Use external observability tools

This topic tells you how to generate metrics for your Tanzu Application Platform (commonly known as TAP) applications to enable observability with external tools. It explains how to set up Prometheus on your cluster or integrate an existing Datadog installation.

About Prometheus metrics

Prometheus is an open-source monitoring tool that defines a simple text-based metrics format with client libraries for a wide range of programming languages and frameworks.

By integrating these client libraries into your applications, you can effortlessly generate metrics in the Prometheus format. These metrics are accessible through an HTTP endpoint, enabling Prometheus and other observability tools to conveniently consume (scrape) them.

For Kubernetes, there is an established convention that facilitates the automatic discovery of pods exposing Prometheus metrics. This involves incorporating specific annotations on the pods exposing information for path and port of the metrics endpoint.

Prometheus and other observability tools like Datadog can discover annotated pods and collect the metrics from the endpoint.

Use Prometheus as your observability tool

There are multiple ways to install Prometheus on your cluster:

- Use the Prometheus Operator
- Use the `kube-prometheus-stack` Helm chart
- Use the Prometheus Helm chart

Prometheus Operator
The Prometheus Operator offers a simplified way to use custom resources to deploy and configure Prometheus, Alertmanager, and related monitoring components.

To install using the Prometheus Operator:

1. Install the Prometheus Operator bundle by running:

```
LATEST=$(curl -s https://api.github.com/repos/prometheus-operator/prometheus-operator/releases/latest | jq -cr .tag_name)
curl -sL https://github.com/prometheus-operator/prometheus-operator/releases/download/${LATEST}/bundle.yaml | kubectl create -f -
```

2. For RBAC-based environments, create the RBAC rules for the Prometheus service account by running:

```
cat <<EOF | kubectl apply -f -
apiVersion: v1
kind: ServiceAccount
metadata:
  name: prometheus
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: prometheus
rules:
- apiGroups: [""]
  resources:
  - nodes
  - nodes/metrics
  - services
  - endpoints
  - pods
  verbs: ["get", "list", "watch"]
- apiGroups: [""]
  resources:
  - configmaps
  verbs: ["get"]
- apiGroups:
  - networking.k8s.io
  resources:
  - ingresses
  verbs: ["get", "list", "watch"]
- nonResourceURLs: ["/metrics"]
  verbs: ["get"]
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: prometheus
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: prometheus
subjects:
- kind: ServiceAccount
  name: prometheus
  namespace: default
EOF
```

3. Configure a Prometheus scraping job. This job must monitor all pods that are marked with the designated Prometheus annotations.

Note

The Prometheus Operator does not support annotation-based discovery of services by default. To enable these annotations, you must set up a custom scrape job configuration.

1. Create a file named `prometheus-scrape-config.yaml` with the following content:

```
# Example scrape config for pods
#
# The relabeling allows the actual pod scrape endpoint to be configure
d through the
# following annotations:
#
# * `prometheus.io/scrape`: Only scrape pods that have a value of `tru
e`.
# * `prometheus.io/scheme`: If the metrics endpoint is secured then yo
u must
# set this to `https` and most likely set the `tls_config` of the scra
pe config.
# * `prometheus.io/path`: If the metrics path is not `/metrics` overri
de this.
# * `prometheus.io/port`: Scrape the pod on the indicated port instead
of the default of `9102`.
- job_name: 'kubernetes-pods'
  honor_labels: true

  kubernetes_sd_configs:
    - role: pod

  relabel_configs:
    - source_labels: [__meta_kubernetes_pod_annotation_prometheus_io_s
crape]
      action: keep
      regex: true
    - source_labels: [__meta_kubernetes_pod_annotation_prometheus_io_s
cheme]
      action: replace
      regex: (https?)
      target_label: __scheme__
    - source_labels: [__meta_kubernetes_pod_annotation_prometheus_io_p
ath]
      action: replace
      target_label: __metrics_path__
      regex: (.+)
    - source_labels: [__meta_kubernetes_pod_annotation_prometheus_io_p
ort, __meta_kubernetes_pod_ip]
      action: replace
      regex: (\d+);(([A-Fa-f0-9]{1,4}::?){1,7}[A-Fa-f0-9]{1,4})
      replacement: '[$2]:$1'
      target_label: __address__
    - source_labels: [__meta_kubernetes_pod_annotation_prometheus_io_p
ort, __meta_kubernetes_pod_ip]
      action: replace
      regex: (\d+);((([0-9]+?)(\.|$)){4})
      replacement: $2:$1
      target_label: __address__
    - action: labelmap
      regex: __meta_kubernetes_pod_annotation_prometheus_io_param_(.+)
      replacement: __param_$1
    - action: labelmap
      regex: __meta_kubernetes_pod_label_(.+)
    - source_labels: [__meta_kubernetes_namespace]
      action: replace
      target_label: namespace
    - source_labels: [__meta_kubernetes_pod_name]
```

```
      action: replace
      target_label: pod
    - source_labels: [__meta_kubernetes_pod_phase]
      regex: Pending|Succeeded|Failed|Completed
      action: drop
    - source_labels: [__meta_kubernetes_pod_node_name]
      action: replace
      target_label: node
```

2. Generate a secret using the file you just created by running:

```
kubectl create secret generic additional-scrape-configs --from-file=pr
ometheus-scrape-config.yaml
```

3. Create a Prometheus resource that uses this secret by running:

```
cat <<EOF | kubectl apply -f -
apiVersion: monitoring.coreos.com/v1
kind: Prometheus
metadata:
  name: prometheus
spec:
  serviceAccountName: prometheus
  podMonitorSelector: {}
  additionalScrapeConfigs:
    name: additional-scrape-configs
    key: prometheus-scrape-config.yaml
  resources:
    requests:
      memory: 400Mi
  enableAdminAPI: false
EOF
```

   The Prometheus Operator automatically detects the configuration and generates a scrape job from it. This job is executed regularly by the Prometheus instance that is set up.

4. To access the Prometheus web interface, you must make port `9090` of the Prometheus server pod accessible outside the cluster through a Kubernetes service or ingress. For development purposes, you can forward the port to your local machine using kubectl.

5. To see the scrape configuration that the Prometheus instance has picked up, run:

```
kubectl get secret prometheus-prometheus -ojson | jq -r '.data["prometheus.ya
ml.gz"]' | base64 -d | gunzip
```

For more information about the Prometheus Operator, including how to persist your metrics or activate alerting features, see the Prometheus Operator documentation.

kube-prometheus-stack Helm chart

The Prometheus community has developed the `kube-prometheus-stack` Helm chart, which establishes a comprehensive cluster monitoring stack. The Helm chart sets up various scraping jobs for metrics related to the Kubernetes cluster.

These are some of its features:

- Includes the Prometheus Operator
- Includes cluster monitoring
- Ensures high availability
- Integrates Node Exporter Grafana dashboards

For more information, see the kube-prometheus-stack Helm chart README in GitHub.

To install the `kube-prometheus-stack` Helm chart:

1. Add the Helm repository by running:

```
helm repo add prometheus-community https://prometheus-community.github.io/hel
m-charts
helm repo update
```

2. Because there isn't a predefined scrape job configuration to support annotation-based discovery of services, you must create the configuration secret `additional-scrape-configs`.

    1. Create a file named `prometheus-scrape-config.yaml` with the following content:

```
# Example scrape config for pods
#
# The relabeling allows the actual pod scrape endpoint to be configure
d through the
# following annotations:
#
# * `prometheus.io/scrape`: Only scrape pods that have a value of `tru
e`.
# * `prometheus.io/scheme`: If the metrics endpoint is secured then yo
u must
# set this to `https` and most likely set the `tls_config` of the scra
pe config.
# * `prometheus.io/path`: If the metrics path is not `/metrics` overri
de this.
# * `prometheus.io/port`: Scrape the pod on the indicated port instead
of the default of `9102`.
- job_name: 'kubernetes-pods'
  honor_labels: true

  kubernetes_sd_configs:
    - role: pod

  relabel_configs:
    - source_labels: [__meta_kubernetes_pod_annotation_prometheus_io_s
crape]
      action: keep
      regex: true
    - source_labels: [__meta_kubernetes_pod_annotation_prometheus_io_s
cheme]
      action: replace
      regex: (https?)
      target_label: __scheme__
    - source_labels: [__meta_kubernetes_pod_annotation_prometheus_io_p
ath]
      action: replace
      target_label: __metrics_path__
      regex: (.+)
    - source_labels: [__meta_kubernetes_pod_annotation_prometheus_io_p
ort, __meta_kubernetes_pod_ip]
      action: replace
      regex: (\d+);(([A-Fa-f0-9]{1,4}::?){1,7}[A-Fa-f0-9]{1,4})
      replacement: '[$2]:$1'
      target_label: __address__
    - source_labels: [__meta_kubernetes_pod_annotation_prometheus_io_p
ort, __meta_kubernetes_pod_ip]
      action: replace
      regex: (\d+);((([0-9]+?)(\.|$)){4})
      replacement: $2:$1
      target_label: __address__
```

```
    - action: labelmap
      regex: __meta_kubernetes_pod_annotation_prometheus_io_param_(.+)
      replacement: __param_$1
    - action: labelmap
      regex: __meta_kubernetes_pod_label_(.+)
    - source_labels: [__meta_kubernetes_namespace]
      action: replace
      target_label: namespace
    - source_labels: [__meta_kubernetes_pod_name]
      action: replace
      target_label: pod
    - source_labels: [__meta_kubernetes_pod_phase]
      regex: Pending|Succeeded|Failed|Completed
      action: drop
    - source_labels: [__meta_kubernetes_pod_node_name]
      action: replace
      target_label: node
```

2. Generate a secret using the file you just created by running:

```
kubectl create secret generic additional-scrape-configs --from-file=pr
ometheus-scrape-config.yaml
```

3. Install the `kube-prometheus-stack` Helm chart by running:

```
helm upgrade --install kube-prometheus-stack prometheus-community/kube-promet
heus-stack \
  --set prometheus.prometheusSpec.additionalScrapeConfigsSecret.name=addition
al-scrape-configs \
  --set prometheus.prometheusSpec.additionalScrapeConfigsSecret.key=prometheu
s-scrape-config.yaml \
  --set prometheus.prometheusSpec.additionalScrapeConfigsSecret.enabled=true
```

4. To see the scrape configuration that the Prometheus instance has picked up, run:

```
kubectl get secret prometheus-kube-prometheus-stack-prometheus -ojson | jq -r
'.data["prometheus.yaml.gz"]' | base64 -d | gunzip
```

Prometheus Helm chart

The Prometheus community provides the Prometheus Helm chart to install Prometheus on your Kubernetes cluster. The Helm chart installs scraping job configurations for pods and services tagged with Prometheus scraping annotations and sets up scraping for metrics related to the Kubernetes cluster. It includes key components such as Alert Manager, kube-state-metrics, Node Exporter, and Push Gateway.

For more information, see the Prometheus Helm chart README in GitHub.

To install the Prometheus Helm chart:

1. Add the Helm repository by running:

```
helm repo add prometheus-community https://prometheus-community.github.io/hel
m-charts
helm repo update
```

2. Install the Prometheus Helm chart by running:

```
helm upgrade --install prometheus prometheus-community/prometheus
```

Use Datadog as your observability tool

If you use Datadog, you can use it to scrape the Prometheus endpoints without having to install Prometheus itself. Datadog automatically gathers Prometheus metrics from pods that are annotated with the default Prometheus annotations. The Datadog Agent forwards the metrics to the Datadog servers.

To use Datadog as your observability tool:

1. Add the Helm repository by running:

   ```
   helm repo add datadog https://helm.datadoghq.com
   helm repo update
   ```

2. Install the Datadog Agent Helm chart by running:

   ```
   helm upgrade --install datadog-operator datadog/datadog-operator
   ```

   Note

   There is a known issue with Datadog Cluster Agent on Azure Kubernetes Service (AKS) clusters. For more information, see the troubleshooting item Datadog agent cannot reconcile webhook on AKS.

3. Generate a new API key in Datadog for the Agent that will push metrics to Datadog. You do this in the Datadog UI, under `Profile/Organization Settings/API Keys`.

4. Create a secret for the Datadog API key by running:

   ```
   kubectl create secret generic datadog-secret --from-literal api-key=API-KEY
   ```

   Where `API-KEY` is the API you generated in the previous step.

5. Install the Datadog Agent by running:

   ```
   cat <<EOF | kubectl apply -f -
   apiVersion: datadoghq.com/v2alpha1
   kind: DatadogAgent
   metadata:
     name: datadog
   spec:
     global:
       clusterName: YOUR-CLUSTER-NAME
       site: DATADOG-HOST-NAME
       credentials:
         apiSecret:
           secretName: datadog-secret
           keyName: api-key
     features:
       prometheusScrape:
         enabled: true
         enableServiceEndpoints: true
   EOF
   ```

   Where:

   - `YOUR-CLUSTER-NAME` is the name of your cluster as you want to see it in Datadog.
   - `DATADOG-HOST-NAME` is your Datadog host name, for example, `datadoghq.eu`.

Enable metric collection on Spring Boot workloads

To enable Spring Boot workloads to create Prometheus metrics, if using Maven, add the following dependencies to your `pom.xml`:

```
<dependencies>
    <dependency>
      <groupId>org.springframework.boot</groupId>
      <artifactId>spring-boot-starter-actuator</artifactId>
    </dependency>
    <dependency>
      <groupId>io.micrometer</groupId>
      <artifactId>micrometer-registry-prometheus</artifactId>
      <scope>runtime</scope>
    </dependency>
</dependencies>
```

This creates default metrics for the JVM, HTTP traffic, and more. For a list of supported metrics, see the Spring Boot documentation.

When deploying Spring Boot workloads on Tanzu Application Platform, the Spring Boot conventions ensure that actuator endpoints are exposed. The Prometheus metrics endpoint is also made accessible.

For Prometheus to find this endpoint on a pod, you must include specific annotations in your `workload.yaml` file. These annotations must align with your configuration. After adding these annotations, deploy the changes:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: spring-petclinic
  annotations:
    prometheus.io/scrape: 'true'
    prometheus.io/path: '/actuator/prometheus'
    prometheus.io/port: '8081'
    # ...
```

For more information about the Spring Boot Prometheus integration, see the Spring Boot Reference Documentation.

Use a Grafana dashboard for Tanzu Application Platform observability

This topic tells you how to configure and set up a public Grafana-Prometheus Helm with Tanzu Application Platform (commonly known as TAP) `CustomResource` metrics collection.

Prerequisites

Before proceeding you must have:

- kubectl
- Helm
- A Kubernetes cluster with Tanzu Application Platform and associated workloads

Download and unzip the Tanzu CLI binary

To download the Tanzu CLI binary and set up the cluster:

1. Go to VMware Tanzu Network.

2. Select 1.9.1 from the release drop-down menu for Tanzu Application Platform.
3. Click **Grafana Dashboard for Tanzu Application Platform (Beta)**.
4. Download `prometheus-grafana-dashboard-for-tap-1.0.0-beta.1.zip`.
5. If on macOS or Linux, unzip `prometheus-grafana-dashboard-for-tap-1.0.0-beta.1.zip`. If you're using Windows, use the Windows extractor tool to unzip it.

Install a public Helm chart

To install a public Helm chart:

1. Apply `tap-metrics.yaml` on the Tanzu Application Platform cluster, which enables collection of the Tanzu Application Platform `CustomResource` metrics.
2. Install a public Helm chart for Prometheus with a public HTTP endpoint in all Tanzu Application Platform clusters where necessary for observability.

   For example, if you have a View cluster, a Build cluster, and a Run cluster:

   1. Set the context to View cluster and install the Prometheus public Helm chart by running:

      ```
      # Add Prometheus helm repo
      helm repo add prometheus-community https://prometheus-community.github.i
      o/helm-charts
      helm repo update

      # Install prometheus chart
      helm install prometheus -f DOWNLOADED-TAP-METRICS-YAML-FILE \
      prometheus-community/kube-prometheus-stack --namespace tap-monitoring --c
      reate-namespace
      ```

   2. Repeat the previous step for the Build cluster and the Run cluster.
   3. You now have a Prometheus endpoint, for each cluster, which acts as a data source for Grafana in later steps. See the public LoadBalancer IP `<PUBLIC_ENDPOINT>` in each cluster where Prometheus is installed by running:

      ```
      kubectl get svc -n tap-monitoring | grep prometheus
      ```

      Example output:

      ```
      $ kubectl get svc -n tap-monitoring | grep prometheus
      prometheus-operated                         ClusterIP      None
      <none>            9090/TCP                       20h
      tap-observability-kube-pro-prometheus       LoadBalancer   10.0.19.222
      <PUBLIC_ENDPOINT> 9090:32357/TCP,8080:31323/TCP   20h
      tap-observability-prometheus-node-exporter  ClusterIP      10.0.34.213
      <none>            9100/TCP                       20h
      ```

      Note

      This example is given only for HTTP endpoints exposed publicly. Your own security policy might require private endpoints, a TLS mechanism, or other restrictions.

Create a Grafana dashboard

To create a Grafana dashboard:

1. Create `grafana-values.yaml` with the following content to establish the Prometheus endpoints with the port (9090 by default for Prometheus):

```
datasources:
    datasources.yaml:
      apiVersion: 1
      datasources:
      - name: prometheus-view-cluster
        type: prometheus
        url: VIEW-CLUSTER-PROMETHEUS-ENDPOINT:9090
        access: proxy
        isDefault: true
      - name: prometheus-build-cluster
        type: prometheus
        url: BUILD-CLUSTER-PROMETHEUS-ENDPOINT:9090
        access: proxy
        isDefault: false
      - name: prometheus-run-cluster
        type: prometheus
        url: RUN-CLUSTER-PROMETHEUS-ENDPOINT:9090
        access: proxy
        isDefault: false
```

2. Install Grafana in a cluster dedicated to the Grafana dashboard by running:

```
kubectl create ns grafana

# Add Grafana Helm repository
helm repo add grafana https://grafana.github.io/helm-charts
helm repo update

# Install the chart by setting your Grafana password
helm install grafana grafana/grafana \
  --namespace grafana \
  --set persistence.storageClassName=DEFAULT-PVC-STORAGE-CLASS \
  --set persistence.enabled=true \
  --set adminPassword='GRAFANA-ENDPOINT-PASSWORD' \
  --values  grafana-values.yaml \
  --set service.type=LoadBalancer
```

   Where:

   - `DEFAULT-PVC-STORAGE-CLASS` is the default PVC storage class. For some examples there is `default` for Azure, `gp2` for Amazon Web Services, and so on.
   - `GRAFANA-ENDPOINT-PASSWORD` is the password for logging in to the Grafana endpoint.

   If any auto-generate mechanism is used, you can get your Grafana user ID and password by running:

```
kubectl get secret --namespace grafana grafana -o jsonpath="{.data.admin-passwo
rd}" | base64 \
--decode ; echo
```

3. Access the Grafana UI by using the `<PUBLIC_ENDPOINT>` created by the default LoadBalancer. This can be configured behind any ingress service.

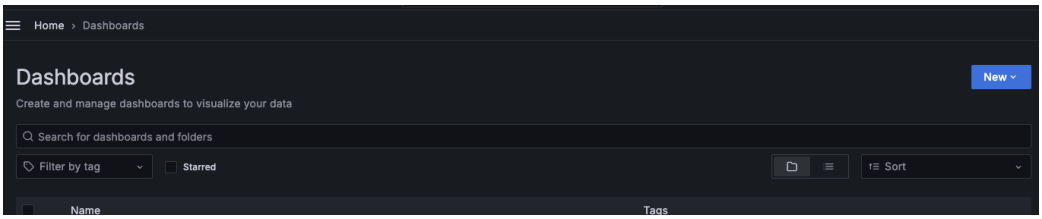
```
kubectl get svc -n grafana
NAME      TYPE           CLUSTER-IP     EXTERNAL-IP        PORT(S)        AGE
grafana   LoadBalancer   10.0.133.110   <PUBLIC_ENDPOINT>  80:31147/TCP   20h
```

4. Log in to the Grafana UI through the endpoint and configured user name and password. The default user name is `admin`.

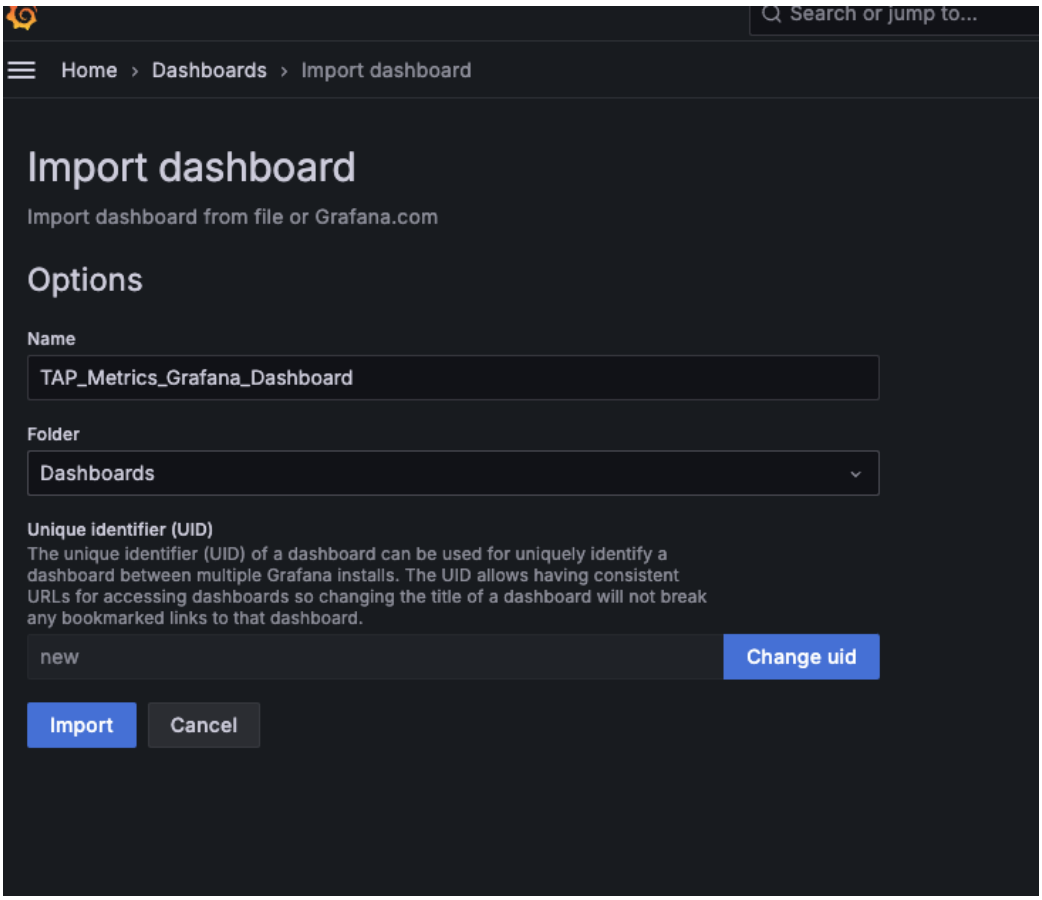
Import the Grafana dashboard

To import `TAP_Metrics_Grafana_Dashboard.json` from the Tanzu Application Platform artifact you downloaded earlier:

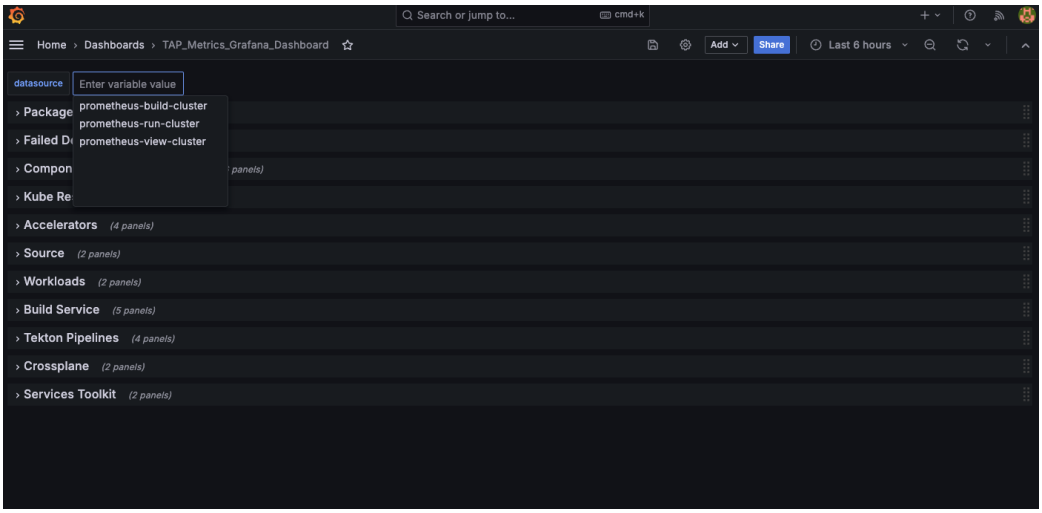
1. Go to the **Dashboards** page.

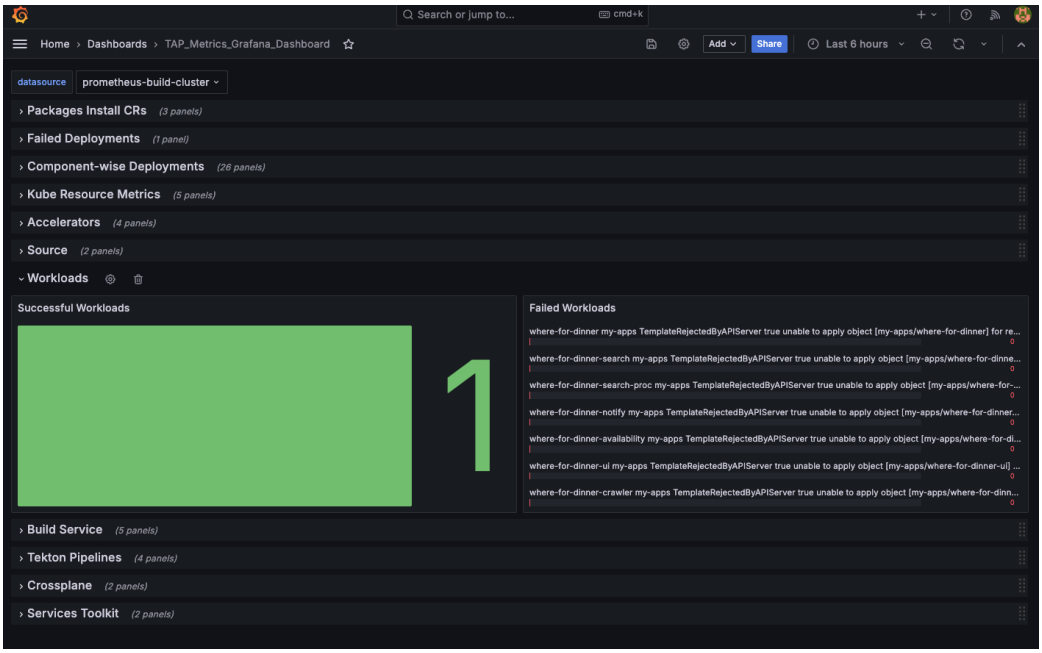


2. Click **New** > **Import**.
3. Select and import the dashboard downloaded earlier named `TAP_Metrics_Grafana_Dashboard.json`.



4. View the Tanzu Application Platform health dashboard for different Tanzu Application Platform clusters by selecting the appropriate datasource.

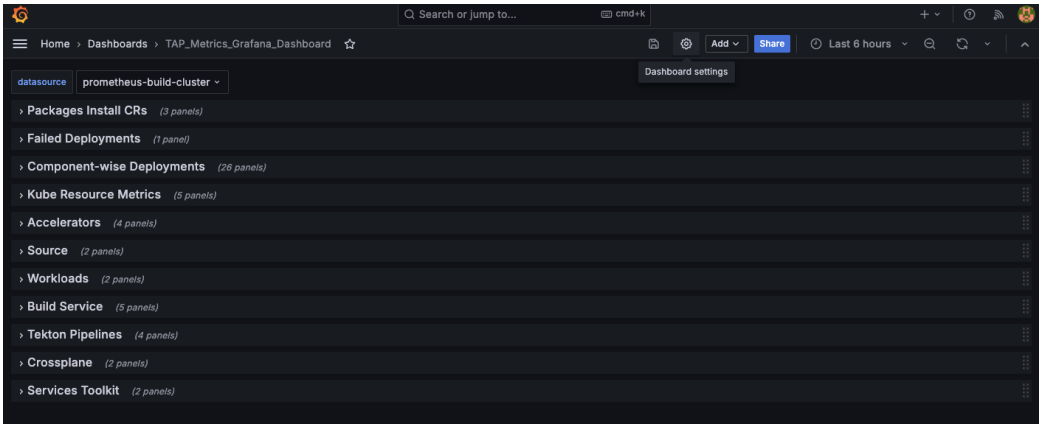




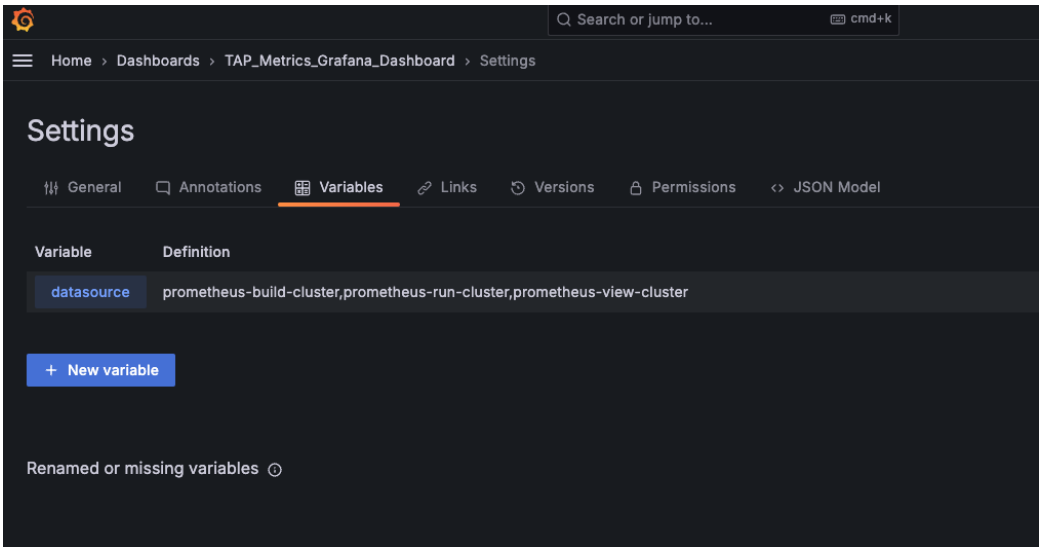
(Optional) Use your own datasources

To use your own set of datasources:

1. Go to **Dashboard Settings**.



2. Go to the **Variables** tab, click the datasource variable, and then update the proper datasource names in the datasource variable.



Search or jump to...
cmd+k

Overview of workloads

This topic provides you with an overview of workload types in Tanzu Application Platform (commonly known as TAP).

Workload features

Tanzu Application Platform allows you to quickly build and test applications regardless of your familiarity with Kubernetes.

You can turn source code into a workload that runs in a container with a URL. You can also use supply chains to build applications that process work from a message queue, or provide arbitrary network services.

A workload allows you to choose application specifications, such as repository location, environment variables, service binding, and so on. For more information about workload creation and management, see Create or update a workload.

The Out of the Box supply chains support a range of workload types, including

- Scalable web applications (`web`)
- Traditional application servers (`server`)
- Background applications (`worker`)
- Serverless functions

You can use a collection of workloads of different types to deploy microservices that function as a logical application. Alternatively, you can deploy your entire application as a single monolith.

If you build your own supply chains, you can define additional deployment methods beyond those in the Out of the Box supply-chain templates.

Available workload types

When using the Out of the Box supply chain, the `apps.tanzu.vmware.com/workload-type` annotation selects which style of deployment is suitable for your application. The valid values are:

Type	Description	Indicators
`web`	Scalable web applications	• Scales based on request load • Automatically exposed by HTTP Ingress • Does not perform background work • Works with Service Bindings • Stateless • Quick startup time

Type	Description	Indicators
`server`	Traditional applications	• Provides HTTP or TCP services on the network • Exposed by external Ingress or LoadBalancer settings • Might perform background work from a queue • Works with Service Bindings • Fixed scaling, no disk persistence • Startup time not an issue
`worker`	Background applications	• Does not provide network services • Not exposed externally as a network service • Performs background work from a queue • Works with Service Bindings • Fixed scaling, no disk persistence • Startup time not an issue

Overview of workloads

This topic provides you with an overview of workload types in Tanzu Application Platform (commonly known as TAP).

Workload features

Tanzu Application Platform allows you to quickly build and test applications regardless of your familiarity with Kubernetes.

You can turn source code into a workload that runs in a container with a URL. You can also use supply chains to build applications that process work from a message queue, or provide arbitrary network services.

A workload allows you to choose application specifications, such as repository location, environment variables, service binding, and so on. For more information about workload creation and management, see Create or update a workload.

The Out of the Box supply chains support a range of workload types, including

When using the Out of the Box supply chain, the `apps.tanzu.vmware.com/workload-type` annotation selects which style of deployment is suitable for your application. The valid values are:

Type	Description	Indicators
`web`	Scalable web applications	• Scales based on request load • Automatically exposed by HTTP Ingress • Does not perform background work • Works with Service Bindings • Stateless • Quick startup time
`server`	Traditional applications	• Provides HTTP or TCP services on the network • Exposed by external Ingress or LoadBalancer settings • Might perform background work from a queue • Works with Service Bindings • Fixed scaling, no disk persistence • Startup time not an issue
`worker`	Background applications	• Does not provide network services • Not exposed externally as a network service • Performs background work from a queue • Works with Service Bindings • Fixed scaling, no disk persistence • Startup time not an issue

Use web workloads

This topic tells you how to use the `web` workload type in Tanzu Application Platform (commonly known as TAP).

Overview

The `web` workload type allows you to deploy web applications on Tanzu Application Platform. Using an application workload specification, you can turn source code into a scalable, stateless application that runs in a container with an automatically-assigned URL. This type of application is often called serverless, and is deployed using Knative.

The `web` workload type is suitable for modern stateless web applications that follow the twelve-factor app methodology and have the following characteristics:

- Perform all work through HTTP requests, including gRPC and WebSocket
- Do not perform work except when processing a request
- Start up quickly
- Store state in external databases instead of storing state locally

Applications using the `web` workload type have the following features:

- Automatic request-based scaling, including scale-to-zero
- Automatic URL provisioning and optional certificate provisioning
- Automatic health-check definitions, if not provided by a convention
- Blue-green application rollouts

When creating a workload with the `tanzu apps workload create` command, you can use the `--type=web` argument to select the `web` workload type. For more information, see Use the web Workload Type later in this topic.

You can also use the `apps.tanzu.vmware.com/workload-type:web` label in the YAML workload description to support this deployment type.

Use the `web` workload type

The `tanzu-java-web-app` workload mentioned in Deploy an app on Tanzu Application Platform is a good match for the `web` workload type. It is a good match because it serves HTTP requests and does not perform any background processing.

You can experiment with the differences between the `web` and `server` workload types by changing the workload type. To change the workload type run:

```
tanzu apps workload apply tanzu-java-web-app --type=server
```

After changing the workload type to `server`, the application does not auto-scale or expose an external URL. For more information about the server workload type, see Use Server workloads.

Switch back to the `web` workload by running:

```
tanzu apps workload apply tanzu-java-web-app --type=web
```

Use this to test which applications can function well as serverless web applications, and which are more suited to the `server` application style.

Use server workloads

This topic tells you how to use the `server` workload type in Tanzu Application Platform (commonly known as TAP).

Overview

The `server` workload type allows you to deploy traditional network applications on Tanzu Application Platform.

Using an application workload specification, you can build and deploy application source code to a manually-scaled Kubernetes deployment which exposes an in-cluster Service endpoint. If required, you can use environment-specific LoadBalancer Services or Ingress resources to expose these applications outside the cluster.

The `server` workload is suitable for traditional applications, including HTTP applications, which have the following characteristics:

- Store state locally
- Run background tasks outside of requests
- Provide multiple network ports or non-HTTP protocols
- Are not a good match for the `web` workload type

An application using the `server` workload type has the following features:

- Does not natively autoscale, but you can use these applications with the Kubernetes Horizontal Pod Autoscaler.
- By default, is exposed only within the cluster using a `ClusterIP` service.

- Uses health checks if defined by a convention.
- Uses a rolling update pattern by default.

When creating a workload with the `tanzu apps workload create` command, you can use the `--type=server` argument to select the `server` workload type. For more information, see Use the server Workload Type later in this topic. You can also use the `apps.tanzu.vmware.com/workload-type:server` annotation in the YAML workload description to support this deployment type.

Use the `server` workload type

The `spring-sensors-consumer-web` workload in Bind an application workload to the service instance in the Get started guide is a good match for the `server` workload type.

This is because it runs continuously to extract information from a RabbitMQ queue, and stores the resulting data locally in memory and presents it through a web UI.

In the Services Toolkit example in Bind an application workload to the service instance, you can update the `spring-sensors-consumer-web` workload to use the `server` supply chain by changing the workload:

```
tanzu apps workload apply spring-sensors-consumer-web --type=server
```

This shows the change in the workload label and prompts you to accept the change. After the workload finishes the new deployment, there are a few differences:

- The workload no longer exposes a URL. It's available within the cluster as `spring-sensors-consumer-web` within the namespace, but you must use `kubectl port-forward service/spring-sensors-consumer-web 8080` to access the web service on port 8080.

  You can set up a Kubernetes Ingress rule to direct traffic from outside the cluster to the workload. Use an Ingress rule to specify that specific host names or paths must be routed to the application. For more information about Ingress rules, see the Kubernetes documentation
- The workload no longer autoscales based on request traffic. For the `spring-sensors-consumer-web` workload, this means that it never spawns a second instance that consumes part of the request queue. Also, it does not scale down to zero instances.

`server`-specific workload parameters

In addition to the common supply chain parameters, `server` workloads can expose one or more network ports from the application to the Kubernetes cluster by using the `ports` parameter. This parameter is a list of port objects, similar to a Kubernetes service specification.

If you do not configure the `ports` parameter, the applied container conventions in the cluster establishes the set of exposed ports.

The following configuration exposes two ports on the Kubernetes cluster under the `my-app` host name:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: my-app
  labels:
    apps.tanzu.vmware.com/workload-type: server
spec:
  params:
  - name: ports
```

```
    value:
    - containerPort: 2025
      name: smtp
      port: 25
    - port: 8080
  ...
```

This snippet configures:

- One service on port 25, which is redirected to port 2025 on the application
- One service on port 8080, which is routed to port 8080 on the application

You can set the `ports` parameter from the `tanzu apps workload create` command as `--param-yaml 'ports=[{"port": 8080}]'`.

The following values are valid within the `ports` argument:

Field	Value
`port`	The port on which the application is exposed to the rest of the cluster
`containerPort`	The port on which the application listens for requests. Defaults to `port` if not set.
`name`	A human-readable name for the port. Defaults to `port` if not set.

Expose `server` workloads outside the cluster

You have several options for exposing `server` workloads outside the cluster:

- Expose server workloads outside the cluster automatically
- Expose HTTP server workloads outside the cluster manually
- Define a workload type that exposes server workloads outside the cluster
- Expose workloads outside the cluster using AVI L4/L7

Use server workloads

This topic tells you how to use the `server` workload type in Tanzu Application Platform (commonly known as TAP).

Overview

The `server` workload type allows you to deploy traditional network applications on Tanzu Application Platform.

Using an application workload specification, you can build and deploy application source code to a manually-scaled Kubernetes deployment which exposes an in-cluster Service endpoint. If required, you can use environment-specific LoadBalancer Services or Ingress resources to expose these applications outside the cluster.

The `server` workload is suitable for traditional applications, including HTTP applications, which have the following characteristics:

- Store state locally
- Run background tasks outside of requests
- Provide multiple network ports or non-HTTP protocols
- Are not a good match for the `web` workload type

An application using the `server` workload type has the following features:

- Does not natively autoscale, but you can use these applications with the Kubernetes Horizontal Pod Autoscaler.
- By default, is exposed only within the cluster using a `ClusterIP` service.
- Uses health checks if defined by a convention.
- Uses a rolling update pattern by default.

When creating a workload with the `tanzu apps workload create` command, you can use the `--type=server` argument to select the `server` workload type. For more information, see Use the server Workload Type later in this topic. You can also use the `apps.tanzu.vmware.com/workload-type:server` annotation in the YAML workload description to support this deployment type.

Use the `server` workload type

The `spring-sensors-consumer-web` workload in Bind an application workload to the service instance in the Get started guide is a good match for the `server` workload type.

This is because it runs continuously to extract information from a RabbitMQ queue, and stores the resulting data locally in memory and presents it through a web UI.

In the Services Toolkit example in Bind an application workload to the service instance, you can update the `spring-sensors-consumer-web` workload to use the `server` supply chain by changing the workload:

```
tanzu apps workload apply spring-sensors-consumer-web --type=server
```

This shows the change in the workload label and prompts you to accept the change. After the workload finishes the new deployment, there are a few differences:

- The workload no longer exposes a URL. It's available within the cluster as `spring-sensors-consumer-web` within the namespace, but you must use `kubectl port-forward service/spring-sensors-consumer-web 8080` to access the web service on port 8080.

  You can set up a Kubernetes Ingress rule to direct traffic from outside the cluster to the workload. Use an Ingress rule to specify that specific host names or paths must be routed to the application. For more information about Ingress rules, see the Kubernetes documentation
- The workload no longer autoscales based on request traffic. For the `spring-sensors-consumer-web` workload, this means that it never spawns a second instance that consumes part of the request queue. Also, it does not scale down to zero instances.

`server`-specific workload parameters

In addition to the common supply chain parameters, `server` workloads can expose one or more network ports from the application to the Kubernetes cluster by using the `ports` parameter. This parameter is a list of port objects, similar to a Kubernetes service specification.

If you do not configure the `ports` parameter, the applied container conventions in the cluster establishes the set of exposed ports.

The following configuration exposes two ports on the Kubernetes cluster under the `my-app` host name:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: my-app
  labels:
```

```
    apps.tanzu.vmware.com/workload-type: server
spec:
  params:
  - name: ports
    value:
    - containerPort: 2025
      name: smtp
      port: 25
    - port: 8080
  ...
```

This snippet configures:

- One service on port 25, which is redirected to port 2025 on the application
- One service on port 8080, which is routed to port 8080 on the application

You can set the `ports` parameter from the `tanzu apps workload create` command as `--param-yaml 'ports=[{"port": 8080}]'`.

The following values are valid within the `ports` argument:

Field	Value
`port`	The port on which the application is exposed to the rest of the cluster
`containerPort`	The port on which the application listens for requests. Defaults to `port` if not set.
`name`	A human-readable name for the port. Defaults to `port` if not set.

Expose `server` workloads outside the cluster

You have several options for exposing `server` workloads outside the cluster:

- Expose server workloads outside the cluster automatically
- Expose HTTP server workloads outside the cluster manually
- Define a workload type that exposes server workloads outside the cluster
- Expose workloads outside the cluster using AVI L4/L7

Expose server workloads outside the cluster automatically

In Tanzu Application Platform (commonly known as TAP) v1.6 and later, Carvel Package Supply Chains produce server workloads that have Ingress by default. For more information, see Overview of the Carvel Package Supply Chains.

Expose HTTP server workloads outside the cluster manually

You can expose HTTP `server` workloads outside the cluster by creating an Ingress resource and using cert-manager to provision TLS-signed certificates. To do so:

1. Using the `spring-sensors-consumer-web` workload from Bind an application workload to the service instance as an example, create the following `Ingress`:

   ```
   apiVersion: networking.k8s.io/v1
   kind: Ingress
   metadata:
    name: spring-sensors-consumer-web
    namespace: DEVELOPER-NAMESPACE
    annotations:
   ```

```
    cert-manager.io/cluster-issuer: tap-ingress-selfsigned
    ingress.kubernetes.io/force-ssl-redirect: "true"
    kubernetes.io/ingress.class: contour
    kubernetes.io/tls-acme: "true"
spec:
 tls:
   - secretName: spring-sensors-consumer-web
     hosts:
       - "spring-sensors-consumer-web.INGRESS-DOMAIN"
 rules:
   - host: "spring-sensors-consumer-web.INGRESS-DOMAIN"
     http:
       paths:
         - pathType: Prefix
           path: /
           backend:
             service:
               name: spring-sensors-consumer-web
               port:
                 number: 8080
```

- Replace `DEVELOPER-NAMESPACE` with your developer namespace.
- Replace `INGRESS-DOMAIN` with the domain name defined in `tap-values.yaml` during the installation.
- Set the annotation `cert-manager.io/cluster-issuer` to the `shared.ingress_issuer` value configured during installation or leave it as `tap-ingress-selfsigned` to use the default value.
- Update the port exposed by your `Service` resource, which is set as `8080` in the example.

2. Access the `server` workload with HTTPS:

```
curl -k https://spring-sensors-consumer-web.INGRESS-DOMAIN
```

Define a workload type that exposes server workloads outside the cluster

Tanzu Application Platform (commonly known as TAP) allows you to create new workload types. You start by adding an `Ingress` resource to the `server-template ClusterConfigTemplate` when this new type of workload is created.

1. Delete the `Ingress` resource previously created.
2. Install the `yq` CLI on your local machine.
3. Save the existing `server-template` in a local file by running:

```
kubectl get ClusterConfigTemplate server-template -o yaml > secure-server-templ
ate.yaml
```

4. Extract the `.spec.ytt` field from this file and create another file by running:

```
yq eval '.spec.ytt' secure-server-template.yaml > spec-ytt.yaml
```

5. In the next step, you add the `Ingress` resource snippet to `spec-ytt.yaml`. This step provides a sample `Ingress` resource snippet. Make the following edits before adding the `Ingress` resource snippet to `spec-ytt.yaml`:
   - Replace `INGRESS-DOMAIN` with the Ingress domain you set during the installation.

- Set the annotation `cert-manager.io/cluster-issuer` to the `shared.ingress_issuer` value configured during installation or leave it as `tap-ingress-selfsigned` to use the default one.
- This configuration is based on your workload service running on port `8080`.

The `Ingress` resource snippet looks like this:

```
---
apiVersion: networking.k8s.io/v1
kind: Ingress
metadata:
  name: #@ data.values.workload.metadata.name
  annotations:
    cert-manager.io/cluster-issuer: tap-ingress-selfsigned
    ingress.kubernetes.io/force-ssl-redirect: "true"
    kubernetes.io/ingress.class: contour
    kubernetes.io/tls-acme: "true"
    kapp.k14s.io/change-rule: "upsert after upserting Services"
  labels: #@ merge_labels({ "app.kubernetes.io/component": "run", "carto.run/wo
rkload-name": data.values.workload.metadata.name })
spec:
  tls:
    - secretName: #@ data.values.workload.metadata.name
      hosts:
        - #@ data.values.workload.metadata.name + ".INGRESS-DOMAIN"
  rules:
    - host: #@ data.values.workload.metadata.name + ".INGRESS-DOMAIN"
      http:
        paths:
          - pathType: Prefix
            path: /
            backend:
              service:
                name: #@ data.values.workload.metadata.name
                port:
                  number: 8080
```

6. Add the `Ingress` resource snippet to the `spec-ytt.yaml` file and save. Look for the `Service` resource, and insert the snippet before the last `#@ end`. For example:

```

# THE TOP OF THE FILE IS NOT SHOWN

---
apiVersion: v1
kind: Service
metadata:
  name: #@ data.values.workload.metadata.name
  labels: #@ merge_labels({ "app.kubernetes.io/component": "run", "carto.run/wo
rkload-name": data.values.workload.metadata.name })
spec:
  selector: #@ data.values.config.metadata.labels
  ports:
  #@ hasattr(data.values.params, "ports") and len(data.values.params.ports) or
assert.fail("one or more ports param must be provided.")
  #@ declared_ports = {}
  #@ if "ports" in data.values.params:
  #@   declared_ports = data.values.params.ports
  #@ else:
  #@   declared_ports = struct.encode([{ "containerPort": 8080, "port": 8080,
"name":   "http"}])
  #@ end
  #@ for p in merge_ports(declared_ports, data.values.config.spec.containers):
  - #@ p
```

```
  #@ end

# NEW INGRESS RESOURCE
---
apiVersion: networking.k8s.io/v1
kind: Ingress
metadata:
  name: #@ data.values.workload.metadata.name
  annotations:
    cert-manager.io/cluster-issuer: tap-ingress-selfsigned
    ingress.kubernetes.io/force-ssl-redirect: "true"
    kubernetes.io/ingress.class: contour
    kubernetes.io/tls-acme: "true"
    kapp.k14s.io/change-rule: "upsert after upserting Services"
  labels: #@ merge_labels({ "app.kubernetes.io/component": "run", "carto.run/wo
rkload-name": data.values.workload.metadata.name })
spec:
  tls:
    - secretName: #@ data.values.workload.metadata.name
      hosts:
        - #@ data.values.workload.metadata.name + ".INGRESS-DOMAIN"
  rules:
    - host: #@ data.values.workload.metadata.name + ".INGRESS-DOMAIN"
      http:
        paths:
          - pathType: Prefix
            path: /
            backend:
              service:
                name: #@ data.values.workload.metadata.name
                port:
                  number: 8080
# END NEW INGRESS RESOURCE

#@ end

---
apiVersion: v1
kind: ConfigMap
metadata:
  name: #@ data.values.workload.metadata.name + "-server"
  labels: #@ merge_labels({ "app.kubernetes.io/component": "config" })
data:
  delivery.yml: #@ yaml.encode(delivery())
```

7. Add the snippet to the `.spec.ytt` property in `secure-server-template.yaml`:

```
SPEC_YTT=$(cat spec-ytt.yaml) yq eval -i '.spec.ytt |= strenv(SPEC_YTT)' secure
-server-template.yaml
```

8. Change the name of the `ClusterConfigTemplate` to `secure-server-template` by running:

```
yq eval -i '.metadata.name = "secure-server-template"' secure-server-template.y
aml
```

9. Create the new `ClusterConfigTemplate` by running:

```
kubectl apply -f secure-server-template.yaml
```

10. Verify the new `ClusterConfigTemplate` is in the cluster by running:

```
kubectl get ClusterConfigTemplate
```

Expected output:

```
kubectl get ClusterConfigTemplate
NAME                      AGE
api-descriptors           82m
config-template           82m
convention-template       82m
secure-server-template    22s
server-template           82m
service-bindings          82m
worker-template           82m
```

11. Add the new workload type to the `tap-values.yaml`. The new workload type is named `secure-server` and the `cluster_config_template_name` is `secure-server-template`.

```
ootb_supply_chain_basic:
  supported_workloads:
    - type: web
      cluster_config_template_name: config-template
    - type: server
      cluster_config_template_name: server-template
    - type: worker
      cluster_config_template_name: worker-template
    - type: secure-server
      cluster_config_template_name: secure-server-template
```

12. Update your Tanzu Application Platform installation as follows:

```
tanzu package installed update tap -p tap.tanzu.vmware.com --values-file \
"/path/to/your/config/tap-values.yaml"  -n tap-install
```

13. Give privileges to the `deliverable` role to manage `Ingress` resources:

```
cat <<EOF | kubectl apply -f -
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
 name: deliverable-with-ingress
 labels:
   apps.tanzu.vmware.com/aggregate-to-deliverable: "true"
rules:
- apiGroups:
 - networking.k8s.io
 resources:
 - ingresses
 verbs:
 - get
 - list
 - watch
 - create
 - patch
 - update
 - delete
 - deletecollection
EOF
```

14. Update the workload type to `secure-server`:

Note

If you created the `Ingress` resource manually in the previous section, delete it before this.

```
tanzu apps workload apply spring-sensors-consumer-web --type=secure-server
```

15. After the process finishes, verify that the resources Deployment, Service, and Ingress appear by running:

    ```
    kubectl get ingress,svc,deploy -l carto.run/workload-name=spring-sensors-consum
    er-web
    ```

    Expected output:

    ```
    kubectl get ingress,svc,deploy -l carto.run/workload-name=tanzu-java-web-app-js
    NAME                                                    CLASS    HOSTS
    ADDRESS          PORTS     AGE
    ingress.networking.k8s.io/spring-sensors-consumer-web   <none>   spring-sensors
    -consumer-web.INGRESS-DOMAIN   34.111.111.111   80, 443   37s

    NAME                                  TYPE        CLUSTER-IP     EXTERNAL-IP
    PORT(S)    AGE
    service/spring-sensors-consumer-web   ClusterIP   10.32.15.194   <none>
    8080/TCP   36m

    NAME                                          READY   UP-TO-DATE   AVAILABLE
    AGE
    deployment.apps/spring-sensors-consumer-web   1/1     1            1
    37s
    ```

16. Access your `secure-server` workload with HTTPS by running:

    ```
    curl -k https://spring-sensors-consumer-web.INGRESS-DOMAIN
    ```

Expose workloads outside the cluster using AVI L4/L7

To expose workloads outside the cluster by using AVI L4/L7, see the Tanzu Reference Architecture documentation.

Use worker workloads

This topic tells you how to create and install a supply chain for the `worker` workload type in Tanzu Application Platform (commonly known as TAP).

Overview

The `worker` workload type allows you to deploy applications that run continuously without network input on Tanzu Application Platform. Using an application workload specification, you can build and deploy application source code to a manually scaled Kubernetes deployment with no network exposure.

The `worker` workload is a good match for applications that manage their own work by reading from a worker or a background scheduled time source, and don't expose any network interfaces.

An application using the `worker` workload type has the following features:

- Does not natively auto-scale but you can use it with the Kubernetes Horizontal Pod Autoscaler
- Does not expose any network services
- Uses health checks if defined by a convention

- Uses a rolling update pattern by default

When creating a workload with `tanzu apps workload create`, you can use the `--type=worker` argument to select the `worker` workload type. For more information, see the Use the worker Workload Type section. You can also use the `apps.tanzu.vmware.com/workload-type:worker` annotation in the YAML workload description to support this deployment type.

Use the `worker` workload type

The `spring-sensors-producer` workload in the example in Consume services on Tanzu Application Platform is a good match for the `worker` workload type. This is because it runs continuously without a UI to report sensor information to a RabbitMQ topic.

If you followed the Services Toolkit example, you can update the `spring-sensors-producer` to use the `worker` supply chain by changing the workload type. To do so, run:

```
tanzu apps workload apply spring-sensors-producer --type=worker
```

This shows a difference in the workload label, and prompts you to accept the change. After the workload finishes the new deployment, there are a few differences:

- The workload no longer has a URL. Because the workload does not present a web UI, this more closely matches the original application intent.
- The workload no longer auto-scales based on request traffic. For the `spring-sensors-producer` workload, this means that it does not scale down to zero instances when there is no request traffic.

Service-to-Service communication

This topic tells you about service-to-service communication for `web` and `server` workloads.

Calling `web` workloads within a cluster

When a `web` workload type is created, a Knative service is deployed to the cluster. To access your application, you need the URL for the route created by the Knative Service.

Obtain the URL by running one of these commands:

- To use the `tanzu apps` command, run:

  ```
  tanzu apps workload get WORKLOAD-NAME --namespace DEVELOPER-NAMESPACE
  ```

- To use the `kubectl get` command, run:

  ```
  kubectl get ksvc WORKLOAD-NAME -n YOUR-DEVELOPER-NAMESPACE -ojsonpath="{status.
  address.url}"
  ```

Note

When calling a Knative service, both the Service name and namespace are required. This behavior is distinct from `server` type workloads, which do not rely on the namespace name to establish service-to-service communication between applications within the same namespace.

Example of service-to-service communication for `web` and `server` workloads

You have three applications deployed to the namespace called `dev-namespace`:

- A `server` type workload named `server-workload`
- A `web` type workload named `web-workload`
- A pod running the busybox image with `curl` that is named `busybox`

Open a shell to the running container of the `busybox` pod and send requests to the `server` and `web` workloads using curl. Specify the namespace for both, as follows:

```
kubectl exec busybox -n dev-namespace -- curl server-workload.dev-namespace.svc.cluste
r.local -v
kubectl exec busybox -n dev-namespace -- curl web-workload.dev-namespace.svc.cluster.l
ocal -v
```

You can alternatively reference a web service as `workload-name.namespace` or `web-workload.dev-namespace` in this example. You can also reference a `server` workload that exists in the same namespace as `workload-name`, or `server-workload`.

Parameter reference

This topic tells you about the default supply chains and templates provided by Tanzu Application Platform (commonly known as TAP). It describes the `workload.spec.params` parameters that are configured in workload objects, and the `deliverable.spec.params` parameters that are configured in the deliverable object.

Workload Parameter Reference

The supply chains and templates provided by the Out of the Box packages contain a series of parameters that customize supply chain behavior. This section describes the `workload.spec.params` parameters that can be configured in workload objects.

The following table provides a list of supply chain resources organized by the resource in the supply chain where they are used. Some of these resources might not be applicable depending on the supply chain in use.

List of Supply Chain Resources for Workload Object

Supply Chain Resource	Output Type	Purpose	Basic	Testing	Scanning
source-provider	Source	Fetches source code	Yes	Yes	Yes
source-tester	Source	Tests source code	No	Yes	Yes
source-scanner	Source	Scans source code	No	No	Yes
image-provider	Image	Builds application container image	Yes	Yes	Yes
image-scanner	Image	Scans application container image	No	No	Yes
config-provider	Podtemplate spec	Tailors a pod spec based on the application image and conventions set up in the cluster	Yes	Yes	Yes
app-config	Kubernetes configuration	Creates Kubernetes config files (knative service/deployment - depending on workload type)	Yes	Yes	Yes

Supply Chain Resource	Output Type	Purpose	Basic	Testing	Scanning
service-bindings	Kubernetes configuration	Adds service bindings to the set of config files	Yes	Yes	Yes
api-descriptors	Kubernetes configuration	Adds api descriptors to the set of config files	Yes	Yes	Yes
config-writer	Kubernetes configuration	Writes configuration to a destination (git or registry) for further deployment to a run cluster	Yes	Yes	Yes
deliverable	Kubernetes configuration	Writes deliverable content to be extracted for use in a run cluster	Yes	Yes	Yes

For information about supply chains, see:

- Out of the Box Supply Chain Basic
- Out of the Box Supply Chain Testing
- Out of the Box Supply Chain Testing Scanning

source-provider

The `source-provider` resource in the supply chain creates objects that fetch either source code or pre-compiled Java applications depending on how the workload is configured. For more information, see Building from Source.

GitRepository

Use `gitrepository` when fetching source code from Git repositories. This resource makes further resources available in the supply chain, such as the contents of the Git repository as a tarball available in the cluster.

Parameters:

Parameter name	Meaning	Example
`gitImplementation`	VMware recommends that you use the underlying library for fetching the source code.	- name: gitImplementation value: go-git
`source_credentials_secret`	The name of the secret in the same namespace as the `Workload` used for providing credentials for fetching source code from the Git repository. For more information, see Git authentication.	- name: source_credentials_secret value: git-credentials
`gitops_ssh_secret`	Deprecated. Use `source_credentials_secret` instead. The name of the secret in the same namespace as the `Workload` used for providing credentials for fetching source code from the Git repository. For more information, see Git authentication.	- name: gitops_ssh_secret value: git-credentials

For information about the features supported by each implementation, see Git implementation in the Flux documentation.

For information about how to create a workload that uses a GitHub repository as the provider of source code, see Create a workload from GitHub repository.

For more information about GitRepository objects, see Git Repository in the Flux documentation.

ImageRepository

Use the ImageRepository when fetching source code from container images. It makes the contents of the container image available as a tarball to further resources in the supply chain. The contents of the container image are fetched by using Git or Maven. For more information, see Create a workload from local source code.

Parameters:

Parameter Name	Meaning	Example
`serviceAccount`	Name of the service account (in the same namespace as the workload) to use to provide the credentials to `ImageRepository` for fetching the container images.	- name: serviceAccount value: default

The `--service-account` flag sets the `spec.serviceAccountName` key in the workload object. To configure the `serviceAccount` parameter, use `--param serviceAccount=SERVICE-ACCOUNT`.

For information about custom resource details, see the ImageRepository reference topic.

For information about how to use ImageRepository with the Tanzu CLI, see Create a workload.

MavenArtifact

When carrying pre-built Java artifacts, `MavenArtifact` makes the artifact available to further resources in the supply chain as a tarball. You can wrap the tarball as a container image for further deployment. Differently from `git` and `image`, its configuration is solely driven by parameters in the workload.

Parameters:

Parameter Name	Meaning	Example
`maven`	Points to the maven artifact to fetch and the polling interval.	- name: maven value: artifactId: springboot-initial groupId: com.example version: RELEASE classifier: sources # optional type: # optional artifactRetryTimeout: 1m0s # optional

For information about the custom resource, see the MavenArtifact reference documentation.

For information about how to use the custom resource with the Tanzu apps CLI plug-in, see the Tanzu CLI Command Reference documentation.

source-tester

The `source-tester` resource is in `ootb-supply-chain-testing` and `ootb-supply-chain-testing-scanning`. This resource is responsible for instantiating a Tekton PipelineRun object that calls the execution of a Tekton Pipeline, in the same namespace as the workload, whenever its inputs change. For example, the source code revision that you want to test changes.

A Runnable object is instantiated to ensure that there's always a run for a particular set of inputs. The parameters are passed from the workload down to Runnable's Pipeline selection mechanism through `testing_pipeline_matching_labels` and the execution of the PipelineRuns through `testing_pipeline_params`.

Parameters:

Parameter name	Meaning	Example
`testing_pipeline_matching_labels`	The set of labels to use when searching for Tekton Pipeline objects in the same namespace as the workload. By default, a Pipeline labeled as `apps.tanzu.vmware.com/pipeline: test` is selected, but when using this parameter, it's possible to override the behavior.	- name: testing_pipeline_matching_labels value: apps.tanzu.com/pipeline: test my.company/language: golang
`testing_pipeline_params`	The set of extra parameters, aside from `source-url` and `source-revision`, to pass to the Tekton Pipeline. The Tekton Pipeline **must** declare both the required parameters `source-url` and `source-revision` and the extra ones declared in this table.	- name: testing_pipeline_params value: verbose: true

For information about how to set up the Workload namespace for testing with Tekton, see Out of the Box Supply Chain with Testing.

For information about how to use the parameters to customize this resource to test using a Jenkins cluster, see Out of the Box Supply Chain with Testing on Jenkins.

source-scanner

The `source-scanner` resource is available in `ootb-supply-chain-testing-scanning`. It scans the source code that is tested by pointing a SourceScan object at the same source code as the tests.

You can customize behavior for both CVEs evaluation with parameters.

Parameters:

Parameter name	Meaning	Example
`scanning_source_template`	The name of the ScanTemplate object (in the same namespace as the workload) to use for running the scans against the source code.	- name: scanning_source_template value: private-source-scan-template
`scanning_source_policy`	The name of the ScanPolicy object (in the same namespace as the workload) to use when evaluating the scan results of a source scan.	- name: scanning_source_policy value: allowlist-policy

For more information, see Out of the Box Supply Chain with Testing and Scanning for details about how to set up the workload namespace with the ScanPolicy and ScanTemplate required for this resource, and SourceScan reference for details about the SourceScan custom resource.

For information about how the artifacts found during scanning are catalogued, see Supply Chain Security Tools for Tanzu – Store.

image-provider

The `image-provider` in the supply chains provides a container image carrying the application already built to further resources.

Different semantics apply, depending on how the workload is configured, for example, if using pre-built images or building from source:

- pre-built: an `ImageRepository` object is created aiming at providing a reference to the latest image found matching the name as specified in `workload.spec.image`

- building from source: an image builder object is created (either Kpack's `Image` or a `Runnable` for creating Tekton TaskRuns for building images from Dockerfiles)

Kpack Image

Use the Kpack Image object to build a container image out of source code or pre-built Java artifact.

This makes the container image available to further resources in the supply chain through a content addressable image reference that's carried to the final deployment objects unchanged. For more information, see Tanzu Build Service.

Parameters:

Parameter name	Meaning	Example
`serviceAccount`	The name of the serviceaccount (in the same namespace as the workload) to use for providing credentials to `Image` for pushing the container images it builds to the configured registry.	- name: serviceAccount value: default
`clusterBuilder`	The name of the Kpack cluster builder to use in the Kpack Image object created.	- name: clusterBuilder value: nodejs-cluster-builder
`buildServiceBindings`	The definition of a list of service bindings to use at build time. For example, providing credentials for fetching dependencies from repositories that require credentials.	- name: buildServiceBindings value: - name: settings-xml kind: Secret apiVersion: v1
`additionalTags`	The additionalTags is a list of locations the built OCI image will be written to in addition to the default tag. Additional tags must be in the same registry as the default tag.	- name: additionalTags value: - my-registry.com/my-app - my-other-registry.com/other-app:other-tag
`live-update`	Enables the use of Tilt's live-update function.	- name: live-update value: "true"

The `--service-account` flag sets the `spec.serviceAccountName` key in the workload object. To configure the `serviceAccount` parameter, use `--param serviceAccount=SERVICE-ACCOUNT`.

For information about the integration with Tanzu Build Service, see Tanzu Build Service Integration.

For information about `live-update`, see Developer Conventions and Overview of Tanzu Developer Tools for IntelliJ.

For information about using Kpack builders with `clusterBuilder`, see Builders.

For information about `buildServiceBindings`, see Service Bindings.

Runnable (TaskRuns for Dockerfile-based builds)

To perform Dockerfile-based builds, all the supply chains instantiate a Runnable object that instantiates Tekton TaskRun objects to call the execution of kaniko builds.

Parameters:

Parameter name	Meaning	Example
`dockerfile`	The relative path to the Dockerfile file in the build context.	./Dockerfile
`docker_build_context`	The relative path to the directory where the build context is.	.
`docker_build_extra_args`	List of flags to pass directly to Kaniko, such as providing arguments to a build.	--build-arg=FOO=BAR

For information about how to use Dockerfile-based builds and limitations associated with the function, see Dockerfile-based builds.

Pre-built image (ImageRepository)

For applications that already have their container images built outside the supply chains, such as providing an image reference under `workload.spec.image`, an `ImageRepository` object is created to keep track of any images pushed under that name.

This makes the content-addressable name, such as the image name containing the digest, available for further resources in the supply chain.

Parameters:

Parameter name	Meaning	Example
`serviceAccount`	The name of the serviceaccount (in the same namespace as the workload) to use for providing the credentials to `ImageRepository` for fetching the container images.	- name: serviceAccount value: default

The `--service-account` flag sets the `spec.serviceAccountName` key in the workload object. To configure the `serviceAccount` parameter, use `--param serviceAccount=...`.

For information about the ImageRepository resource, see the ImageRepository reference documentation. For information about the prebuild image function, see Using a prebuilt image.

image-scanner

The `image-scanner` resource is included only in `ootb-supply-chain-testing-scanning`.

This resource scans a container image (either built by using the supply chain or prebuilt), persisting the results in the store, and gating the image from moving forward in case the CVEs found are not compliant with the ScanPolicy referenced by the ImageScan object create for doing so.

Parameters:

Parameter name	Meaning	Example
`scanning_image_template`	The name of the ScanTemplate object (in the same namespace as the workload) to use for running the scans against a container image.	- name: scanning_image_template value: private-image-scan-template
`scanning_image_policy`	The name of the ScanPolicy object (in the same namespace as the workload) to use when evaluating the scan results of an image scan.	- name: scanning_image_policy value: allowlist-policy

For information about the ImageScan custom resource, see ImageScan reference.

For information about how the artifacts found during scanning are catalogued, see Supply Chain Security Tools for Tanzu – Store.

config-provider

The `config-provider` resource in the supply chains generates a PodTemplateSpec to use in application configs, such as Knative services and deployments, to represent the desired pod configuration to instantiate to run the application in containers. For more information, see PodTemplateSpec in the Kubernetes documentation.

The `config-provider` resource manages a PodIntent object that represents the intention of having PodTemplateSpec enhanced with conventions installed in the cluster whose final representation is then passed forward to other resources to form the final deployment configuration.

Parameters:

Parameter name	Meaning	Example
`serviceAccount`	The name of the serviceaccount (in the same namespace as the workload) to use for providing the necessary credentials to `PodIntent` for fetching the container image to inspect the metadata to pass to convention servers and the serviceAccountName set in the podtemplatespec.	- name: serviceAccount value: default
`annotations`	An extra set of annotations to pass down to the PodTemplateSpec.	- name: annotations value: name: my-application version: v1.2.3 team: store
`debug`	Put the workload in debug mode.	- name: debug value: "true"
`live-update`	Enable live-updating of the code (for innerloop development).	- name: live-update value: "true"

The `--service-account` flag sets the `spec.serviceAccountName` key in the workload object. To configure the `serviceAccount` parameter, use `--param serviceAccount=SERVICE-ACCOUNT`.

For more information about the controller behind `PodIntent`, see Cartographer Conventions.

For more details about the two convention servers enabled by default in Tanzu Application Platform installations, see Developer Conventions and Spring Boot conventions.

app-config

The `app-config` resource prepares a ConfigMap with the Kubernetes configuration that is used for instantiating an application in the form of a particular workload type in a cluster.

The resource is configured in the supply chain to allow, by default, three types of workloads with the selection of which workload type to apply based on the labels set in the workload object created by the developer:

- `apps.tanzu.vmware.com/workload-type: web`
- `apps.tanzu.vmware.com/workload-type: worker`
- `apps.tanzu.vmware.com/workload-type: server`

Only the `server` workload type has the following configurable parameters:

Parameter name	Meaning	example
`ports`	The set of network ports to expose from the application to the Kubernetes cluster.	- name: ports value: - containerPort: 2025 name: smtp port: 25

For more information about the three different types of workloads, see Overview of workloads.

For a more detailed overview of the ports parameter, see server-specific Workload parameters.

service-bindings

The `service-bindings` resource adds ServiceBindings to the set of Kubernetes configuration files to promote for deployment.

Parameters:

Parameter name	Meaning	Example
`annotations`	The extra set of annotations to pass down to the ServiceBinding and ResourceClaim objects.	- name: annotations value: name: my-application version: v1.2.3 team: store

For an example, see the Tanzu CLI Command Reference documentation.

For an overview of the function, see Consume services on Tanzu Application Platform.

api-descriptors

The `api-descriptor` resource adds an APIDescriptor to the set of Kubernetes objects to deploy. This enables API auto registration.

Parameters:

Parameter name	Meaning	Example
`annotations`	An extra set of annotations to pass down to the APIDescriptor object.	- name: annotations value: name: my-application version: v1.2.3 team: store
`api_descriptor`	Information used to fill the state that you want of the APIDescriptor object (its spec).	- name: api_descriptor value: type: openapi location: baseURL: http://petclinic-hard-coded.my-apps.tapdemo.vmware.com/ path: "/v3/api" owner: team-petclinic system: pet-clinics description: "example"

The workload must include the `apis.apps.tanzu.vmware.com/register-api: "true"` label to activate this function.

For more details about API auto registration, see Use API Auto Registration.

config-writer (git or registry)

The `config-writer` resource is responsible for performing the last mile of the supply chain: persisting in an external system (registry or Git repository) the Kubernetes configuration generated throughout the supply chain.

There are three methods:

- Publishing the configuration to a container image registry
- Publishing the configuration to a Git repository by using the push of a commit
- Publishing the configuration to a Git repository by pushing a commit and opening a pull request

For more information about the different modes of operation, see Use GitOps or RegistryOps with Supply Chain Choreographer.

deliverable

The `deliverable` resource creates a `deliverable` object that represents the intention of delivering to the cluster the configurations that are produced by the supply chain.

Parameters:

Parameter name	Meaning	Example
`serviceAccount`	The name of the serviceaccount (in the same namespace as the deliverable) to use for providing the necessary permissions to create the children objects for deploying the objects created by the supply chain to the cluster.	- name: serviceAccount value: default

The `--service-account` flag sets the `spec.serviceAccountName` key in the workload object. To configure the `serviceAccount` parameter, use `--param serviceAccount=SERVICE-ACCOUNT`.

On build clusters where a corresponding `ClusterDelivery` doesn't exist, the deliverable takes no effect (similarly to a workload without a SupplyChain, no action is taken).

Deliverable Parameters Reference

The deliverable object applies the configuration produced by the resources defined by a ClusterSupplyChain to a Kubernetes cluster.

This section describes the `deliverable.spec.params` parameters that can be configured in the deliverable object. The following section describes the two resources defined in the ClusterDelivery resources section. These are part of the `ootb-delivery-basic` package:

List of Cluster Delivery Resources for Deliverable Object

Cluster Delivery Resource	Output Type	Purpose
source provider	Source	Fetches the Kubernetes configuration file from Git repository or image registry
app deployer	Source	Applies configuration produced by a supply chain to the cluster

For information about the ClusterDelivery shipped with `ootb-delivery-basic`, and the templates used by it, see:

- Out of the Box Delivery Basic
- Out of the Templates

For information about the use of the deliverable object in a multicluster environment, see Getting started with multicluster Tanzu Application Platform.

For reference information about deliverable, see Deliverable and Delivery custom resources in the Cartographer documentation.

source-provider

The `source-provider` resource in the basic ClusterDelivery creates objects that continuously fetch Kubernetes configuration files from a Git repository or container image registry so that it can apply those to the cluster.

Regardless of where it fetches that Kubernetes configuration from (Git repository or image registry), it exposes those files to further resources along the ClusterDelivery as a tarball.

GitRepository

A GitRepository object is instantiated when `deliverable.spec.source.git` is configured to continuously look for a Kubernetes configuration pushed to a Git repository, making it available for resources in the ClusterDelivery.

Parameters:

Parameter name	Meaning	Example
`gitImplementation`	VMware recommends that you use the underlying library for fetching the source code. `go-git`.	- name: gitImplementation value: go-git
`source_credentials_secret`	The name of the secret in the same namespace as the `Deliverable` used for providing credentials for fetching build configuration from the Git repository. For more information, see Git authentication.	- name: source_credentials_secret value: git-credentials
`gitops_ssh_secret`	Deprecated. Use `source_credentials_secret` instead. The name of the secret in the same namespace as the `Deliverable` used for providing credentials for fetching build configuration from the Git repository. For more information, see Git authentication.	- name: gitops_ssh_secret value: git-credentials

For information about the features supported by each implementation, see git implementation in the Flux documentation.

For information about how to create a workload that uses a GitHub repository as the provider of source code, see Create a workload from GitHub repository.

For information about GitRepository objects, see GitRepository.

ImageRepository

An ImageRepository object is instantiated when `deliverable.spec.source.image` is configured to continuously look for Kubernetes configuration files pushed to a container image registry as opposed to a Git repository.

Parameters:

Parameter name	Meaning	Example
`serviceAccount`	The name of the service account, in the same namespace as the deliverable, you want to use to provide the necessary permissions for kapp-controller to deploy the objects to the cluster.	- name: serviceAccount value: default

The `--service-account` flag sets the `spec.serviceAccountName` key in the deliverable object. To configure the `serviceAccount` parameter, use `--param serviceAccount=SERVICE-ACCOUNT`.

For information about custom resource details, see the ImageRepository reference documentation.

app deployer

The `app-deploy` resource in the ClusterDelivery applies the Kubernetes configuration that is built by the supply chain, pushed to either a Git repository or image repository, and applied to the cluster.

App

Regardless of where the configuration comes from, an App object is instantiated to deploy the set of Kubernetes configuration files to the cluster.

Parameters:

Parameter name	Meaning	Example
`serviceAccount`	The name of the service account, in the same namespace as the deliverable, you want to use to provide the necessary privileges for `App` to apply the Kubernetes objects to the cluster.	- name: serviceAccount value: default
`gitops_sub_path` (deprecated)	The subdirectory within the configuration bundle used for looking up the files to apply to the Kubernetes cluster.	- name: gitops_sub_path value: ./config

The `gitops_sub_path` parameter is deprecated. Use `deliverable.spec.source.subPath` instead.

The `--service-account` flag sets the `spec.serviceAccountName` key in the deliverable object.

To configure the `serviceAccount` parameter, use `--param serviceAccount=SERVICE-ACCOUNT`.

For details about RBAC and how `kapp-controller` uses the ServiceAccount provided to it using the `serviceAccount` parameter in the `deliverable` object, see kapp-controller's Security Model in the Carvel documentation.

Troubleshoot Tanzu Application Platform

These topics provide you with troubleshooting information to help resolve issues with your Tanzu Application Platform (commonly known as TAP):

- Troubleshoot installing Tanzu Application Platform
- Troubleshoot using Tanzu Application Platform
- Troubleshoot Tanzu Application Platform components
- Troubleshoot Tanzu GitOps Reference Implementation (RI)

Troubleshoot Tanzu Application Platform

These topics provide you with troubleshooting information to help resolve issues with your Tanzu Application Platform (commonly known as TAP):

- Troubleshoot installing Tanzu Application Platform
- Troubleshoot using Tanzu Application Platform
- Troubleshoot Tanzu Application Platform components
- Troubleshoot Tanzu GitOps Reference Implementation (RI)

Troubleshoot installing Tanzu Application Platform

This topic tells you how to troubleshoot installing Tanzu Application Platform (commonly known as TAP).

Developer cannot be verified when installing Tanzu CLI on macOS

You see the following error when you run Tanzu CLI commands, for example `tanzu version`, on macOS:

```
"tanzu" cannot be opened because the developer cannot be verified
```

Explanation

Security settings are preventing installation.

Solution

To resolve this issue:

1. Click **Cancel** in the macOS prompt window.
2. Open **System Preferences** > **Security & Privacy**.
3. Click **General**.
4. Next to the warning message for the Tanzu binary, click **Allow Anyway**.

5. Enter your system username and password in the macOS prompt window to confirm the changes.
6. In the terminal window, run:

   ```
   tanzu version
   ```

7. In the macOS prompt window, click **Open**.

Access `.status.usefulErrorMessage` details

When installing Tanzu Application Platform, you receive an error message that includes the following:

```
(message: Error (see .status.usefulErrorMessage for details))
```

Explanation

A package fails to reconcile and you must access the details in `.status.usefulErrorMessage`.

Solution

Access the details in `.status.usefulErrorMessage` by running:

```
kubectl get packageinstall PACKAGE-NAME -n tap-install -o yaml
```

Where `PACKAGE-NAME` is the name of the package to target.

“Unauthorized to access” error

When running the `tanzu package install` command, you receive an error message that includes the error:

```
UNAUTHORIZED: unauthorized to access repository
```

For example:

```
$ tanzu package install app-live-view -p appliveview.tanzu.vmware.com -v 0.1.0 -n tap-
install --values-file ./app-live-view.yaml

Error: package reconciliation failed: vendir: Error: Syncing directory '0':
  Syncing directory '.' with imgpkgBundle contents:
    Imgpkg: exit status 1 (stderr: Error: Checking if image is bundle: Collecting imag
es: Working with registry.tanzu.vmware.com/app-live-view/application-live-view-install
-bundle@sha256:b13b9ba81bcc985d76607cfc04bcbb8829b4cc2820e64a99e0af840681da12aa: GET h
ttps://registry.tanzu.vmware.com/v2/app-live-view/application-live-view-install-bundl
e/manifests/sha256:b13b9ba81bcc985d76607cfc04bcbb8829b4cc2820e64a99e0af840681da12aa: U
NAUTHORIZED: unauthorized to access repository: app-live-view/application-live-view-in
stall-bundle, action: pull: unauthorized to access repository: app-live-view/applicati
on-live-view-install-bundle, action: pull
```

Note

This example shows an error received when with Application Live View as the package. This error can also occur with other packages.

Explanation

The Tanzu Network credentials needed to access the package may be missing or incorrect.

Solution

To resolve this issue:

1. Repeat the step to create a secret for the namespace. For instructions, see Add the Tanzu Application Platform Package Repository in *Installing the Tanzu Application Platform Package and Profiles*. Ensure that you provide the correct credentials.

   When the secret has the correct credentials, the authentication error should resolve itself and the reconciliation succeed. Do not reinstall the package.

2. List the status of the installed packages to confirm that the reconcile has succeeded. For instructions, see Verify the Installed Packages in *Installing Individual Packages*.

"Serviceaccounts already exists" error

When running the `tanzu package install` command, you receive the following error:

```
failed to create ServiceAccount resource: serviceaccounts already exists
```

For example:

```
$ tanzu package install app-accelerator -p accelerator.apps.tanzu.vmware.com -v 0.2.0
-n tap-install --values-file app-accelerator-values.yaml

Error: failed to create ServiceAccount resource: serviceaccounts "app-accelerator-tap-
install-sa" already exists
```

Note

This example shows an error received with App Accelerator as the package. This error can also occur with other packages.

Explanation

The `tanzu package install` command may be executed again after failing.

Solution

To update the package, run the following command after the first use of the `tanzu package install` command

```
tanzu package installed update
```

After package installation, one or more packages fails to reconcile

You run the `tanzu package install` command and one or more packages fails to install.

For example:

```
tanzu package install tap -p tap.tanzu.vmware.com -v 0.4.0 -n tap-install --values-fil
e tap-values.yaml
- Installing package 'tap.tanzu.vmware.com'
\ Getting package metadata for 'tap.tanzu.vmware.com'
| Creating service account 'tap-tap-install-sa'
/ Creating cluster admin role 'tap-tap-install-cluster-role'
| Creating cluster role binding 'tap-tap-install-cluster-rolebinding'
| Creating secret 'tap-tap-install-values'
```

```
| Creating package resource
- Waiting for 'PackageInstall' reconciliation for 'tap'
/ 'PackageInstall' resource install status: Reconciling
| 'PackageInstall' resource install status: ReconcileFailed

Please consider using 'tanzu package installed update' to update the installed package
with correct settings

Error: resource reconciliation failed: kapp: Error: waiting on reconcile packageinstal
l/tap-gui (packaging.carvel.dev/v1alpha1) namespace: tap-install:
  Finished unsuccessfully (Reconcile failed:  (message: Error (see .status.usefulError
Message for details))). Reconcile failed: Error (see .status.usefulErrorMessage for de
tails)
Error: exit status 1
```

Explanation

Often, the cause is one of the following:

- Your infrastructure provider takes longer to perform tasks than the timeout value allows.
- A race-condition between components exists. For example, a package that uses `Ingress` completes before the shared Tanzu ingress controller becomes available.

The VMware Carvel tools kapp-controller continues to try in a reconciliation loop in these cases. However, if the reconciliation status is `failed` then there might be a configuration issue in the provided `tap-config.yaml` file.

Solution

1. Verify if the installation is still in progress by running:

   ```
   tanzu package installed list -A
   ```

   If the installation is still in progress, the command produces output similar to the following example, and the installation is likely to finish successfully.

   ```
   \ Retrieving installed packages...
     NAME                       PACKAGE-NAME
   PACKAGE-VERSION  STATUS               NAMESPACE

119m
```

In this example, `packageinstall/grype` and `packageinstall/tap` have reconciliation errors.

2. To get more details on the possible cause of a reconciliation failure, run:

   ```
   kubectl describe packageinstall/NAME -n tap-install
   ```

   Where `NAME` is the name of the failing package. For this example it would be `grype`.

3. Use the displayed information to search for a relevant troubleshooting issue in this topic. If none exists, and you are unable to fix the described issue yourself, please contact support.

4. Repeat these diagnosis steps for any other packages that failed to reconcile.

Failure to accept an End User License Agreement error

You cannot access Tanzu Application Platform or one of its components from VMware Tanzu Network.

Explanation

You cannot access Tanzu Application Platform or one of its components from VMware Tanzu Network before accepting the relevant EULA in VMware Tanzu Network.

Solution

Follow the steps in Accept the End User License Agreements in *Installing the Tanzu CLI*.

Ingress is broken on Kind cluster

Your Contour installation cannot provide ingress to workloads when installed on a Kind cluster without a LoadBalancer solution. Your Kind cluster was created with port mappings.

Explanation

In Tanzu Application Platform v1.9.1, the default configuration for `contour.envoy.service.type` is `LoadBalancer`. However, for the Envoy pods to be accessed by using the port mappings on your Kind cluster, the service must be of type `NodePort`.

Solution

Configure `contour.evnoy.service.type` to be `NodePort`. Then, configure `envoy.service.nodePorts.http` and `envoy.service.nodePorts.https` to the corresponding port mappings on your Kind node. Otherwise, the NodePort service is assigned random ports, which are not accessible through your Kind cluster.

Service binding package fails to reconcile

You receive the following error message when deploying or upgrading to Tanzu Application Platform v1.9:

```
ValidationError(Package.spec.template.spec.template[0].ytt.valuesFrom[0]): unknown fie
ld "downwardAPI"
```

Explanation

The version of Cluster Essentials is not supported. To deploy successfully, the `servicebinding.tanzu.vmware.com` package requires Cluster Essentials `v1.3.0` or later.

Solution

Upgrade to Cluster Essentials v1.9. For more information about the upgrade procedures, see the Cluster Essentials documentation.

Reconciliation fails with Supply Chain Security Tools - Scan 2.0 upgrade

When deploying Supply Chain Security Tools - Scan 2.0 `app-scanning.apps.tanzu.vmware.com` to a cluster and upgrading Tanzu Application Platform from v1.6 to v1.7 or later, you might encounter a reconciliation error as follows:

```
Expected to find at least one version, but did not (details: all=1 ->
      after-prereleases-filter=1 -> after-kapp-controller-version-check=1 -> after-con
straints-filter=0)
```

Explanation

The upgrade instructions overwrite the Tanzu Application Platform v1.6 repository with the 1.7 version or later, which leads to a reconciliation error.

Solution

You can resolve this issue by using either of the following two solutions:

1. Upgrade `app-scanning.apps.tanzu.vmware.com` to v0.2.1.
2. Add a new package repository with Tanzu Application Platform v1.6.

Troubleshoot using Tanzu Application Platform

This topic tells you how to troubleshoot using Tanzu Application Platform (commonly known as TAP).

Use events to find possible causes

Events can highlight issues with components in a supply chain. For example, high occurrences of `StampedObjectApplied` or `ResourceOutputChanged` can indicate problems with trashing on a component.

To view the recent events for a workload, run:

```
kubectl describe workload.carto.run <workload-name> -n <workload-ns>
```

Missing build logs after creating a workload

Symptom:

You create a workload, but no logs appear when you run:

```
tanzu apps workload tail workload-name --since 10m --timestamp
```

Explanation:

Common causes include:

- Misconfigured repository
- Misconfigured service account
- Misconfigured registry credentials

Solution:

To resolve this issue, run:

```
kubectl get clusterbuilder.kpack.io -o yaml
```

```
kubectl get image.kpack.io <workload-name> -o yaml
```

```
kubectl get build.kpack.io -o yaml
```

Workload creation stops responding with “Builder default is not ready” message

Symptom:

You can see the “Builder default is not ready” message in either of two places:

1. The “Messages” section of the `tanzu apps workload get my-app` command.
2. The Supply Chain section of Tanzu Developer Portal.

This message indicates there is something wrong with the Builder (the component that builds the container image for your workload).

Explanation:

This message is typically encountered when the core component of the Builder (`kpack`) transitions into a bad state.

Although this isn’t the only scenario where this can happen, `kpack` can transition into a bad state when Tanzu Application Platform is deployed to a local `kind` cluster, and especially when that `kind` cluster is restarted.

Solution:

1. Restart `kpack` by deleting the `kpack-controller` and `kpack-webhook` pods in the `kpack` namespace. Deleting these resources triggers their recreation:
    - `kubectl delete pods --all --namespace kpack`
2. Verify status of the replacement pods:
    - `kubectl get pods --namespace kpack`
3. Verify the workload status after the new kpack pods `STATUS` are `Running`:
    - `tanzu apps workload get YOUR-WORKLOAD-NAME`

“Workload already exists” error after updating the workload

Symptom:

When you update the workload, you receive the following error:

```
Error: workload "default/APP-NAME" already exists
Error: exit status 1
```

Where `APP-NAME` is the name of the app.

For example, when you run:

```
tanzu apps workload create tanzu-java-web-app \
--git-repo https://github.com/dbuchko/tanzu-java-web-app \
--git-branch main \
--type web \
--label apps.tanzu.vmware.com/has-tests=true \
--yes
```

You receive the following error

```
Error: workload "default/tanzu-java-web-app" already exists
Error: exit status 1
```

Explanation:

The app is running before performing a Live Update using the same app name.

Solution:

To resolve this issue, either delete the app or use a different name for the app.

Workload creation fails due to authentication failure in Docker Registry

Symptom:

You might encounter an error message similar to the following when creating or updating a workload by using IDE or `apps` CLI plug-in:

```
Error: Writing 'index.docker.io/shaileshp2922/build-service/tanzu-java-web-app:lates
t': Error while preparing a transport to talk with the registry: Unable to create roun
d tripper: GET https://auth.ipv6.docker.com/token?scope=repository%3Ashaileshp2922%2Fb
uild-service%2Ftanzu-java-web-app%3Apush%2Cpull&service=registry.docker.io: unexpected
status code 401 Unauthorized: {"details":"incorrect username or password"}
```

Explanation:

This type of error frequently occurs when the URL set for `source image` (IDE) or `--source-image` flag (`apps` CLI plug-in) is not Docker registry compliant.

Solution:

1. Verify that you can authenticate directly against the Docker registry and resolve any failures by running:

   ```
   docker login -u USER-NAME
   ```

2. Verify your `--source-image` URL is compliant with Docker.

   The URL in this example `index.docker.io/shaileshp2922/build-service/tanzu-java-web-app` includes nesting. Docker registry, unlike many other registry solutions, does not support nesting.

3. To resolve this issue, you must provide an unnested URL. For example, `index.docker.io/shaileshp2922/tanzu-java-web-app`

Telemetry component logs show errors fetching the “reg-creds” secret

Symptom:

When you view the logs of the `tap-telemetry` controller by running `kubectl logs -n tap-telemetry <tap-telemetry-controller-<hash> -f`, you see the following error:

```
"Error retrieving secret reg-creds on namespace tap-telemetry","error":"secrets \"reg-
creds\" is forbidden: User \"system:serviceaccount:tap-telemetry:controller\" cannot g
et resource \"secrets\" in API group \"\" in the namespace \"tap-telemetry\""
```

Explanation:

The `tap-telemetry` namespace misses a role that allows the controller to list secrets in the `tap-telemetry` namespace. For more information about roles, see Role and ClusterRole Kubernetes documentation.

Solution:

To resolve this issue, run:

```
kubectl patch roles -n tap-telemetry tap-telemetry-controller --type='json' -p='[{"o
p": "add", "path": "/rules/-", "value": {"apiGroups": [""],"resources": ["secrets"],"v
erbs": ["get", "list", "watch"]} }]'
```

Debug convention might not apply

Symptom:

If you upgrade from Tanzu Application Platform v0.4, the debug convention can not apply to the app run image.

Explanation:

The Tanzu Application Platform v0.4 lacks SBOM data.

Solution:

Delete existing app images that were built using Tanzu Application Platform v0.4.

Execute bit not set for App Accelerator build scripts

Symptom:

You cannot execute a build script provided as part of an accelerator.

Explanation:

Build scripts provided as part of an accelerator do not have the execute bit set when a new project is generated from the accelerator.

Solution:

Explicitly set the execute bit by running the `chmod` command:

```
chmod +x BUILD-SCRIPT-NAME
```

Where `BUILD-SCRIPT-NAME` is the name of the build script.

For example, for a project generated from the “Spring PetClinic” accelerator, run:

```
chmod +x ./mvnw
```

“No live information for pod with ID” error

Symptom:

After deploying Tanzu Application Platform workloads, Tanzu Developer Portal shows a “No live information for pod with ID” error.

Explanation:

The connector must discover the application instances and render the details in Tanzu Application Platform GUI.

Solution:

Recreate the Application Live View connector pod by running:

```
kubectl -n app-live-view delete pods -l=name=application-live-view-connector
```

This allows the connector to discover the application instances and render the details in Tanzu Application Platform GUI.

“image-policy-webhook-service not found” error

Symptom:

When installing a Tanzu Application Platform profile, you receive the following error:

```
Internal error occurred: failed calling webhook "image-policy-webhook.signing.apps.tanzu.vmware.com": failed to call webhook: Post "https://image-policy-webhook-service.image-policy-system.svc:443/signing-policy-check?timeout=10s": service "image-policy-webhook-service" not found
```

Explanation:

The “image-policy-webhook-service” service cannot be found.

Solution:

Redeploy the `trainingPortal` resource.

“Increase your cluster resources” error

Symptom:

You receive an “Increase your cluster’s resources” error.

Explanation:

Node pressure can be caused by an insufficient number of nodes or a lack of resources on nodes necessary to deploy the workloads.

Solution:

Follow instructions from your cloud provider to scale out or scale up your cluster.

CrashLoopBackOff from password authentication fails

Symptom:

SCST - Store does not start. You see the following error in the `metadata-store-app` Pod logs:

```
$ kubectl logs pod/metadata-store-app-* -n metadata-store -c metadata-store-app
...
[error] failed to initialize database, got error failed to connect to `host=metadata-store-db user=metadata-store-user database=metadata-store`: server error (FATAL: password authentication failed for user "metadata-store-user" (SQLSTATE 28P01))
```

Explanation:

The database password has changed between deployments. This is not supported.

Solution:

Redeploy the app either with the original database password or follow the latter steps to erase the data on the volume:

1. Deploy `metadata-store app` with kapp.
2. Verify that the `metadata-store-db-*` pod fails.
3. Run:

```
kubectl exec -it metadata-store-db-KUBERNETES-ID -n metadata-store /bin/bash
```

Where `KUBERNETES-ID` is the ID generated by Kubernetes and appended to the pod name.

4. To delete all database data, run:

   ```
   rm -rf /var/lib/postgresql/data/*
   ```

   This is the path found in `postgres-db-deployment.yaml`.

5. Delete the `metadata-store` app with kapp.
6. Deploy the `metadata-store` app with kapp.

Password authentication fails

Symptom:

SCST - Store does not start. You see the following error in the `metadata-store-app` pod logs:

```
$ kubectl logs pod/metadata-store-app-* -n metadata-store -c metadata-store-app
...
[error] failed to initialize database, got error failed to connect to `host=metadata-s
tore-db user=metadata-store-user database=metadata-store`: server error (FATAL: passwo
rd authentication failed for user "metadata-store-user" (SQLSTATE 28P01))
```

Explanation

The database password has changed between deployments. This is not supported.

Solution:

Redeploy the app either with the original database password or follow the latter steps to erase the data on the volume:

1. Deploy `metadata-store app` with kapp.
2. Verify that the `metadata-store-db-*` pod fails.
3. Run:

   ```
   kubectl exec -it metadata-store-db-KUBERNETES-ID -n metadata-store /bin/bash
   ```

   Where `KUBERNETES-ID` is the ID generated by Kubernetes and appended to the pod name.

4. To delete all database data, run:

   ```
   rm -rf /var/lib/postgresql/data/*
   ```

   This is the path found in `postgres-db-deployment.yaml`.

5. Delete the `metadata-store` app with kapp.
6. Deploy the `metadata-store` app with kapp.

`metadata-store-db` pod fails to start

Symptom:

When SCST - Store is deployed, deleted, and then redeployed, the `metadata-store-db` pod fails to start if the database password changed during redeployment.

Explanation:

The persistent volume used by `PostgreSQL` retains old data, even though the retention policy is set to `DELETE`.

Solution:

Redeploy the app either with the original database password or follow the later steps to erase the data on the volume:

1. Deploy `metadata-store app` with kapp.
2. Verify that the `metadata-store-db-*` pod fails.
3. Run:

   ```
   kubectl exec -it metadata-store-db-KUBERNETES-ID -n metadata-store /bin/bash
   ```

   Where `KUBERNETES-ID` is the ID generated by Kubernetes and appended to the pod name.
4. To delete all database data, run:

   ```
   rm -rf /var/lib/postgresql/data/*
   ```

   This is the path found in `postgres-db-deployment.yaml`.
5. Delete the `metadata-store` app with kapp.
6. Deploy the `metadata-store` app with kapp.

Missing persistent volume

Symptom:

After SCST - Store is deployed, `metadata-store-db` pod fails for missing volume while `postgres-db-pv-claim` pvc is in the `PENDING` state.

Explanation:

The cluster where SCST - Store is deployed does not have `storageclass` defined. The provisioner of `storageclass` is responsible for creating the persistent volume after `metadata-store-db` attaches `postgres-db-pv-claim`.

Solution:

1. Verify that your cluster has `storageclass` by running:

   ```
   kubectl get storageclass
   ```
2. Create a `storageclass` in your cluster before deploying SCST - Store. For example:

   ```
   # This is the storageclass that Kind uses
   kubectl apply -f https://raw.githubusercontent.com/rancher/local-path-provision
   er/master/deploy/local-path-storage.yaml

   # set the storage class as default
   kubectl patch storageclass local-path -p '{"metadata": {"annotations":{"storage
   class.kubernetes.io/is-default-class":"true"}}}'
   ```

Failure to connect Tanzu CLI to AWS EKS clusters

Symptom:

When using the Tanzu CLI to connect to AWS EKS clusters, you might see one of the following errors:

- `Error: Unable to connect: connection refused. Confirm kubeconfig details and try again`
- `invalid apiVersion "client.authentication.k8s.io/v1alpha1"`

Explanation:

The cause is Kubernetes v1.24 dropping support for `client.authentication.k8s.io/v1alpha1`. For more information, see aws/aws-cli/issues/6920 in GitHub.

Solution:

Follow these steps to update your `aws-cli` to a supported v2.7.35 or later, and update the `kubeconfig` entry for your EKS clusters:

1. Update `aws-cli` to the latest version. For more information see AWS documentation.
2. Update the `kubeconfig` entry for your EKS clusters:

   ```
   aws eks update-kubeconfig --name ${EKS_CLUSTER_NAME} --region ${REGION}
   ```

3. In a new terminal window, run a Tanzu CLI command to verify the connection issue is resolved. For example:

   ```
   tanzu apps workload list
   ```

   Expect the command to execute without error.

Invalid repository paths are propagated

Symptom:

When inputting `shared.image_registry.project_path`, invalid repository paths are propagated.

Explanation:

The key `shared.image_registry.project_path`, which takes input as `SERVER-NAME/REPO-NAME`, cannot take “/” at the end of the string.

Solution:

Do not append “/” to the end of the string.

---

x509: certificate signed by unknown authority

Explanation:

Tanzu Application Platform v1.4 introduces Shared Ingress Issuer to secure ingress communication by default. The Certificate Authority for Shared Ingress Issuer is generated as self-signed. As a result, you might see one of the following errors:

- `connection refused`
- `x509: certificate signed by unknown authority`

Solution:

You can choose one of the following options to mitigate the issue:

Option 1: Configure the Shared Ingress Issuer's Certificate Authority as a trusted Certificate Authority

Important

This is the recommended option for a secure instance.

Follow these steps to trust the Shared Ingress Issuer's Certificate Authority in Tanzu Application Platform:

1. Extract the ClusterIssuer's Certificate Authority.

   For default installations where `ingress_issuer` is not set in `tap_values.yml`, you can extract the ClusterIssuer's Certificate Authority from cert-manager:

   ```
   kubectl get secret tap-ingress-selfsigned-root-ca -n cert-manager -o yaml | yq
   .data | cut -d' ' -f2 | head -1 | base64 -d
   ```

   If you overrode the default `ingress_issuer` while installing Tanzu Application Platform, you must refer to your issuer's documentation to extract your ClusterIssuer's Certificate Authority instead of using the command above.

2. Add the certificate to the list of trusted certificate authorities by appending the certificate authority to the `shared.ca_cert_data` field in your `tap-values.yml`.

3. Reapply your configuration:

   ```
   tanzu package install tap -p tap.tanzu.vmware.com -v ${TAP_VERSION} --values-fi
   le tap-values.yml -n tap-install
   ```

Option 2: Deactivate the shared ingress issuer

Important

This option is recommended for testing purposes only.

Follow these steps to deactivate TLS for Cloud Native Runtimes, AppSSO and Tanzu Developer Portal:

1. Set `shared.ingress_issuer` to `""` in your `tap-values.yml`:

   ```
   shared:
     ingress_issuer: ""
   ```

2. Reapply your configuration:

   ```
   tanzu package install tap -p tap.tanzu.vmware.com -v ${TAP_VERSION} --values-fi
   le tap-values.yml -n tap-install
   ```

Datadog agent cannot reconcile webhook on AKS

Symptom:

On Azure Kubernetes Service (AKS), you receive an error because the Datadog Cluster Agent cannot reconcile the webhook.

Solution:

> **Note**
>
> This workaround deactivates the admission controller, which might have implications for certain features. See the Datadog documentation or contact support for guidance based on your specific use case.

To work around this issue:

1. Create a custom values file for Datadog named `values.yaml`.
2. Enter the following YAML into your `values.yaml` file, which sets `clusterAgent.admissionController` to `false` and sets the environment variable `DD_ADMISSION_CONTROLLER_ADD_AKS_SELECTORS` to `true`:

   ```
   clusterAgent:
     admissionController:
       enabled: false
     env:
       - name: "DD_ADMISSION_CONTROLLER_ADD_AKS_SELECTORS"
         value: "true"
   ```

3. Install the Datadog Agent Helm chart with your custom `values.yaml` file:

   ```
   helm upgrade --install datadog-operator datadog/datadog-operator -f values.yaml
   ```

Troubleshoot Tanzu Application Platform components

Troubleshoot Tanzu GitOps Reference Implementation (RI)

This topic tells you how to troubleshoot Tanzu GitOps Reference Implementation (commonly known as RI).

Tanzu Sync application error

After the Tanzu Sync application is installed in the cluster, the main resource to check is the sync app in the `tanzu-sync` namespace:

```
kubectl -n tanzu-sync get app/sync --template='{{.status.usefulErrorMessage}}'
```

Example error:

```
kapp: Error: waiting on reconcile packageinstall/tap (packaging.carvel.dev/v1alpha1) n
amespace: tap-install:
  Finished unsuccessfully (Reconcile failed:  (message: Error (see .status.usefulError
Message for details)))
```

This indicates that the resource `packageinstall/tap` in the namespace `tap-install` failed. See the following section for the solution details.

Tanzu Application Platform install error

After the Tanzu Sync application is installed in the cluster, the Tanzu Application Platform starts to install. The resource to check is the Tanzu Application Platform package install in the `tap-install` namespace:

```
kubectl -n tap-install get packageinstall/tap --template='{{.status.usefulErrorMessag
e}}'
```

Common errors

You might encounter one of the following errors:

Given data value is not declared in schema

Error: Reconciliation fails with `Given data value is not declared in schema`

```
^ Reconcile failed:  (message: ytt: Error: Overlaying data values (in following order:
tap-install/.tanzu-managed/version.yaml, additional data values):
One or more data values were invalid
====================================

Given data value is not declared in schema
tap-values.yaml:
    |
  1 | shared:
    |

    = found: shared
    = expected: a map item with the key named "tap_install" (from tap-install/.tanzu-m
anaged/schema--tap-sensitive-values.yaml:3)
```

Problem: The values files were not generated according to the expected schema.

Solution: Ensure both non-sensitive and sensitive Tanzu Application Platform values files to adhere to the schema described in configure values.

Incorrect values example:

```
shared:
  ingress_domain: example.vmware.com
```

Correct values example:

```
tap_install:
  values:
    ingress_domain: example.vmware.com
```

`ExternalSecret` not found

Error: Reconciliation of `ExternalSecret` fails with `secret not found`

Example:

```
kubectl describe ExternalSecret install-registry-dockerconfig -n tanzu-sync

Status:
  Conditions:
    Last Transition Time:  2023-07-20T08:14:04Z
    Message:               could not get secret data from provider
    Reason:                SecretSyncedError
    Status:                False
    Type:                  Ready
Events:
  Type     Reason         Age                   From              Message
  ----     ------         ----                  ----              -------
  Warning  UpdateFailed  12s (x15 over 6m14s)  external-secrets  secret not found
```

- **Problem 1:** Incorrect secret reference

  Solution 1: Ensure the references in `tanzu-sync/app/values/tanzu-sync-vault-values.yaml` and `cluster-config/values/tap-install-vault-values.yaml` are correct.

- **Problem 2:** Incorrect configuration of the secret engine for Vault

  Solution 2: Validate and update the version of the Vault secrets engine configuration to `v1` or `v2`. By default, `v2` is chosen.

  Update `tanzu-sync/app/values/tanzu-sync-vault-values.yaml`:

  ```
  ---
  secrets:
    eso:
      vault:
        ...
        version: "v1" # v1 or v2
  ```

  Update `cluster-config/values/tap-install-vault-values.yaml`:

  ```
  ---
  tap_install:
    secrets:
      eso:
        vault:
          ...
          version: "v1" # v1 or v2
  ```

Error occurs when deleting Kubernetes authentication

Problem: The following error occurs when deleting Kubernetes authentication:

```
./tanzu-sync/vault/scripts/setup/delete-kubernetes-auth.sh
flag provided but not defined: -path
```

Cause: The command to disable vault authentication is incorrect.

Solution: Update the command `vault auth disable -path=$CLUSTER_NAME kubernetes` to `vault auth disable $CLUSTER_NAME` in the file `./tanzu-sync/vault/scripts/setup/delete-kubernetes-auth.sh`

Uninstall your Tanzu Application Platform by using Tanzu CLI

This document tells you how to uninstall Tanzu Application Platform (commonly known as TAP) packages from your Tanzu Application Platform package repository by using Tanzu CLI.

To uninstall Tanzu Application Platform:

- Delete the Packages
- Delete the Tanzu Application Platform Package Repository
- Remove Tanzu CLI, plug-ins, and associated files
- Remove Cluster Essentials

Delete the packages

- If you installed Tanzu Application Platform through predefined profiles, delete the `tap` metadata package by running:

  ```
  tanzu package installed delete tap --namespace tap-install
  ```

- If you installed any additional packages that were not in the predefined profiles, delete the individual packages by running:

  1. List the installed packages by running:

     ```
     tanzu package installed list --namespace tap-install
     ```

  2. Remove a package by running:

     ```
     tanzu package installed delete PACKAGE-NAME --namespace tap-install
     ```

     For example:

     ```
     $ tanzu package installed delete cloud-native-runtimes --namespace tap-in
     stall
     | Uninstalling package 'cloud-native-runtimes' from namespace 'tap-instal
     l'
     / Getting package install for 'cloud-native-runtimes'
     \ Deleting package install 'cloud-native-runtimes' from namespace 'tap-in
     stall'
     \ Package uninstall status: Reconciling
     / Package uninstall status: Deleting
     | Deleting admin role 'cloud-native-runtimes-tap-install-cluster-role'
     | Deleting role binding 'cloud-native-runtimes-tap-install-cluster-rolebi
     nding'
     | Deleting secret 'cloud-native-runtimes-tap-install-values'
     / Deleting service account 'cloud-native-runtimes-tap-install-sa'

      Uninstalled package 'cloud-native-runtimes' from namespace 'tap-install'
     ```

     Where `PACKAGE-NAME` is the name of a package listed in step 1.

3. Repeat step 2 for each individual package installed.

Delete the Tanzu Application Platform package repository

To delete the Tanzu Application Platform package repository:

1. Retrieve the name of the Tanzu Application Platform package repository by running:

   ```
   tanzu package repository list --namespace tap-install
   ```

   For example:

   ```
   $ tanzu package repository list --namespace tap-install
   - Retrieving repositories...
     NAME                  REPOSITORY
   STATUS               DETAILS
     tanzu-tap-repository  registry.tanzu.vmware.com/tanzu-application-platform/ta
   p-packages:0.2.0  Reconcile succeeded
   ```

2. Remove the Tanzu Application Platform package repository by running:

   ```
   tanzu package repository delete PACKAGE-REPO-NAME --namespace tap-install
   ```

   Where `PACKAGE-REPO-NAME` is the name of the packageRepository from the earlier step.

   For example:

   ```
   $ tanzu package repository delete tanzu-tap-repository --namespace tap-install
   - Deleting package repository 'tanzu-tap-repository'...
    Deleted package repository 'tanzu-tap-repository' in namespace 'tap-install'
   ```

Remove Tanzu CLI, plug-ins, and associated files

To completely remove the Tanzu CLI, plug-ins, and associated files, run the script for your OS:

- For Linux or MacOS, run:

  ```
  #!/bin/zsh
  rm -rf $HOME/tanzu/cli        # Remove previously downloaded cli files
  sudo rm /usr/local/bin/tanzu  # Remove CLI binary (executable)
  rm -rf ~/.config/tanzu/       # current location # Remove config directory
  rm -rf ~/.tanzu/              # old location # Remove config directory
  rm -rf ~/.cache/tanzu         # remove cached catalog.yaml
  rm -rf ~/Library/Application\ Support/tanzu-cli/* # Remove plug-ins
  ```

- Uninstall tanzu cli installed using package manager:
  - On mac:

    ```
    brew uninstall vmware-tanzu/tanzu/tanzu-cli
    ```

  - On Linux:

    ```
    sudo apt remove tanzu-cli
    ```

    ```
    sudo yum remove tanzu-cli
    ```

  - On Windows:

```
choco uninstall tanzu-cli
```

Remove Cluster Essentials

To completely remove Cluster Essentials, see Cluster Essentials documentation.

Remove Crossplane resources

To remove Crossplane resources, see Delete Crossplane resources when you uninstall Tanzu Application Platform.

Uninstall Tanzu Application Platform by using GitOps

This document tells you how to uninstall Tanzu Application Platform (commonly known as TAP) when installed by using GitOps.

> **Caution**
>
> Tanzu Application Platform (GitOps) is currently in beta and is intended for evaluation and test purposes only. Do not use in a production environment.

To uninstall your Tanzu Application Platform:

- Delete Tanzu Sync Application
- Delete external resources (ESO installation only)
- Remove the Tanzu CLI, plug-ins, and associated files
- Remove Cluster Essentials

Delete Tanzu Sync Application

> **Caution**
>
> - Deleting Tanzu Sync application removes all associated resources of Tanzu Application Platform on the cluster.
> - You must delete any applications that were installed manually into the `tap-install` namespace, because they might interfere with the deletion of Tanzu Application Platform.

To delete Tanzu Sync Application, run:

```
kapp delete -a tanzu-sync
```

Delete external resources from AWS Secrets Manager

To delete external resources from AWS, run:

```
cd $HOME/REPO-NAME/clusters/CLUSTER-NAME
./tanzu-sync/aws/scripts/setup/delete-irsa.sh
./tanzu-sync/aws/scripts/setup/delete-policies.sh
```

Delete external resources from Hashicorp Vault

To delete external resources from AWS, run:

```
cd $HOME/REPO-NAME/clusters/CLUSTER-NAME
./tanzu-sync/vault/scripts/setup/delete-roles.sh
./tanzu-sync/vault/scripts/setup/delete-policies.sh
./tanzu-sync/vault/scripts/setup/delete-kubernetes-auth.sh
```

Remove the Tanzu CLI, plug-ins, and associated files

To completely remove the Tanzu CLI, plug-ins, and associated files, run the following scrips for Linux or MacOS:

```
#!/bin/zsh
rm -rf $HOME/tanzu/cli         # Remove previously downloaded cli files
sudo rm /usr/local/bin/tanzu   # Remove CLI binary (executable)
rm -rf ~/.config/tanzu/        # current location # Remove config directory
rm -rf ~/.tanzu/               # old location # Remove config directory
rm -rf ~/.cache/tanzu          # remove cached catalog.yaml
rm -rf ~/Library/Application\ Support/tanzu-cli/* # Remove plug-ins
```

Remove Cluster Essentials

To completely remove Cluster Essentials, see Cluster Essentials documentation.

Glossary

This topic gives you definitions of terms used in the Tanzu Application Platform documentation.

A

Terms beginning with “A”.

Term	Definition
API Auto Registration	This Tanzu Application Platform component automates registering API specifications defined in a workload's configuration.
API portal	This Tanzu Application Platform component enables API consumers to find APIs they can use in their own applications.
API Scoring and Validation	This Tanzu Application Platform component focuses on scanning and validating OpenAPI specifications. It ensures your APIs are secure and robust by providing feedback and recommendations early on in the software development life cycle.
Application Accelerator	This Tanzu Application Platform component provides a method to create and use application project templates that codify best practices and ensure that important configurations and structures are in place. Application developers use Application Accelerator to quickly bootstrap applications.
Application Accelerator engine	The component that performs the file transformations specified in an accelerator's `accelerator.yaml` file.
Application Configuration Service	This Tanzu Application Platform component provides a Kubernetes-native experience to enable the runtime configuration of existing Spring applications that were previously leveraged by using Spring Cloud Config Server.
Application Live View	A set of Tanzu Application Platform components that provide insight and troubleshooting capability that helps application developers and application operators look inside running applications.
Application Live View APIServer	This Tanzu Application Platform component is the part of Application Live View that generates a unique token when a user receives access validation to a pod. The Application Live View connector component verifies the token against the Application Live View APIServer before proxying the actuator data from the application. This ensures that the actuator data is secured and only the user who has valid access to view the live information for the pod can retrieve the data.
Application Live View back end	This Tanzu Application Platform component is the central server for Application Live View that contains a list of registered apps. It is responsible for proxying the request to fetch the actuator information related to the app.
Application Live View connector	This Tanzu Application Platform component is the part of Application Live View that is responsible for discovering the app pods running on the Kubernetes cluster and registering the instances to the Application Live View back end for it to be observed. The Application Live View connector is also responsible for proxying the actuator queries to the app pods running in the Kubernetes cluster.
Application Live View convention server	This Tanzu Application Platform component is the part of Application Live View that provides a webhook handler for the Tanzu convention controller. The webhook handler is registered with Tanzu convention controller. The webhook handler detects supply-chain workloads running a Spring Boot. Such workloads are annotated automatically to enable Application Live View to monitor them.
Application Single Sign-On (AppSSO)	This Tanzu Application Platform component provides APIs for curating and consuming a “Single Sign-On as a service” offering on Tanzu Application Platform.

Term	Definition
Aria Operations for Applications dashboard	This Tanzu Application Platform component, powered by Aria Operations for Applications (formerly Tanzu Observability), helps you monitor the health of a cluster by showing whether the deployed Tanzu Application Platform components are behaving as expected.
Artifact Metadata Repository (AMR)	AMR Observer is a set of managed controllers that watches for relevant updates on resources of interest. When relevant events are observed, a CloudEvent is generated and sent to AMR CloudEvent Handler.
Artifact Metadata Repository (AMR) CloudEvent Handler	AMR CloudEvent Handler receives CloudEvents and stores relevant information in the Artifact Metadata Repository or Metadata Store.
Artifact Metadata Repository (AMR) Observer	A set of managed controllers that watches for relevant updates on resources of interest. When relevant events are observed, a CloudEvent is generated and sent to AMR CloudEvent Handler and relayed for storage in the metadata store.
AWS Services	This Tanzu Application Platform component provides integration with AWS. Through integration with Crossplane and Services Toolkit, you can offer services from AWS to apps teams to consume with only minimal setup and configuration required from ops teams.

B

Terms beginning with “B”.

Term	Definition
Bitnami Services	This Tanzu Application Platform component provides a set of services backed by corresponding Bitnami Helm Charts. Through integration with Crossplane and Services Toolkit, these Bitnami Services are immediately ready for apps teams to consume, with no additional setup or configuration required from ops teams.
Build Cluster	A cluster with network access to your run clusters that controls the deployment on all the run clusters.
Build profile	This Tanzu Application Platform profile is intended for the transformation of source revisions to workload revisions. Specifically, hosting workloads and Supply Chains.

C

Terms beginning with “C”.

Term	Definition
Cartographer Conventions	This Tanzu Application Platform component supports defining and applying conventions to pods. It applies these conventions to developer workloads as they are deployed to the platform.
Claim	A mechanism in which requests for service instances can be declared and fulfilled without requiring detailed knowledge of the service instances themselves.
Claimable service instance	Any service instance that you can claim using a resource claim from a namespace.
Class	The common name for a service instance class.

Term	Definition
Class claim	A type of claim that references a class from which a service instance is either selected (pool-based) or provisioned (provisioner-based).
Cloud Native Runtimes	This Tanzu Application Platform component that is a serverless application runtime for Kubernetes. It is based on Knative and runs on a single Kubernetes cluster.
Component	A distinct unit or module within Tanzu Application Platform that performs a specific function or set of functions. Components can be software-based, such as services, APIs, or libraries, or they can be configuration-based, such as profiles or settings. Each component is interoperable and plays a role in the overall functionality and extensibility of Tanzu Application Platform.
Convention controller	The convention controller provides the metadata to the convention server and executes the updates to a PodTemplateSpec in accordance with convention server's requests.
Convention server	The convention server receives and evaluates metadata associated with a workload and requests updates to the PodTemplateSpec associated with that workload. You can have one or more convention servers for a single controller instance.

D

Terms beginning with “D”.

Term	Definition
Developer Conventions	This Tanzu Application Platform component enables you to configure your workloads to support live updates and debug operations.
Dynamic provisioning	A capability of Services Toolkit in which class claims that reference provisioner-based classes are fulfilled automatically through the provisioning of new service instances.

F

Terms beginning with “F”.

Term	Definition
Full profile	This profile contains most Tanzu Application Platform packages. This includes the necessary defaults for the meta-package, or parent Tanzu Application Platform package, subordinate packages, or individual child packages.

I

Terms beginning with “I”.

Term	Definition
Iterate cluster	A cluster for “inner loop” development iteration. Developers connect to the Iterate cluster by using their IDE to rapidly iterate on new software features.
Iterate profile	This Tanzu Application Platform profile is intended for iterative application development.

L

Terms beginning with “L”.

Term	Definition
Local Application Accelerator engine server	Also known as the local engine server. The local engine server allows you to serve your accelerators with their fragments on `localhost`, including any changes you have locally. You can use the VS Code Tanzu App Accelerator extension or the Tanzu CLI Accelerator plug-in to generate new projects based on these local files.
Local Source Proxy (LSP)	This Tanzu Application Platform component serves as a proxy registry server with Open Container Initiative (OCI) compatibility. Its main purpose is to handle image push requests by forwarding them to an external registry server, which is configured through `tap-values.yaml`.

M

Terms beginning with “M”.

Term	Definition
Multicluster	A setup or architecture where multiple Kubernetes clusters are used either for geographical distribution, high availability, scalability, or separation of workloads. In Tanzu Application Platform, multicluster capabilities ensure that you can deploy, manage, and operate applications and platform services across these multiple clusters seamlessly.

N

Terms beginning with “N”.

Term	Definition
Namespace Provisioner	This Tanzu Application Platform component provides an automated way for you to provision namespaces with the resources and namespace-level privileges required for your workloads to function as intended in Tanzu Application Platform.

P

Terms beginning with “P”.

Term	Definition
Package	A package contains the resources needed to install the components needed by the cluster.
Package Repository	A centralized store or registry containing packages that users can access, retrieve, and deploy. A package repository ensures that you have a consistent and curated set of software components, which are versioned and that you can fetch to deploy on your Tanzu Application Platform installation.
Pool-based class	A type of service instance class for which claims are fulfilled by selecting a service instance from a pool.
Profile	A predefined group of Tanzu Application Platform packages that you can deploy. You can deploy the full profile, which includes most Tanzu Application Platform packages, or you can deploy a profile that includes a subset of packages intended to suit a certain use case by deploying the iterate, build, run, or view profiles. The profiles allow Tanzu Application Platform to scale across an organization's multicluster, multi-cloud, or hybrid cloud infrastructure.
Provisioned service	Any service resource that defines a `.status.binding.name` that points to a secret in the same namespace that contains credentials and connectivity information for the resource.
Provisioner-based class	A type of service instance class for which claims are fulfilled by provisioning new service instances.

R

Terms beginning with “R”.

Term	Definition
Resource claim	A type of claim that references a specific service instance.
Run Cluster	The clusters that serve as your deployment environments. They can either be Tanzu Application Platform clusters, or regular Kubernetes clusters, but they must have kapp-controller and Contour installed.
Run profile	This Tanzu Application Platform profile is intended for the transformation of workload revisions to running pods. Specifically, hosting deliveries and deliverables.

S

Terms beginning with “S”.

Term	Definition
Service	A broad, high-level term that describes something used in either the development of, or running of application workloads. It is often, but not exclusively, synonymous with the concept of a backing service as defined by the Twelve Factor App.
Service binding	A mechanism in which service instance credentials and other related connectivity information are automatically communicated to application workloads.
Service Bindings	This Tanzu Application Platform component specifies a Kubernetes-wide specification for communicating service secrets to workloads in an automated way. Service Bindings provides a proprietary package of the Service Binding for Kubernetes open source project.
Service cluster	A service cluster is applicable within the context of Service API Projection and Service Resource Replication. It is a Kubernetes cluster that has Service Resource Lifecycle APIs installed and a corresponding controller managing their life cycle.
Service instance	A service instance is an abstraction over one, or a group, of interrelated service resources that together provide the functions for a particular service. One of the service resources that make up an instance must either adhere to the definition of provisioned service, or be a secret conforming to the service binding specification for Kubernetes. This guarantees that you can claim a service and subsequently bind service instances to application workloads. You make service instances discoverable through service instance classes.
Service instance class	A service instance class is more commonly called a class. Service instance classes provide a way to describe categories of service instances. They enable service instances belonging to the class to be discovered. They come in one of two varieties: pool-based or provisioner-based.
Service Registry	This Tanzu Application Platform component provides on-demand Eureka servers for your Tanzu Application Platform (commonly known as TAP) clusters. With Service Registry, you can create Eureka servers in your namespaces and bind Spring Boot workloads to them.
Service resource	A Kubernetes resource that provides some of the functions related to a Service.
Service resource life cycle API	Any Kubernetes API that you can use to manage the life cycle—create, read, update, and delete (CRUD)—of a service resource.
Services Toolkit	This Tanzu Application Platform component provides backing for service capabilities. This includes the integration of an extensive list of cloud-based and on-prem services, through to the offering and discovery of those services, and finally to the claiming and binding of service instances to application workloads.

Term	Definition
Supply Chain Choreographer	This Tanzu Application Platform component is based on open source Cartographer. It allows App Operators to create pre-approved paths to production by integrating Kubernetes resources with the elements of their existing toolchains, for example, Jenkins.
Supply Chain Security Tools - Policy	This Tanzu Application Platform component helps you ensure that the container images in your registry are not tampered with.
Supply Chain Security Tools - Scan	This Tanzu Application Platform component lets you build and deploy secure, trusted software that complies with your corporate security requirements by using scanning and gatekeeping capabilities.
Supply Chain Security Tools - Store	This Tanzu Application Platform component saves software bills of materials (SBoMs) to a database and allows you to query for image, source code, package, and vulnerability relationships.

T

Terms beginning with “T”.

Term	Definition
Tanzu Application Platform Telemetry	This is a set of objects that collect data about the use of Tanzu Application Platform and send it back to VMware for product improvements.
Tanzu Build Service	This Tanzu Application Platform component enables you to automate container creation, management, and governance at an enterprise scale. Tanzu Build Service uses the open-source Cloud Native Buildpacks project to turn application source code into container images.
Tanzu Buildpacks	Buildpacks provide framework and runtime support for applications. Use Buildpacks to determine what dependencies are required for your applications to communicate with bound services. Tanzu Buildpacks provides a proprietary package of the Paketo Buildpacks open-source project.
Tanzu CLI	A command-line tool that connects you to Tanzu.
Tanzu CLI plug-in	Tanzu CLI has a pluggable architecture. Plug-ins extend the Tanzu CLI core with additional CLI commands. Each plug-in is an executable binary that packages a group of CLI commands.
Tanzu CLI plug-in group	Tanzu CLI commands are organized into command groups. For each Tanzu Application Platform version, there is a Tanzu CLI plug-in group.
Tanzu Developer Portal	This Tanzu Application Platform component enables developers to view apps and services running for an organization, including dependencies, relationships, technical documentation, and the service status.
Tanzu Developer Portal Configurator	This tool is used for customizing Tanzu Developer Portal with Backstage plug-ins.
Tanzu Developer Tools for IntelliJ	This extension for IntelliJ IDEA helps you develop with Tanzu Application Platform and enables you to rapidly iterate on your workloads on supported Kubernetes clusters that have Tanzu Application Platform installed.
Tanzu Developer Tools for Visual Studio	This extension for Visual Studio helps you develop with Tanzu Application Platform and enables you to rapidly iterate on your workloads on supported Kubernetes clusters that have Tanzu Application Platform installed.
Tanzu Developer Tools for VS Code	This extension for Visual Studio Code helps you develop with Tanzu Application Platform and enables you to rapidly iterate on your workloads on supported Kubernetes clusters that have Tanzu Application Platform installed.

Term	Definition
Tanzu GitOps Reference Implementation (RI)	This is built upon Carvel, which shares the same packaging APIs as Tanzu Application Platform. Carvel packaging APIs support all the GitOps features and enables a native GitOps flow.
Tanzu Service CLI plug-in	A plug-in for the Tanzu CLI used by application operators and application developers to create claims for service instances.

U

Terms beginning with “U”.

Term	Definition
Unmanaged service	The services available in the Bitnami Services package where the resulting service instances run on the cluster, that is, they are not a managed service running in the cloud.

V

Terms beginning with “V”.

Term	Definition
VMware Tanzu Application Catalog	A customizable selection of trusted, pre-packaged application components that are continuously maintained and verifiably tested for use in production environments.
View Cluster	The cluster that runs the web applications for Tanzu Application Platform.
View profile	This Tanzu Application Platform profile is intended for instances of applications related to centralized developer experiences. Specifically, Tanzu Developer Portal and Metadata Store.

W

Terms beginning with “W”.

Term	Definition
Workload cluster	A cluster that has developer-created applications running on it. A workload cluster is applicable within the context of Service API Projection and Service Resource Replication.

Component documentation for Tanzu Application Platform

Tanzu Application Platform (commonly known as TAP) is a modular platform that you can enhance by installing components. Most of the Tanzu Application Platform components are documented in this section. In some cases, a component's documentation is hosted on a separate site, and you'll find a link to it in this section.

Component documentation for Tanzu Application Platform

Tanzu Application Platform (commonly known as TAP) is a modular platform that you can enhance by installing components. Most of the Tanzu Application Platform components are documented in this section. In some cases, a component's documentation is hosted on a separate site, and you'll find a link to it in this section.

Overview of Tanzu CLI

This topic tells you about the Tanzu command-line interface (commonly known as Tanzu CLI).

Tanzu CLI

The Tanzu CLI is a command-line interface that connects you to Tanzu. For example, some functions of Tanzu CLI include:

- Configure the Tanzu CLI itself
- Install and manage packages
- Run Tanzu services and components
- Create and manage application workloads

For more information about Tanzu CLI, see the VMware Tanzu CLI documentation.

Tanzu CLI architecture

The Tanzu CLI has a pluggable architecture. Plug-ins extend the Tanzu CLI core with additional CLI commands. Use the `vmware-tap/default:v1.9` plug-in group with Tanzu Application Platform. For more information, see Install Tanzu CLI plug-ins.

The `vmware-tap/default:v1.9` plug-in group consists of the following plug-ins:

```
NAME              DESCRIPTION                                                TAR
GET      VERSION
  telemetry         configure cluster-wide settings for vmware tanzu telemetry       g
lobal      v1.1.0
  accelerator       Manage accelerators in a Kubernetes cluster                      k
ubernetes  v1.7.0
  apps              Applications on Kubernetes                                       k
ubernetes  v0.12.1
  build-service     plugin to interact with tanzu build service (tbs) crds           k
```

```
ubernetes  v1.0.0
  external-secrets  interacts with external-secrets.io resources                    k
ubernetes  v0.1.0
  insight           post & query image, package, source, and vulnerability data      k
ubernetes  v1.7.0
  package           Tanzu package management                                         k
ubernetes  v0.29.0
  secret            Tanzu secret management                                          k
ubernetes  v0.29.0
  services          Commands for working with service instances, classes and claims  k
ubernetes  v0.8.0
```

Note

The Telemetry, Package, and Secret plug-ins are not Tanzu Application Platform specific, they are common to a number of other plug-in groups, for more information, see Command Groups in the Tanzu CLI Product Documentation.

Command Reference Documentation	Release Notes
Accelerator command reference	Accelerator release notes
Apps command reference	Apps release notes
Build Service command reference	Build Service release notes
External Secrets command reference	External Secrets release notes
Insight command reference	Insight release notes
Services command reference	Services release notes

Tanzu CLI installation

To install the Tanzu CLI, see Install Tanzu CLI.

Tanzu CLI command groups

Tanzu CLI commands are organized into command groups. View a list of available command groups by running:

```
tanzu
```

The list of command groups that you see depends on which CLI plug-ins are installed on your local machine.

Install new plug-ins

Install the CLI plug-ins required for Tanzu Application Platform by running:

```
tanzu plugin install --group vmware-tap/default:v1.9
```

Plug-ins for the Tanzu CLI are distributed by using a centralized plug-in repository.

The centralized plug-in repository contains:

- CLI plug-ins, which you can install individually

- Plug-in groups, which are a collection of plug-ins that you can install by using a single command

To discover and install plug-ins and plug-in groups:

1. Discover which plug-ins or plug-in groups are available for installation by running:

```
tanzu plugin search
```

```
tanzu plugin group search
```

> **Note**
>
> Include the `--show-details` flag to see all plug-in or group versions available for installation.

2. Install the latest version of a plug-in or plug-in group by running:

```
tanzu plugin install PLUG-IN-NAME
```

```
tanzu plugin install --group GROUP-NAME
```

3. Install a specific version of a plug-in or plug-in group by running:

```
tanzu plugin install PLUG-IN-NAME --version VERSION
```

```
tanzu plugin install --group GROUP-NAME:VERSION
```

Overview of Tanzu CLI

This topic tells you about the Tanzu command-line interface (commonly known as Tanzu CLI).

Tanzu CLI

The Tanzu CLI is a command-line interface that connects you to Tanzu. For example, some functions of Tanzu CLI include:

- Configure the Tanzu CLI itself
- Install and manage packages
- Run Tanzu services and components
- Create and manage application workloads

For more information about Tanzu CLI, see the VMware Tanzu CLI documentation.

Tanzu CLI architecture

The Tanzu CLI has a pluggable architecture. Plug-ins extend the Tanzu CLI core with additional CLI commands. Use the `vmware-tap/default:v1.9` plug-in group with Tanzu Application Platform. For more information, see Install Tanzu CLI plug-ins.

The `vmware-tap/default:v1.9` plug-in group consists of the following plug-ins:

```
NAME              DESCRIPTION                                                 TAR
GET      VERSION
```

```

Tanzu CLI installation

To install the Tanzu CLI, see Install Tanzu CLI.

Tanzu CLI command groups

Tanzu CLI commands are organized into command groups. View a list of available command groups by running:

```
tanzu
```

The list of command groups that you see depends on which CLI plug-ins are installed on your local machine.

Install new plug-ins

Install the CLI plug-ins required for Tanzu Application Platform by running:

```
tanzu plugin install --group vmware-tap/default:v1.9
```

Plug-ins for the Tanzu CLI are distributed by using a centralized plug-in repository.

The centralized plug-in repository contains:

- CLI plug-ins, which you can install individually
- Plug-in groups, which are a collection of plug-ins that you can install by using a single command

To discover and install plug-ins and plug-in groups:

1. Discover which plug-ins or plug-in groups are available for installation by running:

   ```
   tanzu plugin search
   ```

   ```
   tanzu plugin group search
   ```

   

   Note

   Include the `--show-details` flag to see all plug-in or group versions available for installation.

2. Install the latest version of a plug-in or plug-in group by running:

   ```
   tanzu plugin install PLUG-IN-NAME
   ```

   ```
   tanzu plugin install --group GROUP-NAME
   ```

3. Install a specific version of a plug-in or plug-in group by running:

   ```
   tanzu plugin install PLUG-IN-NAME --version VERSION
   ```

   ```
   tanzu plugin install --group GROUP-NAME:VERSION
   ```

Overview of Tanzu CLI plug-ins

The topics in this section tell you about the Tanzu CLI plug-ins in Tanzu Application Platform (commonly known as TAP).

- accelerator - The Application Accelerator Tanzu CLI plug-in includes commands for developers and operators to create and use accelerators.
- apps - This Tanzu Apps CLI plug-in provides the ability to create, view, update, and delete application workloads on any Kubernetes cluster that has the Tanzu Application Platform components installed.
- build-service - The Tanzu Build Service CLI plug-in provides the ability to view all the Tanzu Build Service resources on any Kubernetes cluster.
- insight - The Tanzu Insight CLI plug-in enables querying vulnerability, image, and package data.

Overview of Tanzu Apps CLI plug-in

This topic gives you an overview of the Tanzu Apps CLI plug-in. Use the Tanzu Apps CLI plug-in to create, view, update, and delete application workloads on any Kubernetes cluster that has the Tanzu Application Platform (commonly known as TAP) components installed.

About workloads

Tanzu Application Platform enables you to quickly build and test applications regardless of your familiarity with Kubernetes. You can turn source code into a workload that runs in a container with a URL. A workload enables you to choose application specifications, such as repository location, environment variables, and service binding.

Tanzu Application Platform can support a range of workloads, including a serverless process that starts on demand, a constellation of microservices that functions as a logical application, or a small hello-world test application.

For information about installing the Tanzu Apps CLI plug-in, see Install Tanzu Apps CLI.

Overview of Tanzu Apps CLI plug-in

This topic gives you an overview of the Tanzu Apps CLI plug-in. Use the Tanzu Apps CLI plug-in to create, view, update, and delete application workloads on any Kubernetes cluster that has the Tanzu Application Platform (commonly known as TAP) components installed.

About workloads

Tanzu Application Platform enables you to quickly build and test applications regardless of your familiarity with Kubernetes. You can turn source code into a workload that runs in a container with a URL. A workload enables you to choose application specifications, such as repository location, environment variables, and service binding.

Tanzu Application Platform can support a range of workloads, including a serverless process that starts on demand, a constellation of microservices that functions as a logical application, or a small hello-world test application.

For information about installing the Tanzu Apps CLI plug-in, see Install Tanzu Apps CLI.

Get started with Apps CLI plug-in

The Getting Started section contains the following topics:

- Install the Apps CLI plug-in
- Configure the Apps CLI plug-in

Install Tanzu Apps CLI plug-in

This topic tells you how to install the Tanzu Apps CLI plug-in on Tanzu Application Platform (commonly known as TAP).

Prerequisites

Ensure that you installed or updated the core Tanzu CLI. For more information, see Install Tanzu CLI.

Install Tanzu Apps CLI plug-in

Run:

```
tanzu plugin install apps --group vmware-tap/default:v1.9
```

Verify that the plug-in is installed correctly:

```
tanzu apps version
# sample output
v0.12.1
```

Uninstall Tanzu Apps CLI

Run:

```
tanzu plugin delete apps
```

Configure the Tanzu Apps CLI plug-in

This topic tells you how to configure the Tanzu Apps CLI plug-in on Tanzu Application Platform (commonly known as TAP).

Changing clusters with –context

The Tanzu Apps CLI plug-in references the default kubeconfig file to access a Kubernetes cluster. When you run a `tanzu apps` command, the Tanzu Apps CLI plug-in uses the default context. The default context is defined in the kubeconfig file located by default in: `HOME/.kube/config`.

There are two ways to change the target cluster:

1. Use `kubectl config use-context CONTEXT-NAME` to change the default context. All subsequent `tanzu apps` commands target the cluster defined in the new default kubeconfig context.
2. Include the `--context CONTEXT-NAME` flag when running any `tanzu apps` command.

Note

Any subsequent `tanzu apps` commands that do not include the `--context CONTENT-NAME` flag continue to use the default context set in the kubeconfig.

Overriding the default kubeconfig

There are two approaches to overriding the default kubeconfig:

1. To change the kubeconfig the Tanzu Apps CLI will reference, set the environment variable `KUBECONFIG=PATH` . All subsequent `tanzu apps` commands reference the non-default kubeconfig assigned to the environment variable.
2. Include the `--kubeconfig path` flag when running any `tanzu apps` command.

Note

Any subsequent `tanzu apps` commands that do not include the `--context CONTEXT-NAME` flag continue to use the default context set in the kubeconfig.

For more information about kubeconfig, see the Kubernetes documentation.

Suppressing color with –no-color flag

Most Apps Plug-in commands have emojis and colored output. In some cases, color, emojis, and other characters are not needed, such as for automated scripting, or where the misinterpretation of these features by a terminal could result in a poor user experience. Use the `--no-color` flag to suppress color, emojis, and animation.

The following example creates a workload with code from `--local-path`. The `--no-color` flag suppresses the emojis and animated upload progress bar:

```
tanzu apps workload apply my-workload --local-path path/to/my/source --type web --no-c
olor
The files and/or directories listed in the .tanzuignore file are being excluded from t
he uploaded source code.
Publishing source in "path/to/my/source" to "local-source-proxy.tap-local-source-syste
m.svc.cluster.local/source:default-my-workload""...
Published source

Create workload:
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1
      3 + |kind: Workload
      4 + |metadata:
      5 + |  annotations:
      6 + |    local-source-proxy.apps.tanzu.vmware.com: registry.io/project/source:de
fault-my-workload@sha256:447db92e289dbe3a6969521917496ff2b6b0a1d6fbff1beec3af726430ce8
493
      7 + |  labels:
      8 + |    apps.tanzu.vmware.com/workload-type: web
      9 + |  name: my-workload
     10 + |  namespace: default
     11 + |spec:
     12 + |  source:
     13 + |    image: registry.io/project/source:default-my-workload@sha256:447db92e28
9dbe3a6969521917496ff2b6b0a1d6fbff1beec3af726430ce8493
? Do you want to create this workload? [yN]:
```

Persist the suppression of color, emojis, and animation across commands by setting the `NO_COLOR` environment variable.

```
export NO_COLOR=true
```

`tanzuignore` file

Use the optional `.tanzuignore` file at the root of your project directory to indicate which files or directories in your project are not required to build or run your application such as `README.md`, .git, or docs. Including these files in your `.tanzuignore` provides the following benefits:

1. Items included in the `.tanzuignore` file are not uploaded when you upload your source code. This helps to avoid unnecessary consumption of resources.
2. When iterating on code with the `--live-update` flag enabled, changes to directories or files listed in the `.tanzuignore` file do not trigger the automatic re-deployment of source code.

The following are some guidelines for the `.tanzuignore` file:

- The `.tanzuignore` file should include a reference to itself, as it provides no value when deployed.
- Directories must not end with the system separator `/`, or `\`.
- Add comments using hashtag `#`.
- If the `.tanzuignore` file contains files or directories that are not found in the source code, they are ignored.

Example of a .tanzuignore file

```
.tanzuignore # must contain itself in order to be ignored
# This is a comment
this/is/a/folder/to/exclude

this-is-a-file.ext
```

Registry flags and environment variables

You can either trust a custom certificate on a system or pass the path to the certificate via flags. Environment variables can also be set to avoid having to pass the flags and values for every command incantation.

Below is a list of each of the flags with the corresponding environment variable equivalent in parenthesis:

- `--registry-ca-cert`: This is the path of the self-signed certificate needed for the custom or private registry (`TANZU_APPS_REGISTRY_CA_CERT`).
- `--registry-password`: Use this when the registry requires credentials to push (`TANZU_APPS_REGISTRY_PASSWORD`).
- `--registry-username`: Use with `--registry-password` to set the registry credentials (`TANZU_APPS_REGISTRY_USERNAME`).
- `--registry-token`: Set when the registry authentication is done through a token (`TANZU_APPS_REGISTRY_TOKEN`).

For example:

```
tanzu apps workload apply WORKLOAD \
--local-path PATH-TO-REPO --source-image registry.url.nip.io/PACKAGE/IMAGE \
--type web --registry-ca-cert path/to/ca/cert.nip.io.crt \
--registry-username USERNAME \
--registry-password PASSWORD
```

Alternatively, run as:

```
export TANZU_APPS_REGISTRY_CA_CERT=path/to/ca/cert.nip.io.crt
export TANZU_APPS_REGISTRY_PASSWORD=USERNAME
export TANZU_APPS_REGISTRY_USERNAME=PASSWORD

tanzu apps workload apply WORKLOAD \
--local-path PATH-TO-REPO \
--source-image registry.url.nip.io/PACKAGE/IMAGE
```

Use the `--type` flag to specify the type of workload. Persist the workload type value across commands by setting the `TANZU_APPS_TYPE` environment variable. The default value of `web` is set automatically if no `--type` flag or `TANZU_APPS_TYPE` value is provided.

```
export TANZU_APPS_TYPE=server
```

Autocompletion

The Tanzu Apps CLI plug-in provides auto-completion support for commands, positional arguments, flags, and flag values.

Add one of the following commands to the shell config file according to your setup:

Bash

```
tanzu completion bash >  HOME/.tanzu/completion.bash.inc
```

Zsh

```
echo "autoload -U compinit; compinit" >> ~/.zshrc
tanzu completion zsh > "${fpath[1]}/_tanzu"
```

Tanzu Apps CLI plug-in dependency matrix

This topic tells you which versions of Cartographer are supported in Tanzu Application Platform (commonly known as TAP).

Tanzu Application Platform Version	Apps CLI Version	Required Cartographer Version
v1.3.x	v0.9.x	v0.5.x or later
v1.4.x	v0.10.x	v0.6.x or later
v1.5.x	v0.11.x	v0.7.x or later
v1.6.x	v0.12.x	v0.7.x or later

Check Cartographer version

To see the Cartographer version installed in the cluster, run:

```
kubectl get -n tap-install packageinstalls.packaging.carvel.dev cartographer
```

Tanzu Apps CLI plug-in tutorials

This section contains the following topics:

- Create/Update a Workload
- Get Workload Status
- Delete a workload

Create or update a workload

This topic tells you how to create a workload in Tanzu Application Platform (commonly known as TAP) from a `workload.yaml` file, a URL, a Git source, a local source, and a pre-built image.

For more information about the different types of workload creation, see Supply Chain How-to-guides.

Create a workload from a `workload.yaml` file or from a URL

You can create a workload from a `workload.yaml` file or from a URL.

Create a workload from a YAML file

In many cases, workload life cycles are managed through CLI commands. However, there might be cases where managing the workload through direct interactions and edits of a `yaml` file is preferred. The Apps CLI plug-in supports using `yaml` files to meet the requirements.

When a workload is managed using a `yaml` file, that file must contain a single workload definition.

For example, a valid file looks similar to the following example:

```
---
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: tanzu-java-web-app
  labels:
    app.kubernetes.io/part-of: tanzu-java-web-app
    apps.tanzu.vmware.com/workload-type: web
spec:
  source:
    git:
      url: https://github.com/vmware-tanzu/application-accelerator-samples
      ref:
        tag: tap-1.6.0
    subPath: tanzu-java-web-app
```

To create a workload from a file like the earlier example:

```
tanzu apps workload create --file my-workload-file.yaml
```

Note

When flags are passed in combination with `--file my-workload-file.yaml` the flag values take precedence over the associated property or values in the YAML.

Create a workload from stdin

The workload `yaml` definition can also be passed in through stdin as follows:

```
tanzu apps workload create --file - --yes
```

The console waits for input, and the content with valid `yaml` definitions for a workload can either be written or pasted. Then click `Ctrl-D` three times to start the workload creation. This can also be done with the `workload apply` command.

To pass a workload through `stdin`, the `--yes` flag is required. If not provided, the command fails.

```
tanzu apps workload create -f -y
  WARNING: Configuration file update strategy is changing. By default, provided config
uration files will replace rather than merge existing configuration. The change will t
ake place in the January 2024 TAP release (use "--update-strategy" to control strategy
explicitly).

---
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: tanzu-java-web-app
  labels:
    app.kubernetes.io/part-of: tanzu-java-web-app
    apps.tanzu.vmware.com/workload-type: web
spec:
  source:
    git:
      url: https://github.com/vmware-tanzu/application-accelerator-samples
      ref:
        tag: tap-1.6.0
```

```
    subPath: tanzu-java-web-app
  Create workload:
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1
      3 + |kind: Workload
      4 + |metadata:
      5 + |  labels:
      6 + |    app.kubernetes.io/part-of: tanzu-java-web-app
      7 + |    apps.tanzu.vmware.com/workload-type: server
      8 + |  name: tanzu-java-web-app
      9 + |  namespace: default
     10 + |spec:
     11 + |  source:
     12 + |    git:
     13 + |      ref:
     14 + |        tag: tap-1.6.0
     15 + |      url: https://github.com/vmware-tanzu/application-accelerator-samples
     16 + |    subPath: tanzu-java-web-app
  Created workload "tanzu-java-web-app"

To see logs:   "tanzu apps workload tail tanzu-java-web-app --timestamp --since 1h"
To get status: "tanzu apps workload get tanzu-java-web-app"
```

Create a workload from URL

Another way to pass a workload with the `--file` flag is using a URL, which must contain a raw file with the workload definition.

Create workload from Git source

Use the `--git-repo`, `--git-branch`, `--git-tag`, and `--git-commit` flags to create a workload from an existing Git repository. This allows the supply chain to get the source from the given repository to deploy the application.

To create a named workload and specify a Git source code location, run:

```
tanzu apps workload apply tanzu-java-web-app --git-repo https://github.com/vmware-tanz
u/application-accelerator-samples --sub-path tanzu-java-web-app --git-tag tap-1.6.0 --
type web
```

Respond `Y` to prompts to complete process.

Where:

- `tanzu-java-web-app` is the name of the workload.
- `--git-repo` is the location of the code to build the workload from.
- `--sub-path` (optional) is the relative path inside the repository to treat as application root.
- `--git-tag` (optional) specifies which tag in the repository to pull the code from.
- `--git-branch` (optional) specifies which branch in the repository to pull the code from.
- `--type` distinguishes the workload type.

This process can also be done with non-publicly accessible repositories. These require authentication using credentials stored in a Kubernetes secret. The supply chain is in charge of managing these credentials.

View the full list of supported workload configuration options by running `tanzu apps workload apply --help`.

Unset Git fields

There are various ways to update a workload. Use flags to change workload fields. Use a YAML file with the required changes, and run the `tanzu apps workload apply` with the `--update-strategy` set as `replace`. For more information, see Control Workload Merge Behavior.

To delete fields, set the `--git-*` flags as empty strings within the command. This removes the `workload.spec.source.git` fields.

For example, for a workload that includes specifications such as `--git-tag`, `--git-commit` or `--git-branch`, remove these by setting them as empty strings in the command as shown in the following example:

```
# existing workload definition
---
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  labels:
    apps.tanzu.vmware.com/workload-type: web
  name: tanzu-java-web-app
  namespace: default
spec:
  source:
    git:
      ref:
        branch: main
        tag: tap-1.6.0
      url: https://github.com/vmware-tanzu/application-accelerator-samples
    subPath: tanzu-java-web-app
```

```
# Update the workload to remove one of its git fields
tanzu apps workload apply tanzu-java-web-app --git-branch ""
  Update workload:
...
  9,  9   |spec:
 10, 10   |  source:
 11, 11   |    git:
 12, 12   |      ref:
 13     - |        branch: main
 14, 13   |        tag: tap-1.6.0
 15, 14   |      url: https://github.com/vmware-tanzu/application-accelerator-samples
 16, 15   |    subPath: tanzu-java-web-app
  Really update the workload "tanzu-java-web-app"? [yN]: y
  Updated workload "tanzu-java-web-app"

To see logs:   "tanzu apps workload tail tanzu-java-web-app --timestamp --since 1h"
To get status: "tanzu apps workload get tanzu-java-web-app"

# Export the workload to see that `spec.source.git.ref.tag` is not part of the definit
ion
tanzu apps workload get tanzu-java-web-app --export
---
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  labels:
    apps.tanzu.vmware.com/workload-type: web
  name: tanzu-java-web-app
  namespace: default
spec:

```

```
      url: https://github.com/vmware-tanzu/application-accelerator-samples
    subPath: tanzu-java-web-app
```

Note

If `--git-repo` is set to empty, then the whole Git section is removed from the workload definition.

```
tanzu apps workload apply tanzu-java-web-app --git-repo ""
  Update workload:
...
  5,  5   |  labels:
  6,  6   |    apps.tanzu.vmware.com/workload-type: web
  7,  7   |  name: tanzu-java-web-app
  8,  8   |  namespace: default
  9      - |spec:
 10      - |  source:
 11      - |    git:
 12      - |      ref:
 13      - |        tag: tap-1.6.0
 14      - |      url: https://github.com/vmware-tanzu/application-accelerator-samples
 15      - |    subPath: tanzu-java-web-app
       9 + |spec: {}
  NOTICE: no source code or image has been specified for this workload.
  Really update the workload "tanzu-java-web-app"? [yN]: y
  Updated workload "tanzu-java-web-app"

To see logs:   "tanzu apps workload tail tanzu-java-web-app --timestamp --since 1h"
To get status: "tanzu apps workload get tanzu-java-web-app"

# Export the workload and check that the git source section does not exist
tanzu apps workload get tanzu-java-web-app --export
---
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  labels:
    apps.tanzu.vmware.com/workload-type: web
  name: tanzu-java-web-app
  namespace: default
spec: {}
```

Subpath

Use the `--subpath` flag to create workloads within a repository, where the repository, such as a monorepo, consists of multiple folders or projects.

```
# The Git repository for this sample contains several applications, each on its own fo
lder
tanzu apps workload apply tanzu-where-for-dinner --git-repo https://github.com/vmware-
tanzu/application-accelerator-samples --git-branch main --sub-path where-for-dinner
  Create workload:
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1
      3 + |kind: Workload
      4 + |metadata:
      5 + |  labels:
      6 + |    apps.tanzu.vmware.com/workload-type: web
      7 + |  name: tanzu-where-for-dinner
      8 + |  namespace: default
      9 + |spec:
```

```
     10 + |  source:
     11 + |    git:
     12 + |      ref:
     13 + |        branch: main
     14 + |      url: https://github.com/vmware-tanzu/application-accelerator-samples
     15 + |    subPath: where-for-dinner
  Do you want to create this workload? [yN]: y
  Created workload "tanzu-where-for-dinner"

To see logs:   "tanzu apps workload tail tanzu-where-for-dinner --timestamp --since 1
h"
To get status: "tanzu apps workload get tanzu-where-for-dinner"
```

Create a workload from Local Source

There are multiple ways to upload local source code to a Tanzu Application Platform cluster.

Using Local Source Proxy

Use Local Source Proxy to push local source code to the registry configured during Tanzu Application Platform installation.

For more information, see Install Local Source Proxy. To create a workload that pushes to an already configured registry through Local Source Proxy, use `--local-path` flag without `--source-image`, like the following example:

```
# Point the local path flag to the folder containing the source code
tanzu apps workload create tanzu-java-web-app --local-path /path/to/java/app

The files and/ directories listed in the .tanzuignore file are being excluded from t
he uploaded source code.
Publishing source in "/path/to/java/app" to "local-source-proxy.tap-local-source-sys
tem.svc.cluster.local/source:default-tanzu-java-web-app"...
  Published source

  Create workload:
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1
      3 + |kind: Workload
      4 + |metadata:
      5 + |  annotations:
      6 + |    local-source-proxy.apps.tanzu.vmware.com: registry.io/project/source:
default-tanzu-java-web-app@sha256:447db92e289dbe3a6969521917496ff2b6b0a1d6fbff1beec3
af726430ce8493
      7 + |  labels:
      8 + |    apps.tanzu.vmware.com/workload-type: web
      9 + |  name: tanzu-java-web-app
     10 + |  namespace: default
     11 + |spec:
     12 + |  source:
     13 + |    image: registry.io/project/source:default-tanzu-java-web-app@sha256:4
47db92e289dbe3a6969521917496ff2b6b0a1d6fbff1beec3af726430ce8493
  Do you want to create this workload? [yN]:
```

Note

A workload created using Local Source Proxy is easily recognizable because it has the `local-source-proxy.apps.tanzu.vmware.com` annotation with a value the same as the `spec.source.image` field.

Using Source Image

If the Local Source Proxy component is not installed, upload your local source code to a registry of your choice by passing in the `--source-image` flag. Use this flag to specify the registry path where the local source code is uploaded as an image. Both the cluster and the developer's machine must be configured to properly provide credentials for accessing the container image registry where the local source code is published to. For more information about authentication requirements, see Building from Local Source. To create a workload using a source image, use `--local-path` flag with `--source-image`, like the following example:

```
tanzu apps workload create tanzu-java-web-app --local-path /path/to/java/app --sourc
e-image registry.io/path/to/project/image-name

The files and directories listed in the .tanzuignore file are being excluded from th
e uploaded source code.
Publishing source in "." to "registry.io/path/to/project/image-name"...
  Published source

  Create workload:
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1
      3 + |kind: Workload
      4 + |metadata:
      5 + |  labels:
      6 + |    apps.tanzu.vmware.com/workload-type: web
      7 + |  name: tanzu-java-web-app
      8 + |  namespace: default
      9 + |spec:
     10 + |  source:
     11 + |    image: registry.io/path/to/project/image-name:latest@sha256:447db92e28
9dbe3a6969521917496ff2b6b0a1d6fbff1beec3af726430ce8493
  Do you want to create this workload? [yN]:
```

`--live-update`

Use the `--live-update` flag to ensure that local source code changes are reflected quickly on the running workload. This is particularly valuable when iterating on features that require the workload to be deployed and running to validate.

Live update is ideally situated for running from within one of our supported IDE extensions, but it can also be utilized independently as shown in the following Spring Boot application example:

Spring Boot application example

Prerequisites: Tilt must be installed on the client.

1. Clone the repository by running:

   ```
   git clone https://github.com/vmware-tanzu/application-accelerator-samples
   ```

2. Change into the `tanzu-java-web-app` directory.
3. In `Tiltfile`, first, change the `SOURCE_IMAGE` variable to use your registry and project.
4. At the very end of the file add:

   ```
   allow_k8s_contexts('your-cluster-name')
   ```

5. Inside the directory, run:

   ```
   tanzu apps workload apply tanzu-java-web-app --live-update --local-path . -s
   gcr.io/PROJECT/tanzu-java-web-app-live-update -y
   ```

Expected output:

```
The files and directories listed in the .tanzuignore file are being excluded fr
om the uploaded source code.
Publishing source in "." to "gcr.io/PROJECT/tanzu-java-web-app-live-update"...
  Published source

  Create workload:
   1 + |---
   2 + |apiVersion: carto.run/v1alpha1
   3 + |kind: Workload

Subpath

For local source workloads, specify a subpath. A subpath points to a specific subfolder within the root folder.

```
# After cloning repo in https://github.com/vmware-tanzu/application-accelerator-sample
s and install Local Source Proxy

cd application-accelerator-samples
tanzu apps workload apply tanzu-java-web-app --local-path . --sub-path tanzu-java-web-
app
Publishing source in "." to "local-source-proxy.tap-local-source-system.svc.cluster.lo
cal/source:default-tanzu-java-web-app"...
  Published source

  Create workload:
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1

     14 + |    subPath: tanzu-java-web-app
  Do you want to create this workload? [yN]: y
  Created workload "tanzu-java-web-app"

To see logs:   "tanzu apps workload tail tanzu-java-web-app --timestamp --since 1h"
To get status: "tanzu apps workload get tanzu-java-web-app"
```

Create a workload from a pre-built image

Create a workload from an existing registry image by providing the reference to that image through the `--image` flag. The supply chain references the provided registry image when the workload is deployed.

For example:

```
tanzu apps workload create petclinic-image --image springcommunity/spring-framework-pe
tclinic
  Create workload:
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1
      3 + |kind: Workload
      4 + |metadata:
      5 + |  labels:
      6 + |    apps.tanzu.vmware.com/workload-type: web
      7 + |  name: petclinic-image
      8 + |  namespace: default
      9 + |spec:
     10 + |  image: springcommunity/spring-framework-petclinic
  Do you want to create this workload? [yN]:
```

For information about requirements for prebuilt images and how to configure prebuilt images in a supply chains, see Use an existing image with Supply Chain Choreographer.

Create a workload from a Maven repository artifact

Create a workload from a Maven repository artifact by setting some specific properties as YAML parameters or using `--maven-*` flags in the workload when using the supply chain. For more information about Maven repository artifact, see Source-Controller.

The Maven repository URL is set when the supply chain is created.

Maven workload created with `--maven-*` flags

To create a Maven workload using the CLI provided flags, run:

```
tanzu apps workload apply my-workload \
      --maven-artifact hello-world \
      --maven-type jar
      --maven-version 0.0.1 \
      --maven-group carto.run \
      --type web -y
```

For information about available commands, see the Tanzu CLI Command Reference documentation.

Maven workload created with YAML or JSON parameters

- Param name: maven
- Param value:
    - YAML:

    ```
    artifactId: ...
    type: ... # default jar if not provided
    version: ...
    groupId: ...
    ```

    - JSON:

    ```
    {
        "artifactId": ...,
        "type": ..., // default jar if not provided
        "version": ...,
        "groupId": ...
    }
    ```

For example, to create a workload from a Maven artifact using parameters, run:

```
# YAML
tanzu apps workload create my-workload --type web --param-yaml maven=$"artifactId:hell
o-world\ntype:jar\nversion:0.0.1\ngroupId:carto.run"

# JSON
tanzu apps workload create my-workload --type web --param-yaml maven="{"artifactId":"h
ello-world", "type": "jar", "version": "0.0.1", "groupId": "carto.run"}"
```

For information about how to configure the Maven artifact authentication credentials, see Maven Repository Secret.

Create a workload from a Dockerfile

For any source-based supply chains, when you specify the new dockerfile parameter in a workload, the builds switch from using Kpack to using kaniko. Source-based supply chains are supply chains that don't take a pre-built image. kaniko is an open-source tool for building container images from a Dockerfile without running Docker inside a container. For more information, see Dockerfile-based builds.

Get workload status

This topic tells you about the Tanzu Apps CLI plug-in commands you can use to get information about the status of a workload.

tanzu apps workload list

The `tanzu apps workload list` command gets a list of the workloads present in the cluster, either in the current namespace, in another namespace, or all namespaces.

Filter the list result by the `--namespace`, `--type` or `--app` flags. The `--output` flag supports the `yaml` and `json` formats.

–all-namespaces, -A flag

Show workloads in all namespaces in the cluster.

```
tanzu apps workload list -A

NAMESPACE   TYPE   NAME                  APP                  READY
AGE
default     web    nginx4                <empty>              Ready
7d9h
default     web    rmq-sample-app        <empty>              Ready
179m
default     web    spring-pet-clinic     <empty>              Unknown
3h1m
default     web    tanzu-java-web-app    tanzu-java-web-app   Ready
40m
nginx-ns    web    nginx2                <empty>              TemplateRejectedByAPISer
ver   8d
```

–app flag

Filter workloads by application. Shows workloads for the application specified in the command.

```
tanzu apps workload list --app spring-petclinic

NAME                TYPE   READY     AGE
spring-petclinic2   web    Unknown   29d
spring-petclinic3   web    Ready     29d
```

–namespace, -n flag

Filter workloads by namespace. Lists all the workloads present in the specified namespace.

```
tanzu apps workload list --namespace my-namespace

NAME   TYPE   APP       READY                          AGE
app1   web    <empty>   TemplateRejectedByAPIServer   8d
app2   web    <empty>   Ready                          8d
app3   web    <empty>   Unknown                        8d
```

–output, -o flag

List all workloads in the specified namespace in `yaml`, `yml` or `json` format.

- yaml/yaml

```
# shorthand for --output is -o
# alternatives are
# tanzu apps workload list -o yaml / -o json
# tanzu apps workload list -oyaml / -ojson
tanzu apps workload list --output yaml
```

```

tanzu apps workload get

The `tanzu apps workload get` command provides detailed information and status about a workload. Filter workloads with the `--namespace` flag, which specifies the namespace where the workload is deployed.

There are multiple sections in the workload get command output. The following data is displayed:

- Name of the workload and its status.
- Displays source information of workload.
- If the workload was matched with a supply chain, the name of the supply chain is provided.

- A table providing the name, status, health, and resulting resource for each step defined in the supply chain or delivery for the workload.
- If there are any issues, such as errors or status messages associated with any of the steps defined by the supply chain or delivery for the workload, the name and corresponding message are included in the `Messages` section.
- Workload related resource information and status like services claims, related pods, and Knative services.

At the very end of the command output, a hint to follow up commands is also displayed.

Note

The `Supply Chain` and `Delivery` sections are included in the command output depending on whether those resources are present on the target cluster, for example, if the target includes only build components, there is no `Delivery` resources available and therefore the `Delivery` section is not included in the command output.

```
# --namespace flag shorthand is -n
# An alternative way to use this command is
# tanzu apps workload get tanzu-java-web-app -n development
tanzu apps workload get tanzu-java-web-app --namespace development

tanzu apps workload tail

`tanzu apps workload tail` checks the runtime logs of a workload. The workload can be filtered by the namespace it was created on by using the `--namespace` flag, and the workload logs can also be filtered by a specific `--component`.

Use the `--since` flag to retrieve logs within a specific time-frame and display them with their `--timestamp`.

```
tanzu apps workload tail tanzu-java-web-app -n development --since 1h --component buil
d --timestamp

tail a workload while creating or applying a workload

You can tail a workload directly as part of the `tanzu apps workload create` or `tanzu apps workload apply` commands by providing the `--tail` flag and you can display timestamps for each log entry by including the `--tail-timestamp` flag.

```
tanzu apps workload apply tanzu-java-web-app --git-repo https://github.com/vmware-tanz
u/application-accelerator-samples --git-tag tap-1.6.0 --sub-path tanzu-java-web-app --
tail --tail-timestamp
   Create workload:
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1
      3 + |kind: Workload
      4 + |metadata:
      5 + |  labels:
      6 + |    apps.tanzu.vmware.com/workload-type: web
      7 + |  name: tanzu-java-web-app
      8 + |  namespace: default
      9 + |spec:
     10 + |  source:
     11 + |    git:
     12 + |      ref:
     13 + |        tag: tap-1.6.0
     14 + |      url: https://github.com/vmware-tanzu/application-accelerator-samples
     15 + |    subPath: tanzu-java-web-app
  Do you want to create this workload? [yN]: y

–export flag

A clean workload definition export can be committed to GitHub or applied to a different environment without having to make significant edits because the export only includes the fields specified by the developer who created it.

By default, the `--export` flag is configured to display the workload in `yaml` format. However, the behavior can be modified by combining it with the `--output` flag, which accepts `yaml`, `yml`, and `json` as values.

For example, if a workload is created with:

```
tanzu apps workload apply tanzu-where-for-dinner --git-repo https://github.com/vmware-
tanzu/application-accelerator-samples --git-branch main --sub-path where-for-dinner
```

When querying the workload with `--export`, the default export format in `yaml` is as follows:

```
# with yaml format
tanzu apps workload get tanzu-where-for-dinner --export
```

```
---
apiVersion: carto.run/v1alpha1

–output flag with `tanzu apps workload apply` command

Use this flag to retrieve the workload in the `yaml`, `yml`, or `json` format after it is applied. When combined with the `--yes` flag, all prompts are bypassed, and only the workload definition is returned. Additionally, use the `--wait` or `--tail` flags, to retrieve the workload with its current status.

```
tanzu apps workload create tanzu-where-for-dinner --git-repo https://github.com/vmware
-tanzu/application-accelerator-samples --git-branch main --sub-path where-for-dinner -
oyaml
  Create workload:
      1 + |---
      2 + |apiVersion: carto.run/v1alpha1
      3 + |kind: Workload
      4 + |metadata:

}
```

Delete a workload

This topic tells you about the Tanzu Apps CLI plug-in `tanzu apps workload delete` command.

Use the `tanzu apps workload delete` command to remove one or more workloads from a specific namespace on the target cluster.

Note

This command does not automatically remove a workload's corresponding images from the registry.

To specify the workload for deletion, either provide the workload name and namespace or use a `yaml` file containing the workload definition.

To control the deletion process, use the `--wait` flag, which waits until the workload is deleted, or the `--wait-timeout` flag, which sets a specific timeout duration for the deletion process.

Delete all workloads in a namespace

Delete workloads all at once with the `--all` flag. If there is a particular namespace where all workloads should be deleted, use the `--namespace` flag to specify it.

```
# --namespace shorthand is -n
# an alternative for this same command is
# tanzu apps workload delete --all -n my-namespace
tanzu apps workload delete --all --namespace my-namespace
  Really delete all workloads in the namespace "my-namespace"? Yes
  Deleted workloads in namespace "my-namespace"
```

Apps CLI plug-in how-to-guides

The how-to-guides section contains the following topics:

- Integrate with Local Source Proxy
- Manage workload merge behavior

Integrate with Local Source Proxy

This topic tells you how to integrate the Tanzu Apps CLI with Local Source Proxy.

You can configure workloads to push local source code to a registry that is predefined using the Local Source Proxy component.

For more information about Local Source Proxy, see Overview of Local Source Proxy and Create a workload from Local Source.

Check Local Source Proxy health

To check the installation and health of Local Source Proxy and determine if failures originate from the Local Source Proxy or the upstream registry, run:

```
tanzu apps local-source-proxy health
```

This returns an overview of the health of the Local Source Proxy. This information is obtained directly from the Local Source Proxy and provides a status code and message.

Use the `--output` flag to specify one of the following formats: `yaml`, `yml`, and `json`. The default format is `yaml`.

The API is called at the `/health` endpoint, and there are five possible outputs based on the response received:

- All checks pass. Format is `yaml`.

  ```
  user_has_permission: true
  reachable: true
  upstream_authenticated: true
  overall_health: true
  message: "All health checks passed"
  ```

- You do not have permission to list the service. The possible reason is a 403 error from the Kubernetes API Server. Format is `yaml`.

  ```
  user_has_permission: false
  reachable: false
  upstream_authenticated: false
  overall_health: false
  ```

```
message: "The current user does not have permission to access the local source
proxy"
```

- You can list the services, but it's not there. The possible reason is a 404 error from the Kubernetes API Server. Format is Source-Controller

```
user_has_permission: true
reachable: false
upstream_authenticated: false
overall_health: false
message: "Local source proxy is not installed on the cluster"
```

- `/health` from Local Source Proxy returns a 5xx. Format is `yaml`.

```
user_has_permission: true
reachable: true
upstream_authenticated: false
overall_health: false
message: "Local source proxy is not healthy. Error: <error>"
```

- `/health` from upstream returns a non-2xx, 4xx, 5xx. `/health` from Local Source Proxy will still be 2xx. Format is `yaml`.

```
user_has_permission: true
reachable: true
upstream_authenticated: false
overall_health: false
message: "Local source proxy was unable to authenticate against the target regi
stry. Error: <error>"
```

- All checks pass. Format is `json`.

```
{
"user_has_permission": true
"reachable": true
"upstream_authenticated": true
"overall_health": true
"message": ""
}
```

Update the local source code for workloads

To create a workload from local source code, there are two options available:

1. Use Local Source Proxy, which automatically defaults to a predefined registry.
2. Use the `--source-image` flag to specify a registry. You must be authenticated to access the registry.

To distinguish whether a workload was created with the Local Source Proxy or the `--source-image` flag, check if the workload contains the `local-source-proxy.apps.tanzu.vmware.com` annotation. This annotation indicates the method used to create the workload.

For more information, see Create a workload from Local Source.

Use the `--source-image` flag

After a workload is created using the `--source-image` flag, it is not possible to update it to use Local Source Proxy. However, you do not need to repeatedly specify the `--source-image` flag during subsequent updates, as it is retrieved from the existing workload specification within the cluster. If

you do want to change the registry or storage location for the source code, specify the `--source-image` flag again with a new value.

```
# create a workload using source image
# inside the local source code folder
tanzu apps workload apply java-web-app --local-path . -s my-registry.io/my-project/jav
a-app
The files and/or directories listed in the .tanzuignore file are being excluded from t
he uploaded source code.

  Really update the workload "java-web-app"? [yN]:
```

Manage workload merge behavior

This topic tells you how to manage the workload update behavior with the Tanzu Apps CLI `--update-strategy` flag.

When updating a workload from a file, manage the workload update behavior with the `--update-strategy` flag. There are two possible values: `merge` or `replace`. The default value is `merge`.

merge

If the `--file workload.yaml` deletes an existing on-cluster property or value, it is not removed from the on-cluster definition. If the `--file workload.yaml` includes a new property or value, it is added to the on-cluster workload property value. If the `--file workload.yaml` updates an existing value for a property, it is updated on the on-cluster definition.

replace

The on-cluster workload is updated to exactly what is specified in the `--file workload.yaml` definition.

The current default merge strategy intents to prevent unintentional deletions of critical properties from existing workloads.

Note

The default value for the `--update-strategy flag` will change from merge to replace in Tanzu Application Platform v1.7.0 and later.

Examples of the outcomes of both the `merge` and `replace` values are provided in the following examples:

- ```
  # Export workload if there is no previous yaml definition
  tanzu apps workload get spring-petclinic --export > spring-petclinic.yaml

  # modify the workload definition
  vi rmq-sample-app.yaml
  ---
  apiVersion: carto.run/v1alpha1
  kind: Workload
  metadata:
  name: spring-petclinic
  labels:
    app.kubernetes.io/part-of: spring-petclinic
    apps.tanzu.vmware.com/workload-type: web
  spec:
  resources:
    requests:
      memory: 1Gi
    limits:           # delete this line
      memory: 1Gi     # delete this line
      cpu: 500m       # delete this line
  source:
    git:
      url: https://github.com/sample-accelerators/spring-petclinic
      ref:
        tag: tap-1.1
  ```

After saving the file, to verify how both of the update strategy options behave, run:

```
tanzu apps workload apply -f ./spring-petclinic.yaml --update-strategy merge # if flag
is not specified, merge is taken as default
```

This produces the following output:

```
  WARNING: Configuration file update strategy is changing. By default, provided config
uration files
will replace rather than merge existing configuration. The change will take place in t
```
```

```
he January 2024
Tanzu Application Platform release (use "--update-strategy" to control strategy explic
itly).

Workload is unchanged, skipping update
```

By contrast, use `replace` as follows:

```
tanzu apps workload apply -f ./spring-petclinic.yaml --update-strategy replace
```

This produces the following output:

```
  WARNING: Configuration file update strategy is changing. By default, provided config
uration files
will replace rather than merge existing configuration. The change will take place in t
he January 2024
Tanzu Application Platform release (use "--update-strategy" to control strategy explic
itly).

  Update workload:
...
  8,  8   |  name: spring-petclinic
  9,  9   |  namespace: default
 10, 10   |spec:
 11, 11   |  resources:
 12     - |    limits:
 13     - |      cpu: 500m
 14     - |      memory: 1Gi
 15, 12   |    requests:
 16, 13   |      memory: 1Gi
 17, 14   |  source:
 18, 15   |    git:
...
  Really update the workload "spring-petclinic"? [yN]:
```

The lines that were deleted in the `yaml` file are deleted as well in the workload running in the cluster. The only text boxes that remain exactly as they were created are the system populated metadata text boxes; `resourceVersion`, `uuid`, `generation`, `creationTimestamp`, and `deletionTimestamp`.

Troubleshoot Apps CLI

The troubleshooting section contains the following topics:

- Troubleshooting workloads
- Troubleshooting local source proxy integration

Troubleshoot workloads

This topic tells you how to use the Tanzu Apps CLI plug-in to troubleshoot workloads in Tanzu Application Platform (commonly known as TAP).

Check build logs

After a workload is created, tail the workload to view the build and runtime logs.

Run:

```
tanzu apps workload tail WORKLOAD --since 10m --timestamp
```

Where:

- `WORKLOAD` is the name of the workload.
- `--since` is optional.The amount of time to go back to begin streaming logs. The default is 1 second.
- `--timestamp` is optional. Prints the timestamp with each log entry.

Get the workload status and details

After the workload build process is complete, a Knative service can be created to run the workload. Workload details can be viewed at any time during the process. Some details, such as the workload URL, are only available after the workload is running.

Run:

```
tanzu apps workload get WORKLOAD
```

Where:

`WORKLOAD` is the name of the workload to be checked.

Now the workload should be in a running state. When the workload is created, `tanzu apps workload get` includes the URL for the running workload. In some terminals, you can **Ctrl+click** the URL to view it. You can also copy the URL into a web browser to see the application.

Common workload errors

A workload can either be ready, be in an error state, or have an unknown status.

There are known errors that cause the workload to enter an error or unknown status. Look at the supply chain or delivery steps for status and review the messages section for clues when the workload appears to be having issues.

Local Path Development Error Cases

The section describes the cause and resolution for some of the most common issues.

Message: Writing `registry/project/repo/workload:latest`: Writing image: Unexpected status code *401 Unauthorized* (HEAD responses have no body, use GET for details)

Cause: Apps plug-in cannot talk to the registry because the registry credentials are missing or invalid.

Resolution: Run `docker logout registry` and `docker login registry` commands and specify the valid credentials for the registry.

Message: Writing `registry/project/workload:latest`: Writing image: HEAD Unexpected status code *400 Bad Request* (HEAD responses have no body, use GET for details)

Cause: Certain registries like Harbor or GCR have a concept of `Project`. A 400 Bad request is sent when either the project does not exist, the user does not have access to it, or the path in the `--source-image` flag is missing either project or repository.

Resolution: Fix the path in the `--source-image` flag value to point to a valid repository path.

WorkloadLabelsMissing/SupplyChainNotFound

Message: No supply chain found where full selector is satisfied by `labels: map[app.kubernetes.io/part-of:spring-petclinic]`.

Cause: The labels and attributes in the workload object did not fully satisfy any installed supply chain on the cluster.

Resolution: Use the `tanzu apps cluster-supply-chain list` (alias `csc`) and `tanzu apps csc get <supply-chain-name>` commands to see the workload selection criteria for the supply chain available on the cluster. Apply any missing labels to a workload by using `tanzu apps workload apply --label required-label-name=required-label-value`. For example:

```
tanzu apps workload apply workload-name —-type web
# or
tanzu apps workload apply workload-name --label apps.tanzu.vmware.com/workload-type=we
b
```

MissingValueAtPath

Message: Waiting to read value `[.status.artifact.url]` from resource gitrepository.source.toolkit.fluxcd.io in namespace `[ns]`

Possible Cause 1: The Git `url/tag/branch/commit` parameters passed in the workload are not valid.

Resolution 1: Fix the invalid Git parameters by using `tanzu apps workload apply`.

Possible Cause 2: The Git repository is not accessible from the cluster.

Resolution 2: Configure the cluster networking or the Git repository networking so that they can communicate with each other.

Possible Cause 3: The namespace is missing the Git secret for communicating with the private repository.

Resolution 3: For more information, see Git authentication.

TemplateRejectedByAPIServer

Message: Unable to apply object `[ns/workload-name]` for resource `[source-provider]` in supply chain `[source-to-url]`: failed to get unstructured `[ns/workload-name]` from API server: imagerepositories.source.apps.tanzu.vmware.com “workload-name” is forbidden: User “system:serviceaccount:ns:default” cannot get resource “imagerepositories” in API group “source.apps.tanzu.vmware.com” in the namespace “ns”

Cause: This error happens when the service account in the workload object does not have permission to create objects that are stamped out by the supply chain.

Resolution: Set up the Set up developer namespaces to use your installed packages with the required service account and permissions. For more information, see Developer namespace setup for Supply Chain Security Tools - Store.

Review supply chain steps

After a workload is created with the `tanzu apps workload create` or `tanzu apps workload apply` command, run the `tanzu apps workload get` command to display the current condition of each supply chain.

For example:

```
...
  Supply Chain
   name:   source-to-url

   NAME                READY   HEALTHY   UPDATED   RESOURCE
   source-provider     True    True      71m       gitrepositories.source.toolkit.fluxc
d.io/spring-petclinic
```

```
   image-provider     True    True      70m       images.kpack.io/spring-petclinic
   config-provider    True    True      69m       podintents.conventions.carto.run/spr
ing-petclinic
   app-config         True    True      69m       configmaps/spring-petclinic
   service-bindings   True    True      69m       configmaps/spring-petclinic-with-cla
ims
   api-descriptors    True    True      69m       configmaps/spring-petclinic-with-api
-descriptors
   config-writer      True    True      69m       runnables.carto.run/spring-petclinic
-config-writer

  Delivery
   name:   delivery-basic

   NAME               READY   HEALTHY   UPDATED   RESOURCE
   source-provider    True    True      69m       imagerepositories.source.apps.tanzu.v
mware.com/spring-petclinic-delivery
   deployer           True    True      69m       apps.kappctrl.k14s.io/spring-petclini
c

  Messages
   No messages found.
...
```

The `Supply Chain` section displays the supply chain steps associated with the workload. If a step fails, the `READY` column value is `Unknown` or `False`, and the `HEALTHY` column value is `False`. If a resource is in the `Unknown` or `False` status, inspect it with:

```
kubectl describe RESOURCE-NAME
```

Where `RESOURCE-NAME` is the name of the stamped out resource, displayed in the `RESOURCE` column.

For example, if `tanzu apps workload get` command returns this resource:

```
NAME               READY   HEALTHY   UPDATED   RESOURCE
source-provider    False   False     3h12m     gitrepositories.source.toolkit.fluxcd.i
o/spring-petclinic
```

The resource can be checked with:

```
kubectl describe gitrepositories.source.toolkit.fluxcd.io/spring-petclinic
```

The `Messages` section might give a hint about what went wrong in the process. For example, a message similar to the following is shown:

```
  Messages
   Workload [HealthyConditionRule]:   failed to checkout and determine revision: faile
d to resolve commit object for '425ae9a2a2f84d195a9f3862668e8b2abf81418a': object not
found
```

This might mean that the commit does not belong to the specified branch or does not exist in the repository.

Troubleshooting Local Source Proxy integration

This topic tells you how to troubleshoot the Tanzu Apps CLI plug-in integration with Local Source Proxy.

Use the following topics to troubleshoot the Local Source Proxy integration:

Integrate with Local Source Proxy

Troubleshoot Local Source Proxy.

Tanzu Apps CLI plug-in command reference

The Tanzu Apps CLI plug-in command reference has moved to the Tanzu CLI Command Reference documentation.

Overview of Tanzu Accelerator CLI

The Tanzu Accelerator Tanzu CLI includes commands for developers and operators to create and use accelerators.

Server API connections for operators and developers

The Tanzu Accelerator CLI must connect to a server for all provided commands except for the `help` and `version` commands.

Operators typically use **create**, **update**, and **delete** commands for managing accelerators in a Kubernetes context. They also use the **fragment** commands to manage accelerator fragments. These commands require a Kubernetes context where the operator is already authenticated and is authorized to create and edit the accelerator resources. Operators can also use the **get** and **list** commands by using the same authentication. For any of these commands, the operator can specify the `--context` flag to access accelerators in a specific Kubernetes context.

Developers use the **list**, **get**, and **generate** commands for using accelerators available in an Application Accelerator server. Developers use the `--server-url` to point to the Application Accelerator server they want to use.

You can either use the proxy that is part of TAP-GUI or you can use the URL for the Application Accelerator server, if that is configured to be exposed. VMware recommends using the TAP-GUI address.

Using TAP-GUI URL

1. Specify `--server-url` as:

   ```
   https://tap-gui.DOMAIN
   ```

   Where `DOMAIN` defaults to the `shared.ingress_domain` value provided in the Tanzu Application Platform values file.

2. Add the following flags to the `tap-values.yaml` file when `shared.ingress_domain` is set.

   ```
   accelerator:
     ingress:
       include: true
   ```

Using Application Accelerator Server URL

If you cannot use the TAP-GUI URL, the fallback is to use Application Accelerator server directly. In this case the URL depends on the configuration settings for Application Accelerator:

- For installations configured with a **shared ingress** and where the Application Accelerator server is configured to use the ingress, use `https://accelerator.<domain>` where `domain`

defaults to the `shared.ingress_domain` value provided in the values file of Tanzu Application Platform.

- For installations using a **LoadBalancer**, look up the External IP address by using:

  ```
  kubectl get -n accelerator-system service/acc-server
  ```

  Use `http://<External-IP>` as the URL.

- For any other configuration, you can use port forwarding by using:

  ```
  kubectl port-forward service/acc-server -n accelerator-system 8877:80
  ```

  Use `http://localhost:8877` as the URL.

Using “ACC_SERVER_URL” environment variable

The developer can set an `ACC_SERVER_URL` environment variable to avoid having to provide the same `--server-url` flag for every command. Run `export ACC_SERVER_URL=<URL>` for the terminal session in use. If the developer explicitly specifies the `--server-url` flag, it overrides the `ACC_SERVER_URL` environment variable if it is set.

Installation

To install the Tanzu Accelerator CLI plug-in, see Install new CLI plug-ins.

Command reference

For information about available commands, see the Tanzu CLI Command Reference documentation.

Overview of Tanzu Accelerator CLI

The Tanzu Accelerator Tanzu CLI includes commands for developers and operators to create and use accelerators.

Server API connections for operators and developers

The Tanzu Accelerator CLI must connect to a server for all provided commands except for the `help` and `version` commands.

Operators typically use **create**, **update**, and **delete** commands for managing accelerators in a Kubernetes context. They also use the **fragment** commands to manage accelerator fragments. These commands require a Kubernetes context where the operator is already authenticated and is authorized to create and edit the accelerator resources. Operators can also use the **get** and **list** commands by using the same authentication. For any of these commands, the operator can specify the `--context` flag to access accelerators in a specific Kubernetes context.

Developers use the **list**, **get**, and **generate** commands for using accelerators available in an Application Accelerator server. Developers use the `--server-url` to point to the Application Accelerator server they want to use.

You can either use the proxy that is part of TAP-GUI or you can use the URL for the Application Accelerator server, if that is configured to be exposed. VMware recommends using the TAP-GUI address.

Using TAP-GUI URL

1. Specify `--server-url` as:

   ```
   https://tap-gui.DOMAIN
   ```

   Where `DOMAIN` defaults to the `shared.ingress_domain` value provided in the Tanzu Application Platform values file.

2. Add the following flags to the `tap-values.yaml` file when `shared.ingress_domain` is set.

   ```
   accelerator:
     ingress:
       include: true
   ```

Using Application Accelerator Server URL

If you cannot use the TAP-GUI URL, the fallback is to use Application Accelerator server directly. In this case the URL depends on the configuration settings for Application Accelerator:

- For installations configured with a **shared ingress** and where the Application Accelerator server is configured to use the ingress, use `https://accelerator.<domain>` where `domain` defaults to the `shared.ingress_domain` value provided in the values file of Tanzu Application Platform.
- For installations using a **LoadBalancer**, look up the External IP address by using:

  ```
  kubectl get -n accelerator-system service/acc-server
  ```

  Use `http://<External-IP>` as the URL.

- For any other configuration, you can use port forwarding by using:

  ```
  kubectl port-forward service/acc-server -n accelerator-system 8877:80
  ```

  Use `http://localhost:8877` as the URL.

Using “ACC_SERVER_URL” environment variable

The developer can set an `ACC_SERVER_URL` environment variable to avoid having to provide the same `--server-url` flag for every command. Run `export ACC_SERVER_URL=<URL>` for the terminal session in use. If the developer explicitly specifies the `--server-url` flag, it overrides the `ACC_SERVER_URL` environment variable if it is set.

Installation

To install the Tanzu Accelerator CLI plug-in, see Install new CLI plug-ins.

Command reference

For information about available commands, see the Tanzu CLI Command Reference documentation.

Tanzu Accelerator CLI plug-in command reference

The Tanzu Accelerator CLI plug-in command reference has moved to the Tanzu CLI Command Reference documentation.

Overview of Build Service CLI plug-in

The Tanzu Build Service CLI plug-in command reference has moved to the Tanzu CLI Command Reference documentation.

Overview of Tanzu Insight plug-in

The Tanzu Insight CLI plug-in helps you query vulnerability, image, and package data.

Follow these steps to install, configure, and use your Tanzu Insight CLI plug-in:

Note: Prior to using the CLI plug-in, you must install the Supply Chain Security Tools - Store, either as its own package, or as part of Tanzu Application Platform View profile.

1. Install the Tanzu Insight plug-in. The Tanzu Insight plug-in is in the Tanzu Application Platform plug-ins group, see Install Tanzu CLI plug-ins.
2. Configure your Tanzu Insight CLI plug-in.

When the Tanzu Insight CLI plug-in is set up, complete the following steps:

1. Add data to your Supply Chain Security Tools - Store
2. Query vulnerabilities, images, and packages
3. Query Software Bill of Material reports
4. Triage vulnerabilities

Overview of Tanzu Insight plug-in

The Tanzu Insight CLI plug-in helps you query vulnerability, image, and package data.

Follow these steps to install, configure, and use your Tanzu Insight CLI plug-in:

Note: Prior to using the CLI plug-in, you must install the Supply Chain Security Tools - Store, either as its own package, or as part of Tanzu Application Platform View profile.

1. Install the Tanzu Insight plug-in. The Tanzu Insight plug-in is in the Tanzu Application Platform plug-ins group, see Install Tanzu CLI plug-ins.
2. Configure your Tanzu Insight CLI plug-in.

When the Tanzu Insight CLI plug-in is set up, complete the following steps:

1. Add data to your Supply Chain Security Tools - Store
2. Query vulnerabilities, images, and packages
3. Query Software Bill of Material reports
4. Triage vulnerabilities

Configure your Tanzu Insight CLI plug-in

This topic tells you how to configure your Tanzu Insight CLI plug-in.

Set the target and certificate authority (CA) certificate

These instructions are for the recommended configuration where Ingress is enabled. For instructions on non Ingress setups, see Configure target endpoint and certificate.

Set the endpoint host to `metadata-store.INGRESS-DOMAIN`, such as `metadata-store.example.domain.com`. Where `INGRESS-DOMAIN` isthe value of the `ingress_domain` property in your deployment yaml.

Note In a multi-cluster setup, a DNS record is **required** for the domain. The below instructions for single cluster setup do not apply, skip to Set Target section.

Single Cluster setup

In a single-cluster setup, a DNS record is still recommended. However, if no accessible DNS record exists for the domain, edit the `/etc/hosts` file to add a local record:

```
ENVOY_IP=$(kubectl get svc envoy -n tanzu-system-ingress -o jsonpath="{.status.loadBal
ancer.ingress[0].ip}")

# Replace with your domain
METADATA_STORE_DOMAIN="metadata-store.example.domain.com"

# Delete any previously added entry
sudo sed -i '' "/$METADATA_STORE_DOMAIN/d" /etc/hosts

echo "$ENVOY_IP $METADATA_STORE_DOMAIN" | sudo tee -a /etc/hosts > /dev/null
```

Set Target

To get the certificate, run:

```
kubectl get secret tap-ingress-selfsigned-root-ca -n cert-manager -o json | jq -r '.da
ta."ca.crt"' | base64 -d > insight-ca.crt
```

Set the target by running:

```
tanzu insight config set-target https://$METADATA_STORE_DOMAIN --ca-cert insight-ca.cr
t
```

Important

The `tanzu insight config set-target` does not initiate a test connection. Use `tanzu insight health` to test connecting using the configured endpoint and CA certificate. Neither commands test whether the access token is correct. For that you must use the plug-in to add data and query data.

Set the access token

When using the `insight` plug-in, you must set the `METADATA_STORE_ACCESS_TOKEN` environment variable, or use the `--access-token` flag. VMware discourages using the `--access-token` flag as the token appears in your shell history.

The following command retrieves the access token from the default `metadata-store-read-write-client` service account and stores it in `METADATA_STORE_ACCESS_TOKEN`:

```
export METADATA_STORE_ACCESS_TOKEN=$(kubectl get secrets metadata-store-read-write-cli
ent -n metadata-store -o jsonpath="{.data.token}" | base64 -d)
```

Verify the connection

Verify that your configuration is correct and you can make a connection using `tanzu insight health`.

Important

The `tanzu insight health` command tests the configured endpoint and CA certificate. However, it does not test whether the access token is correct. For that, you must use the plug-in to add and query data.

For example:

```
$ tanzu insight health
Success: Reached Metadata Store!
```

Query vulnerabilities, images, and packages

This topic tells you how to query the database to understand vulnerability, image, and dependency relationships. The Tanzu Insight CLI plug-in queries the database for vulnerability scan reports or Software Bill of Materials (commonly known as SBoM) files.

Supported use cases

The following are use cases supported by the CLI:

- What packages and CVEs exist in a particular image? (`image`)
- What dependencies are affected by a specific CVE? (`vulnerabilities`)

Query using the Tanzu Insight CLI plug-in

Install the Tanzu Insight plug-in. The Tanzu Insight plug-in is in the Tanzu Application Platform plug-ins group, see Install Tanzu CLI plug-ins.

There are four commands for querying and adding data.

- `image` - Post an image SBOM or query images for packages and vulnerabilities.
- `package` - Query packages for vulnerabilities or by image or source code.
- `source` - Post a source code SBOM or query source code for packages and vulnerabilities.
- `vulnerabilities` - Query vulnerabilities by image, package, or source code.

For more information about Tanzu Insight CLI plug-in commands, see the VMware Tanzu CLI documentation.

Example 1: What packages and CVEs does a specific image contain?

To query an image scan for vulnerabilities, you need the image digest value, which you can get from the image scan resource.

Find an image digest value

Find an image digest value using Supply Chain Tools - Scan 2.0 or Supply Chain Tools - Scan Pre-2.0.

Find an image digest using Supply Chain Tools - Scan 2.0

When using Supply Chain Tools - Scan 2.0, find the image digest value by looking inside the corresponding image vulnerability scan custom resource.

To get a list of image vulnerability scans, run:

```
kubectl get imagevulnerabilityscan -n WORKLOAD-NAMESPACE
```

For example:

```
$ kubectl get imagevulnerabilityscan -n my-apps
NAME                                 SUCCEEDED   REASON
tanzu-java-web-app-grype-scan-jb76m   True        Succeeded
```

The name of the image vulnerability scan starts with the name of the workload.

To describe the image vulnerability scan, run:

```
kubectl describe imagevulnerabilityscan IMAGE-VULNERABILITY-SCAN-NAME -n WORKLOAD-NAME
SPACE
```

For example:

```
kubectl describe imagevulnerabilityscan tanzu-java-web-app-grype-scan-jb76m -n my-apps
```

In the resource, look for the `Spec.Image` field. The value points to the image that was scanned, including its digest.

For example:

```
Spec:
  Image: fake.oci-registry.io/dev-cluster/supply-chain-apps/tanzu-java-web-app-my-apps
@sha256:a24a8d8eb724b6816f244925cc6625a84c15f6ced6a19335121343424be693cd
```

In this example, the image digest value is:
`sha256:a24a8d8eb724b6816f244925cc6625a84c15f6ced6a19335121343424be693cd`

Find an image digest value using Supply Chain Tools - Scan Pre-2.0

When using Supply Chain Tools - Scan Pre-2.0, find the image digest value by looking inside the corresponding image scan custom resource.

Run:

```
kubectl get imagescan WORKLOAD-NAME -n WORKLOAD-NAMESPACE
```

For example:

```
kubectl get imagescan tanzu-java-web-app -n my-apps
```

In the resource, look for the `Spec.Registry.Image` field. The value points to the image that was scanned, including its digest.

For example:

```
Spec:
  Registry:
    Image: fake.oci-registry.io/dev-cluster/supply-chain-apps/tanzu-java-web-app-my-ap
ps@sha256:e8c648533c4c7440ee9a93142ac7480205e0f7669e4f86771cede8bfaacdc2cf
```

In this example, the image digest is:
`sha256:e8c648533c4c7440ee9a93142ac7480205e0f7669e4f86771cede8bfaacdc2cf`

Query an image with the image digest value

Run:

```
tanzu insight image get --digest DIGEST
```

Where:

- `DIGEST` is the component version or image digest.

For example:

```
$ tanzu insight image get --digest sha256:sha256:e8c648533c4c7440ee9a93142ac7480205e0f
7669e4f86771cede8bfaacdc2cf
Registry:       fake.oci-registry.com
Image Name:     dev-cluster/supply-chain-apps/tanzu-java-web-app-my-apps
Digest:         sha256:sha256:e8c648533c4c7440ee9a93142ac7480205e0f7669e4f86771cede8bf
aacdc2cf
Packages:
        1. alpine-baselayout@3.1.2-r0
        2. alpine-keys@2.1-r2
        3. apk-tools@2.10.4-r2
        CVEs:
                1. CVE-2021-30139 (High)
                2. CVE-2021-36159 (Critical)
        4. busybox@1.30.1-r3
        CVEs:
                1. CVE-2021-28831 (High)
...
```

Example #: What dependencies are affected by a specific CVE?

Run:

```
tanzu insight vulnerabilities get --cveid CVE-IDENTIFIER
```

Where:

- `CVE-IDENTIFIER` is the CVE identifier, for example, CVE-2021-30139.

For example:

```
$ tanzu insight vulnerabilities get --cveid CVE-2010-4051
1. CVE-2010-4051 (Low)
Packages:
        1. libc-bin@2.28-10
        2. libc-l10n@2.28-10
        3. libc6@2.28-10
        4. locales@2.28-10
```

Add data

For more information about manually adding data, see [Add Data](Add data to your Supply Chain Security Tools - Store.hbs.md).

Add data to your Supply Chain Security Tools - Store

This topic tells you how to add vulnerability scan reports or Software Bill of Materials (commonly known as SBoM) files to your Supply Chain Security Tools (commonly known as SCST) - Store.

Supported formats and file types

Currently, only CycloneDX XML and JSON files are accepted.

Source commits and image files have been tested. Additional file types might work, but are not fully supported (for example, JAR files).

If you are not using a source commit or image file, you must ensure the `component.version` field in the CycloneDX file is non-null.

Generate a CycloneDX file

A CycloneDX file is needed to post data. Supply Chain Security Tools - Scan outputs CycloneDX files automatically. For more information, see Supply Chain Security Tools - Scan.

To generate a file to post manually, use Grype or another tool in the CycloneDX Tool Center.

To use Grype to scan an image and generate an image report in CycloneDX format:

1. Install Grype.
2. Scan the image and generate a report by running:

   ```
   grype REPO:TAG -o cyclonedx > IMAGE-CVE-REPORT
   ```

   Where:

   - `REPO` is the name of your repository
   - `TAG` is the name of a tag
   - `IMAGE-CVE-REPORT` is the resulting file name of the Grype image scan report

   For example:

   ```
   $ grype docker.io/checkr/flagr:1.1.12 -o cyclonedx > image-cve-report
    ✔ Vulnerability DB        [updated]
    ✔ Parsed image
    ✔ Cataloged packages      [21 packages]
    ✔ Scanned image           [8 vulnerabilities]
   ```

Add data with the Tanzu Insight plug-in

Use the following commands to add data:

- `image add`
- `source add`

If you are not using a source commit or image file, you can select either option.

Example #1: Add an image report

To use a CycloneDX-formatted image report:

1. Run:

   ```
   tanzu insight image add --cyclonedxtype TYPE --path IMAGE-CVE-REPORT
   ```

   Where:

   - `TYPE` specifies XML or JSON, the two supported file types
   - `IMAGE-CVE-REPORT` is the location of a Cyclone DX formatted file

For example:

```
$ tanzu insight image add --cyclonedxtype xml --path downloads/image-cve-report
Image report created.
```

Note

The Metadata Store only stores a subset of CycloneDX file data. Support for more data might be added in the future.

Example #2: Add a source report

To use a CycloneDX-formatted source report:

1. Run:

   ```
   tanzu insight source add --cyclonedxtype TYPE --path SOURCE-CVE-REPORT
   ```

   Where:

   - `TYPE` specifies XML or JSON, the two supported file types
   - `SOURCE-CVE-REPORT` is the location of a Cyclone DX formatted file

   For example:

   ```
   $ tanzu insight source add --cyclonedxtype json --path source-cve-report
   Source report created.
   ```

Note

Supply Chain Security Tools - Store only stores a subset of a CycloneDX file's data. Support for more data might be added in the future.

Query Software Bill of Materials Reports

This topic tells you how to query the database to retrieve a Software Bill of Materials (SBoM) report for a specific image.

Use the `tanzu insight report get --uid` command to query the database to retrieve an SBoM report.

Firstly, query for a list of existing SBoM reports associated with an image, and when you have determined the unique identifier (UID) for an SBoM report, query for a specific SBoM report.

Querying for a specific SBoM report returns all common vulnerabilities and exposures (CVEs), and packages for an image for a specific point in time with a specific vulnerability scan tool.

The information returned is similar to the SBoM returned by the `tanzu insight image get --digest` command. However, the output returned is not for a specific point in time with a specific vulnerability scan tool. For more information about querying for images, see the What packages and CVEs does a specific image contain example.

Query the database to retrieve an SBoM report

1. Query for the list of all reports associated with an image. To fetch a specific SBoM report, you must retrieve the unique identifier (UID) for the SBoM report. Use the unique identifier returned by this command in the next step. Run:

   ```
   tanzu insight report list --digest DIGEST
   ```

   Where:

   - `DIGEST` is the component version or image digest.

   For example:

   ```
   $ tanzu insight report list --digest sha256:20521f76ff3d27f436e03dc666cc97a511b
   be71e8e8495f851d0f4bf57b0bab6
   1.      UID:            b84bd3e8-8d71-4012-a7fa-310d4406658c
     Entity Type:          image
     Entity UID:   sha256:20521f76ff3d27f436e03dc666cc97a511bbe71e8e8495f851d0f4bf
   57b0bab6

       Vendor:  anchore
   ```

2. Fetch a specific SBoM report based on the UID returned in output in the previous step. In the output in the previous step, the report UID for the image on `2022-07-15`, is `b6bed111-24eb-4814-9cbd-bbc26dd76d7f`. Use this UID to fetch the SBoM report. Run:

   ```
   tanzu insight report get --uid UID
   ```

   Where:

   - `UID` specifies the SBoM report unique identifier

   For example:

```
$ tanzu insight report get --uid b6bed111-24eb-4814-9cbd-bbc26dd76d7f
UID:               b6bed111-24eb-4814-9cbd-bbc26dd76d7f

```

This SBoM report only includes packages and vulnerabilities for this image on this specific date and time and the vulnerability scan tool version.

Triage vulnerabilities (alpha)

This topic tells you how to add vulnerability analysis associated with a workload in the Supply Chain Security Tools (SCST) - Store. This is an experimental feature, and the API is prone to changes in subsequent releases.

Important

The capability to triage scan results in SCST - Store is in the alpha stage, which means that it is still in early development and is subject to change at any point. You might encounter unexpected behavior from it.

Triage

Vulnerability analysis, or triage is the process of evaluating a reported vulnerability to decide on an effective remediation plan. Triage helps application teams generate useful insights about the

vulnerabilities in their software so that they can make the right decisions about when and how to mitigate them. The current implementation of triage follows CycloneDX's Vulnerability Exploitability eXchange (VEX) specification, and is designed specifically to work with Tanzu workloads.

Prerequisites

Before you begin vulnerability analysis, you must:

- Install the Tanzu Insight plug-in. The Tanzu Insight plug-in is in the Tanzu Application Platform plug-ins group, see Install Tanzu CLI plug-ins.
- Add vulnerability scan reports to the SCST - Store. You can do this either by using the `tanzu insight image add` command or by installing the SCST - Scan. For more information, see Add data and Supply Chain Security Tools - Scan.

Create vulnerability analyses

A vulnerability analysis contains the following data:

1. state: Declares the current state of an occurrence of a vulnerability, after automated or manual analysis.
2. justification: The rationale of why the impact analysis state was asserted.
3. response: A response to the vulnerability by the manufacturer, supplier, or project responsible for the affected component or service.
4. comment: Free form comments to provide additional details.

For more information about the supported values for each of these fields, see the Tanzu CLI Command Reference documentation.

For example, if you are interested in a vulnerability affecting a specific image in your workload, and are investigating its impact, you can add this information to the SCST - Store:

```
tanzu insight triage update \
  --cveid $CVEID \
  --pkg-name $PKG-NAME \
  --pkg-version $PKG-VERSION \
  --img-digest $IMG-DIGEST \
  --artifact-group-uid $ARTIFACT-GROUP-UID \
  --state in_triage
```

Where:

- `CVEID` is the unique identifier of the vulnerability
- `PKG-NAME` and `PKG-VERSION` are the name and version of the Application and OS package affected by the vulnerability
- `IMG-DIGEST` is the digest of the image that contains the affected Application and OS package
- `ARTIFACT-GROUP-UID` is the unique identifier for the workload that contains the image. If your workload was deployed with Tanzu CLI, you can find its unique identifier with the following command:

  ```
  kubectl get workload $MY_WORKLOAD_NAME --namespace $MY_WORKLOAD_NAMESPACE --out
  put jsonpath='{.metadata.uid}'
  ```

Note

> If your affected package is linked to a source instead of an image, you can use `--src-commit` instead of `--img-digest`

As you continue to investigate the vulnerability, you can update your analysis with the latest findings by using the `tanzu insight triage update` command as many times as needed.

View existing analysis

To view all the existing analysis in SCST - Store, run:

```
tanzu insight triage list
```

The results are paginated by default. You can switch the current page or the number of results returned by providing the `--page` or `--limit` flags respectively. You can also filter the results by image or source. For more information, use the `--help` flag or see the Tanzu CLI Command Reference documentation.

Copy an analysis

Sometimes, you might run into scenarios where an existing analysis might be shared between multiple images, for example, when a new version of an existing image is deployed by your workload and it contains the same vulnerability as the previous version, or when you create an analysis for an image that is shared between multiple workloads.

To speed up triage in those cases, you can use the `copy` subcommand:

```
tanzu insight triage copy \
  --triage-uid-to-copy $TRIAGE-UID \
  --img-digest $TARGET-IMAGE
```

Where:

- `TRIAGE-UID` is the uid of an existing analysis
- `TARGET-IMAGE` is the digest of an image you want to copy the analysis to

The following conditions are required for this action:

1. If specified, the targeted image or source must contain the package affected by the vulnerability in the existing analysis.
2. If only an image or source is specified, they must belong to the same workload as the one in the existing analysis.
3. If only an `artifact-group-uid` is specified, it must contain the image or source associated with the existing analysis.

> **Note**
>
> The responsibility of assessing a vulnerability's impact is up to the person in charge of triage. Images and sources with the same package and version might use the package differently and might not have the same analysis values.

Rebase multiple analyses

When you carry out vulnerability analysis on a workload image, you might want to carry this forward after the workload source code is updated and a new image is built and deployed. This process is

called rebase, and you can run it with the following command:

```
tanzu insight triage rebase \
  --img-digest $TARGET-IMAGE
  --artifact-group-uid $ARTIFACT-GROUP-UID
```

Where:

- `TARGET-IMAGE` is the digest of the image you want to rebase the analysis into
- `ARTIFACT-GROUP-UID` is the unique identifier for the workload that contains the image, and where existing analysis will be searched for

This command returns a list of existing analyses that can be automatically rebased into your target image. Each analysis on the list meets all the following criteria:

- The analysis exists for a vulnerability that the target image is affected by.
- The analysis is linked to a previous version of an image.
- There is no existing analysis for the same vulnerability and the target image, or their state is ‘in_triage’

In this context, image A is considered to be a previous version of image B when they have the same name, different digests and image A was created before image B. This will be bound on the workload’s context, using the provided `--artifact-group-uid`.

Known limitations

1. You can only rebase analyses for images, sources are not currently supported.
2. If you are deploying Tanzu Application Platform workloads from pre-built images, or have a custom Supply Chain that changes the name of the deployed image in between builds, you can’t use this feature and must manually copy the existing analyses, see Copy an analysis above.

Tanzu Insight CLI plug-in command reference

The Tanzu Insight CLI plug-in command reference has moved to the Tanzu CLI Command Reference documentation.

Overview of API Auto Registration

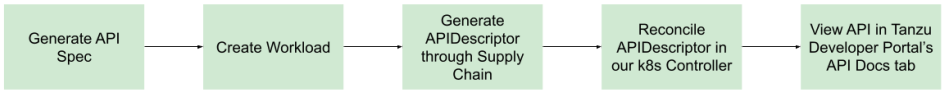
This topic gives you an overview of API Auto Registration for Tanzu Application Platform.

Overview

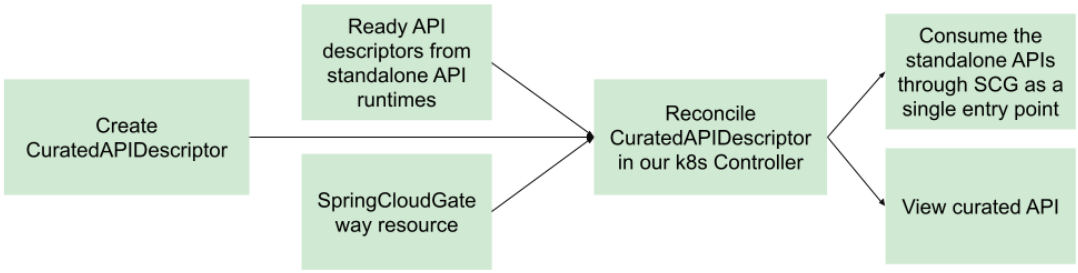
API Auto Registration automatically generates API specifications from a workload’s configuration and registration of the API entity in the Tanzu Developer Portal’s catalog. You can access the registered API specification in Tanzu Developer Portal with no additional steps. As an experimental alpha feature, API Auto Registration generates a curated API by combining APIs exposed from multiple workloads.

You can use an automated workflow with a supply chain to create and manage a Kubernetes Custom Resource (CR) of kind `APIDescriptor` from your workload. API Auto Registration’s Kubernetes controller periodically reconciles the CR and updates the API entity in Tanzu Developer Portal to achieve automated API specification registration from origin workloads.

You can also use API Auto Registration without supply chain automation, with other GitOps processes, or by directly applying an `APIDescriptor` CR to the cluster.



For combining and curating multiple standalone APIDescriptors in your run clusters, you can configure and apply `CuratedAPIDescriptor` to your clusters to provide a single curated entry point for users consuming your APIs. With Spring Cloud Gateway for Kubernetes available as the route provider, API Auto Registration's Kubernetes controller automatically generates and manages necessary routing resources for the curated API. If configured, each curated API is exposed and navigable on your preferred Spring Cloud Gateway instance.



Getting started

For information about API Auto Registration architecture, the `APIDescriptor` CR, the `CuratedAPIDescriptor` CR, and API entities in Tanzu Developer Portal, see Key Concepts.

For information about configuring iterate, run, and full Tanzu Application Platform cluster profiles, see Configure API Auto Registration.

For information about generating API specifications and registering them with Tanzu Developer Portal catalog, see Use API Auto Registration.

For information about curating workloads into Curated APIs and generating Spring Cloud Gateway resources, see API Curation (alpha).

For information about other profiles, install the `api-auto-registration` package. See Install API Auto Registration.

For information about troubleshooting and debugging API Auto Registration, see Troubleshooting.

Overview of API Auto Registration

For information about other profiles, install the `api-auto-registration` package. See Install API Auto Registration.

For information about troubleshooting and debugging API Auto Registration, see Troubleshooting.

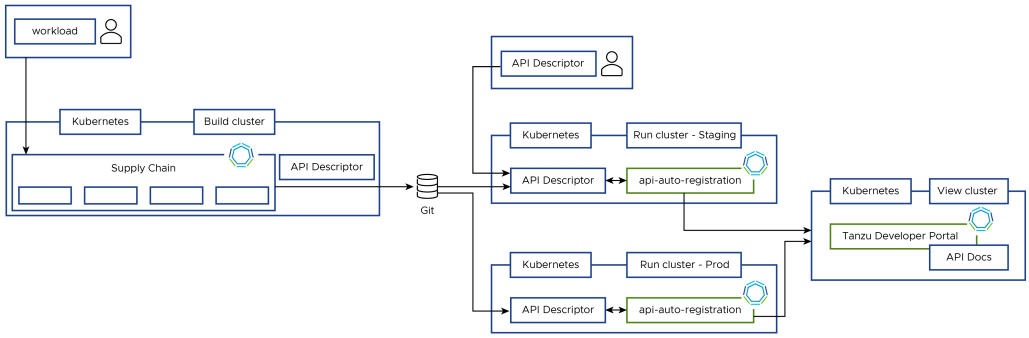
Key Concepts for API Auto Registration

This topic explains key concepts you use with API Auto Registration.

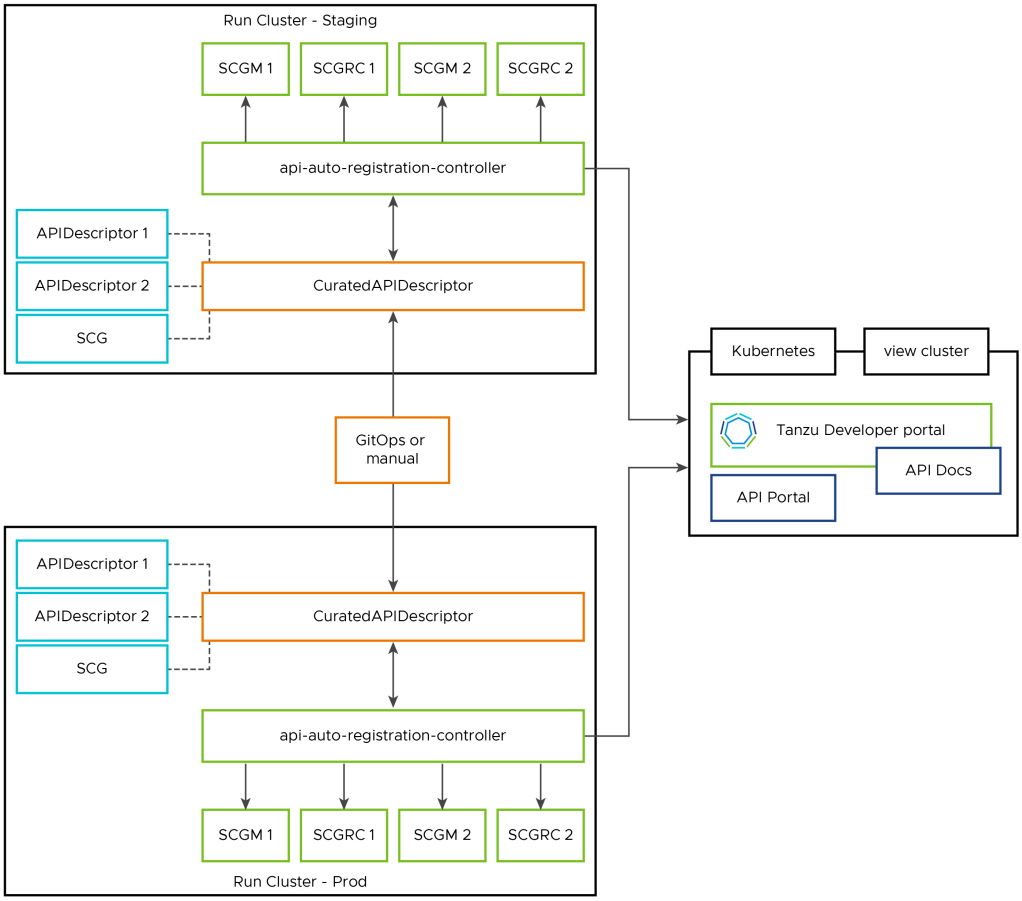
API Auto Registration architecture

You can use the full potential of API Auto Registration by using a distributed environment, as shown in the following diagrams:

- The workloads that expose APIs through the supply chains cause generated `APIDescriptors`. This triggers API Auto Registration's Kubernetes controller to generate and register API entities in Tanzu Developer Portal.



- Aggregate one or more `CuratedAPIDescriptor` into a curated API by using `APIDescriptors`. Optionally, this can trigger Spring Cloud Gateway routing resource generation for the referenced APIs.



APIDescriptor custom resource explained

To initiate API registration, the supply chain must create the custom resource of type `APIDescriptor` automatically or through other processes. The information from this custom resource constructs an API entity in Tanzu Developer Portal.

This custom resource exposes the following text boxes:

```
apiVersion: apis.apps.tanzu.vmware.com/v1alpha1
kind: APIDescriptor
metadata:
```

```
  name:                    # name of your APIDescriptor
  namespace:               # optional: namespace of your APIDescriptor
spec:
  type:                    # type of the API spec. oneOf(openapi, grpc, asyncapi, graph
ql)
  description:             # description for the API exposed
  system:                  # system that the API is part of
  owner:                   # person/team that owns the API
  location:
    apiSpec:
      path:                # sub-path where the API spec is available (previously `loca
tion.path`)
      url:                 # optional: static absolute base URL for the API spec
    server:                # base URL object where the API spec is available. oneOf(ur
l, ref) (previously `location.baseURL`)
      url:                 # optional: static absolute base URL for the API server
      ref:                 # optional: object ref to oneOf(HTTPProxy, Knative Service,
Ingress)
        apiVersion:
        kind:
        name:
        namespace:
```

The text boxes cause specific behavior in Tanzu Developer Portal:

- The system and owner are copied to the API entity. You might have to separately create and add the System and Group kind to the catalog.
- Tanzu Developer Portal uses the namespace for the API entity where the APIDescriptor CR is applied. This causes the API entity's name, system, and owner to all be in that namespace.
- To explicitly use a system or owner in a different namespace, you can specify that in the `system: my-namespace/my-other-system` or `owner: my-namespace/my-other-team` text boxes.
- If the system or owner you are trying to link doesn't have a namespace specified, you can qualify them with the `default` namespace. For example, `system: default/my-default-system`

Important

`spec.location.path` is deprecated in favor of `spec.location.apiSpec.path`, and `spec.location.baseURL` is deprecated in favor of `spec.location.server`. This change supports having a different API server location from the specification's location. These deprecated fields will be removed in Tanzu Application Platform 1.8.

With an absolute URL

To create an APIDescriptor with a static `server.url`, you must apply the following YAML to your cluster.

```
apiVersion: apis.apps.tanzu.vmware.com/v1alpha1
kind: APIDescriptor
metadata:
  name: sample-absolute-url
spec:
  type: openapi
  description: A set of API endpoints to manage the resources within the petclinic ap
p.
  system: spring-petclinic
```

```
  owner: team-petclinic
  location:
    apiSpec:
      path: "/v3/api-docs.yaml"
    server:
      url: https://myservice.mynamespace.svc.cluster.local:6789
```

With an object ref

You can use an object reference, instead of hard coding the URL, to point to a HTTPProxy, Knative Service, or Ingress. VMware does not support referencing Kubernetes `Service` with Object Ref. To point to your Kubernetes `Service` directly, you can use the static URL with cluster DNS address. For example, `https://myservice.mynamespace.svc.cluster.local:6789`.

With an HTTPPRoxy object ref

This section includes an example YAML that points to an HTTPProxy from which the controller extracts the `.spec.virtualhost.fqdn` as the baseURL.

```
apiVersion: apis.apps.tanzu.vmware.com/v1alpha1
kind: APIDescriptor
metadata:
  name: sample-contour-ref
spec:
  type: openapi
  description: A set of API endpoints to manage the resources within the petclinic ap
p.
  system: spring-petclinic
  owner: team-petclinic
  location:
    apiSpec:
      path: "/test/openapi"
    server:
      ref:
        apiVersion: projectcontour.io/v1
        kind: HTTPProxy
        name: my-httpproxy
        namespace: my-namespace # optional
```

With a Knative service object ref

To use a Knative Service, your controller reads the `status.url` as the baseURL. For example:

```
# all other fields similar to the above example
    server:
      ref:
        apiVersion: serving.knative.dev/v1
        kind: Service
        name: my-knative-service
        namespace: my-namespace # optional
```

With an ingress object ref

To use an Ingress instead, your controller reads the URL from the jsonPath specified. When jsonPath is left empty, your controller reads the `"{.spec.rules[0].host}"` as the URL. For example:

```
# all other fields similar to the above example
    server:
      ref:
```

```
        apiVersion: networking.k8s.io/v1
        kind: Ingress
        name: my-ingress
        jsonPath: "{.spec.rules[1].host}"
        namespace: my-namespace # optional
```

APIDescriptor status fields

When API Auto Registration processes an APIDescriptor, it adds several fields describing the progress to the `status`. Including `conditions`, which provides information useful for troubleshooting. For information about the conditions, see Troubleshoot API Auto Registration.

In addition to `conditions`, the `status` contains other useful fields showing the resolved API's details. The following is a list of these fields with a brief explanation of what they contain.

```
status:
  registeredEntityURL:    # Url of the corresponding API Entity in Tanzu Developer Por
tal
  registeredTapUID:       # Unique identifier for the corresponding API Entity in Tanz
u Developer Portal
  resolvedAPIServerURL:   # Url to the API runtime server
  resolvedAPISpecURL:     # Url used to retrieve the full API Spec by Api Auto Registr
ation
  resolvedAPISpec:        # Full API Spec as retrieved by Api Auto Registration
  resolvedAPISpecHash:    # Hash value of the `resolvedAPISpec`. This field can be use
d to see whether the spec has been updated or not.
  apiSpecLastUpdateTime:  # Timestamp representing the server time when API Spec was l
ast updated. It is not guaranteed to be set in happens-before order across separate op
erations. It is represented in RFC3339 form and is in UTC.
```

CuratedAPIDescriptor custom resource explained

To curate one or more Workload OpenAPI specifications into a single aggregated API, create a custom resource of type `CuratedAPIDescriptor`. The information from this custom resource references a list of APIDescriptors and how path-based routing aggregates them.

If you specify a valid route provider, for example, `spring-cloud-gateway` for Spring Cloud Gateway for Kubernetes (SCG), the API Auto Registration controller finds the SpringCloudGateway resource and automatically creates the following routing resources for you to expose your curated APIs as:

- SpringCloudGatewayRouteConfig (SCGRC): a custom resource that describes all the API endpoints and optional routing modifiers to access the endpoints. This is generated from the resolved OpenAPI Specification of the APIDescriptor through SCG OpenAPI conversion service.
- SpringCloudGatewayMapping (SCGM): a custom resource that binds a SCGRC resource to a SCG resource.

This custom resource exposes the following text boxes:

```
apiVersion: apis.apps.tanzu.vmware.com/v1alpha1
kind: CuratedAPIDescriptor
metadata:
  name:                 # name of your CuratedAPIDescriptor
  namespace:            # optional: namespace of your CuratedAPIDescriptor
  annotations:
    "apis.apps.tanzu.vmware.com/route-provider": "spring-cloud-gateway"   # specify ro
ute provider
spec:
  type: openapi         # type of the API spec. oneOf(openapi, grpc, asyncapi, graphq
l)
  title:                # title of the curated API
```

```
  description:          # description of the curated API spec
  documentation:        # documentation for the curated API spec
  groupId:              # groupID of the curated API.
  version:              # version of the curated API
  apiDescriptors:
    - name:             # name of a APIDescriptor to include in this curated API
      namespace:        # namespace of the APIDescriptor
      pathPrefix:       # Path prefix that the API endpoints from the linked APIDescri
ptor should have
      routeConfig:
        ssoEnabled:     # whether to enable SSO on the gateway to perform authenticati
on for users
        tokenRelay:     # whether to enable TokenRelay on the gateway to pass along th
e SSO ID token to the upstream service. This setting depends on `ssoEnabled`.
        filters:        # additional service lever filters to set on all the endpoints
in this API
    - ...
```

There are some key behaviors generated from the text boxes:

- The `apis.apps.tanzu.vmware.com/route-provider` annotation specified how you want to provide routing to the curated API. VMware only supports `spring-cloud-gateway`.
- `groupId` is a concept that's aligned with API portal to group APIs from different high-availability zones/locations or with different `version`.
- `groupId` and `version` identify a matching gateway that route traffic for the curated API
- `routeConfig` section specifies service level configuration you add when generating the routing resource for the API. For information about spring-cloud-gateway fields, see OpenAPI route conversion.
    - Prior to Spring Cloud Gateway (SCG) for Kubernetes v2.1.3, there is a known issue in the SCG OpenAPI Conversion Service to support adding token relay at the service level. The `tokenRelay: true` setting only works with SCG v2.1.3 and above.
    - `routeConfig.filters` section specifies service level filters for all the routes exposed in each API. You can add modifications to your endpoints, such as `RateLimit=5,10s` or `RemoveRequestHeader=X-Request-Foo`. For information about available filters, see SCG commercial filters.
    - Your controller automatically prepends each endpoint path with the `pathPrefix` you specified for each APIDescriptor, and adds the `StripPrefix` filter to the end of the filter list to facilitate a successful path-based redirect. Additionally, you can add more `StripPrefix` filters to the service level filters to skip common paths in your specifications that are not in your service.

CuratedAPIDescriptor status fields

When processing an CuratedAPIDescriptor, several fields are added to the `status`. One of these is `conditions`, which provide information useful for troubleshooting. The conditions are explained in the Troubleshooting Guide.

In addition to `conditions` the `status` contains a couple of other useful fields. The following is a list of these fields with a brief explanation of what they contain.

```
status:
  ResolvedBaseURL:        # Base url to access the curated API. Empty if no route prov
ider is configured.
  ResolvedAPISpecURL:     # Url to the generated aggregated API spec
  AggregatedAPISpec:      # Generated full API Spec as aggregated by Api Auto Registra
tion
  AggregatedAPISpecHash:  # Hash of the aggregated API Spec. This field can be used to
see whether the spec has been updated or not.
```

```
  LastUpdateTime:         # Timestamp representing the server time when API Spec was l
ast updated. It is not guaranteed to be set in happens-before order across separate op
erations. It is represented in RFC3339 form and is in UTC.
  MatchedGateway:         # The Gateway resource the curated API is matched on. We cur
rently only support SCG.
```

Install API Auto Registration

This topic describes how you can install API Auto Registration from the Tanzu Application Platform package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install API Auto Registration. For information about profiles, see Components and installation profiles.

Tanzu Application Platform prerequisites

Before installing API Auto Registration, complete all prerequisites to install Tanzu Application Platform. See Tanzu Application Platform Prerequisites.

Using with TLS

Starting in Tanzu Application Platform v1.4, TLS is turned on by default for several components. API Auto Registration automatically trusts the CA for the shared `ingress_issuer` when using the default ClusterIssuer `tap-ingress-selfsigned`. This change means that a `Certificate` is automatically generated using this issuer.

If you do not want a `Certificate` to generate automatically, you can set the `auto_generate_cert` flag to `false` in the values file. To replace the default with a custom ingress issuer, see Security and compliance. Whenever you do not use the default ClusterIssuer `tap-ingress-selfsigned`, do not automatically generate certificates, or use other custom CAs, you must manually set the certificate. See Troubleshooting.

Install

To install the API Auto Registration package:

1. List version information for the package by running:

   ```
   tanzu package available list apis.apps.tanzu.vmware.com --namespace tap-install
   ```

   For example:

   ```
   $ tanzu package available list apis.apps.tanzu.vmware.com --namespace tap-insta
   ll
   - Retrieving package versions for apis.apps.tanzu.vmware.com...
     NAME                                VERSION  RELEASED-AT
     apis.apps.tanzu.vmware.com  0.1.0        2022-08-30 19:00:00 -0500 -05
     apis.apps.tanzu.vmware.com  0.2.0        2022-11-24 12:20:00 -0500 -05
   ```

2. (Optional) Gather values schema.

   Display values schema of the package:

```
tanzu package available get apis.apps.tanzu.vmware.com/VERSION-NUMBER --values-
schema --namespace tap-install
```

Where `VERSION-NUMBER` is the version of the package you retrieved.

For example:

```
tanzu package available get apis.apps.tanzu.vmware.com/0.4.0 --values-schema --
namespace tap-install

Retrieving package details for apis.apps.tanzu.vmware.com/0.4.0...
KEY                                                         DEFAULT
TYPE     DESCRIPTION
ca_cert_data
string   Optional: PEM-encoded certificate data for the controller to trust TL
S.
ingress_issuer
string   Optional: Name of the default cluster issuer used to generate certific
ates
auto_generate_cert                                          true
boolean  Flag that indicates if a cert-manager certificate should be generated
using the ingress_issuer. Only applies if the ingress_issuer is specified conne
ctions with a custom CA
cluster_name                                                dev
string   Name of the cluster used for setting the API entity lifecycle in TAP G
UI. The value should be unique for each run cluster.
route_provider.spring_cloud_gateway.enabled                 false
boolean  Flag that indicates if VMware Spring Cloud Gateway for Kubernetes is s
upported as route provider
route_provider.spring_cloud_gateway.scg_openapi_service_url  http://scg-openapi
-service.spring-cloud-gateway.svc.cluster.local  string   FQDN URL for SCG oper
ator openapi conversion service
sync_period                                                 5m
string   Time period used for reconciling an APIDescriptor
cluster_name                                                dev
string   Name of the cluster that will be used for setting the API entity lifec
ycle in TAP GUI. The value should be unique for each run cluster.
curated_api_server.port                                     8082
integer
curated_api_server.service_type                             ClusterIP
string
sync_period                                                 5m
string   Time period used for reconciling an APIDescriptor.
tap_gui_url                                                 http://server.tap-
gui.svc.cluster.local:7000                        string   FQDN URL for TAP GUI.
replicas                                                    1
integer  Number of controller replicas to deploy.
resources.limits.cpu                                        500m
string   CPU limit of the controller.
resources.limits.memory                                     500Mi
string   Memory limit of the controller.
resources.requests.cpu                                      20m
string   CPU request of the controller.
resources.requests.memory                                   100Mi
string   Memory request of the controller.
logging_profile                                             production
string   Logging profile for controller. If set to development, use console log
ging with full stack traces, else use JSON logging.
```

3. Locate the Tanzu Developer Portal (formerly Tanzu Application Platform GUI) URL.

   When running a full profile on a Tanzu Application Platform cluster, the default value of Tanzu Developer Portal URL is sufficient. You can edit this to match the externally available

FQDN of Tanzu Developer Portal to display the entity URL in the externally accessible APIDescriptor status.

When installed in a run cluster or with a profile where Tanzu Developer Portal is not installed in the same cluster, you must set the `tap_gui_url` parameters correctly for successful entity registration with Tanzu Developer Portal.

You can locate the `tap_gui_url` by going to the view cluster with the Tanzu Developer Portal you want to register the entity with:

```
kubectl get secret tap-values -n tap-install -o jsonpath="{.data['tap-values\.y
aml']}" | base64 -d | yq '.tap_gui.app_config.app.baseUrl'
```

4. (Optional) VMware recommends creating `api-auto-registration-values.yaml`.

   To overwrite the default values when installing the package, create a `api-auto-registration-values.yaml` file:

   ```
   tap_gui_url: https://tap-gui.view-cluster.com
   cluster_name: staging-us-east
   ca_cert_data:  |
       -----BEGIN CERTIFICATE-----
       MIIFXzCCA0egAwIBAgIJAJYm37SFocjlMA0GCSqGSIb3DQEBDQUAMEY...
       -----END CERTIFICATE-----
   sync_period: 2m
   ```

5. Install the package using Tanzu CLI:

   ```
   tanzu package install api-auto-registration
   --package apis.apps.tanzu.vmware.com
   --namespace tap-install
   --version VERSION-NUMBER
   --values-file api-auto-registration-values.yaml
   ```

   Where `VERSION-NUMBER` is the version of the package you retrieved in the earlier step.

6. Verify the package installation by running:

   ```
   tanzu package installed get api-auto-registration -n tap-install
   ```

   Verify that `STATUS` is `Reconcile succeeded`:

   ```
   kubectl get pods -n api-auto-registration
   ```

7. Verify that applying an APIDescriptor resource to your cluster causes the `STATUS` showing `Ready`:

   ```
   kubectl apply -f - <<EOF
   apiVersion: apis.apps.tanzu.vmware.com/v1alpha1
   kind: APIDescriptor
   metadata:
     name: sample-api-descriptor-with-absolute-url
   spec:
     type: openapi
     description: A sample APIDescriptor to validate package installation successf
   ul
     system: test-installation
     owner: test-installation
     location:
       apiSpec:
         path: "/api/v3/openapi.json"
       server:
   ```

```
      url: https://petstore3.swagger.io
EOF
```

Verify that the APIDescriptor status shows `Ready`:

```
kubectl get apidescriptors
NAME                                        STATUS
sample-api-descriptor-with-absolute-url     Ready

kubectl get apidescriptors -owide
NAME                                        STATUS    TAP GUI ENTITY URL     API
SPEC URL
sample-api-descriptor-with-absolute-url     Ready     <url-to-the-entity>    <ur
l-to-the-api-spec>
```

If the status does not show `Ready`, you can inspect and show the reason by running:

```
kubectl get apidescriptor sample-api-descriptor-with-absolute-url -o jsonpath
='{.status.conditions[?(@.type=="Ready")].message}'
```

Verify that the entity is created in your Tanzu Developer Portal: `TAP-GUI-URL/catalog/default/api/sample-api-descriptor-with-absolute-url`

Configure API Auto Registration

This topic describes configuration options for API Auto Registration.

Update install values for api-auto-registration package

You can view the values available for the package by finding the available package version and finding the corresponding schema. After you select the values that you want to update, update them either by updating the `tap` package or by updating the `api-auto-registration` package if you installed it on its own.

1. Find the version of the available package:

```
tanzu package available list apis.apps.tanzu.vmware.com -n tap-install

/ Retrieving package versions for apis.apps.tanzu.vmware.com...
NAME                        VERSION  RELEASED-AT
apis.apps.tanzu.vmware.com  0.4.0    2023-10-31 13:47:14 -0400 EDT
```

2. Explore the values available:

```
tanzu package available get apis.apps.tanzu.vmware.com/VERSION-NUMBER --values-
schema --namespace tap-install
```

Where `VERSION-NUMBER` is the version of the package listed in the earlier step.

For example:

```
tanzu package available get apis.apps.tanzu.vmware.com/0.4.0 --values-schema --
namespace tap-install

Retrieving package details for apis.apps.tanzu.vmware.com/0.4.0...
KEY                       DEFAULT                                          TYPE
DESCRIPTION
ca_cert_data                                                               string
Optional: PEM-encoded certificate data for the controller to trust TLS.
ingress_issuer                                                             string
Optional: Name of the default cluster issuer used to generate certificates
```

```
auto_generate_cert         true                                          boolea
n  Flag that indicates if a cert-manager certificate should be generated using
the ingress_issuer. Only applies if the ingress_issuer is specified
connections with a custom CA
cluster_name               dev                                           string
Name of the cluster used for setting the API entity lifecycle in TAP GUI. The v
alue should be unique for each run cluster.
sync_period                5m                                            string
Time period used for reconciling an APIDescriptor.
tap_gui_url                http://server.tap-gui.svc.cluster.local:7000  string
FQDN URL for TAP GUI.
replicas                   1                                             intege
r  Number of controller replicas to deploy.
resources.limits.cpu       500m                                          string
CPU limit of the controller.
resources.limits.memory    500Mi                                         string
Memory limit of the controller.
resources.requests.cpu     20m                                           string
CPU request of the controller.
resources.requests.memory  100Mi                                         string
Memory request of the controller.
logging_profile            production                                    string
Logging profile for controller. If set to development, use console logging with
full stack traces, else use JSON logging.
```

3. Create `api-auto-registration-values.yaml` if you installed the API Auto Registration package on its own.

4. Update the tap-values.yaml if you used a package to install.

   A `api-auto-registration-values.yaml` file might contain the following:

   ```
   tap_gui_url: https://tap-gui.view-cluster.com
   cluster_name: staging-us-east
   ca_cert_data:  |
       -----BEGIN CERTIFICATE-----
       MIIFXzCCA0egAwIBAgIJAJYm37SFocjlMA0GCSqGSIb3DQEBDQUAMEY...
       -----END CERTIFICATE-----
   ```

   A `tap-values.yaml` file might contain the following values, in addition to other values.

   ```
   shared:
       ingress_domain: "INGRESS-DOMAIN"
       ingress_issuer: # Optional: can denote a cert-manager.io/v1/ClusterIssuer o
   f your choice. Defaults to "tap-ingress-selfsigned".
       ca_cert_data: | # To be passed if using custom certificates.
           -----BEGIN CERTIFICATE-----
           MIIFXzCCA0egAwIBAgIJAJYm37SFocjlMA0GCSqGSIb3DQEBDQUAMEY...
           -----END CERTIFICATE-----
   api_auto_registration:
       tap_gui_url: https://tap-gui.view-cluster.com
       cluster_name: staging-us-east
   ```

   See the Full Profile sample.

5. If you installed the API Auto Registration package on its own, not as part of Tanzu Application Platform, update the package using the Tanzu CLI:

   ```
   tanzu package installed update api-auto-registration
   --package apis.apps.tanzu.vmware.com
   --namespace tap-install
   --version $VERSION
   --values-file api-auto-registration-values.yaml
   ```

6. If you installed API Auto Registration as part of Tanzu Application Platform, see Upgrading Tanzu Application Platform.

Use API Auto Registration

This topic describes how you can use API Auto Registration.

Overview

The run profile requires you to update the install values before proceeding. For iterate and full profiles, the default values work but you might prefer to update them. For information about profiles, see About Tanzu Application Platform profiles.

Prerequisites

API Auto Registration requires the following:

1. A location exposing a dynamic or static API specification.
2. An APIDescriptor Custom Resource (CR) with that location created in the cluster.
3. (Optional) Configurations:
    1. Cross-Origin Resource Sharing (CORS) for OpenAPI specifications
    2. Connect the component to the auto-registered API in Tanzu Developer Portal

Configurations

To generate OpenAPI Spec:

- By creating a simple Spring Boot app
- By scaffolding a new project using App Accelerator Template
- In an existing Spring Boot project

To create APIDescriptor Custom Resource:

- Using Out Of The Box Supply Chains
- Using Custom Supply Chains
- Using other GitOps processes or Manually

Additional configurations:

- CORS for viewing OpenAPI Spec in Tanzu Developer Portal
- Connection between the Component and API in Tanzu Developer Portal

Generate OpenAPI specifications

This section tells you how to generate OpenAPI specifications.

Using a Spring Boot app with a REST service

You can use a Spring Boot example app built using Building a RESTful Web Service guide. and has the Springdoc dependency.

Example of a workload using the Spring Boot app:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: simple-rest-app
  labels:
    ...
    apis.apps.tanzu.vmware.com/register-api: "true"
spec:
  source:
    ...
  params:
    - name: api_descriptor
      value:
        type: openapi
        location:
          path: "/v3/api-docs"
        system: dev
        owner: team-a
        description: "A set of API endpoints."
```

Using App Accelerator template

If you are creating a new application exposing an API, you might use the java-rest-service App Accelerator template to get a pre-built app that includes a `workload.yaml` with a basic REST API. From your Tanzu Developer Portal Accelerators tab, search for the accelerator and scaffold it according to your needs.

Using an existing Spring Boot project using springdoc

If you have an existing Spring Boot app that exposes an API, you can generate OpenAPI specifications using springdoc. See the springdoc documentation

After you have springdoc configured and an OpenAPI automatically generated, you can choose one of the following methods to create the APIDescriptor custom resource:

- VMware recommends having your Spring Boot app to be managed using Workloads and the Out-Of-The-Box (OOTB) supply chain. See the Use Out-Of-The-Box (OOTB) supply chains for further instructions.
- To use custom supply chains, see Using Custom Supply Chains. -To use a different Gitops process or manage the APIDescriptor CR manually, see the Using other GitOps processes or Manually section.

Create APIDescriptor custom resource

This section tells you how to create an APIDescriptor custom resource.

Use Out-Of-The-Box (OOTB) supply chains

All the Out-Of-The-Box (OOTB) supply chains are modified so that they can use API Auto Registration. If you want your workload to be auto registered, you must make modifications to your workload YAML:

1. Add the label `apis.apps.tanzu.vmware.com/register-api: "true"`.
2. Add a parameter of `type api_descriptor`:

```
params:
  - name: api_descriptor
    value:
      type: openapi   # We currently support any of openapi, aysncapi, graphq
```

```
l, grpc
        location:
          path: "/v3/api-docs"  # The path to the api documentation
          baseURL: "http://my-spec.url" # Optional: The base URL to the api doc
umentation if not served from the API runtime
        owner: team-petclinic   # The team that owns this
        system: petclinic       # The Backstage system entity this API belongs
to
        description: "A set of API endpoints to manage the resources within the
petclinic app."
```

The default supply chains use Knative to deploy your applications and are referenced as the server location for the generated APIDescriptor.

For API specifications, there are 2 options for the location:

- If the API specifications are generated and served from your application endpoint, the only location information you must set is the path to the API documentation. The controller can figure out the base URL by using the Knative server reference.
- If your API specifications are served from a static location, you can hardcode the URL using the `location.baseURL` property.

Example workload that exposes the API specifications from a Knative service:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: petclinic-knative
  labels:
    ...
    apis.apps.tanzu.vmware.com/register-api: "true"
spec:
  source:
    ...
  params:
    - name: api_descriptor
      value:
        type: openapi
        location:
          path: "/v3/api-docs"
        system: pet-clinics
        owner: team-petclinic
        description: "A set of API endpoints to manage the resources within the petcli
nic app."
```

Example of a workload with a hardcoded URL to the API documentation:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: petclinic-hard-coded
  labels:
    ...
    apis.apps.tanzu.vmware.com/register-api: "true"
spec:
  source:
    ...
  params:
    - name: api_descriptor
      value:
        type: openapi
        location:
          baseURL: http://petclinic-hard-coded.my-apps.tapdemo.vmware.com/
```

```
          path: "/v3/api-docs"
        owner: team-petclinic
        system: pet-clinics
        description: "A set of API endpoints to manage the resources within the petcli
nic app."
```

After the supply chain runs, it creates an `APIDescriptor` custom resource. Tanzu Application Platform uses this resource to auto register your API. See APIDescriptor explained.

Using custom supply chains

If you are creating custom supply chains, you can still use API Auto Registration. To write a supply chain pipeline, use `ClusterConfigTemplate` by the name of `config-template` in your pipeline. To write a custom task, verify how the template is written to read parameters, interpret baseURL from Knative Services, and construct APIDescriptor CRs.

In the Delivery pipeline, you must directly create an APIDescriptor custom resource. You must grant permissions to create the CR from the delivery pipeline.

For information about APIDescriptors, see APIDescriptor explained.

Using other GitOps processes or manually

Using your GitOps process, or manually, you must stamp out an APIDescriptor CR and apply it in the cluster you choose. Specify all the required fields for an APIDescriptor CR to reconcile.

For information about APIDescriptors, see APIDescriptor explained.

Additional configuration

This section tells you how to perform additional configuration.

Setting up CORS for OpenAPI specifications

The agent, usually a browser, uses the CORS protocol to verify whether the current origin uses an API. To use the `Try it out`` feature for OpenAPI specifications from the API Documentation plug-in, you must configure CORS to allow successful requests.

Your API must be configured to allow CORS Requests from Tanzu Developer Portal. How you accomplish this varies based on your programming language and framework. If you are using Spring, see CORS support in spring framework.

At a high level, your API must accept the Tanzu Developer Portal domain must be accepted as a valid cross-origin.

To do this:

- **Origins allowed** header: `Access-Control-Allow-Origin`: A list of comma-separated values. This list must include your Tanzu Developer Portal host.
- **Methods allowed** header: `Access-Control-Allow-Method`: Must allow the method used by your API. Also confirm that your API supports preflight requests, a valid response to the OPTIONS HTTP method.
- **Headers allowed** header: `Access-Control-Allow-Headers`: If the API requires any header, you must include it in the API configuration or your authorization server.

Connecting the component to the API in Tanzu Developer Portal

When the API-producing component is added to the Tanzu Developer Portal catalog, it is helpful to connect the component to the API. By connecting the two entities, the catalog graph visualizes

this relationship for users. To connect the entities you must add the `.spec.providesApis` in your component.yaml where you can list all the APIs it provides using string reference format. Ensure that you follow the `namespace/name` format instead of `name`, otherwise the namespace defaults to the component's namespace, typically `default`. The name is the auto-registered API's name. VMware recommends updating the `component.yaml` with the API name after the auto-registration finishes.

The following is an example of a `component.yaml` with string entity reference to an API:

```
apiVersion: backstage.io/v1alpha1
kind: Component
metadata:
  name: petclinic
  namespace: petclinic-systems
  description: Petstore
spec:
  type: service
  lifecycle: dev
  owner: team-petclinic
  providesApis:
    - internal/petclinic-api-dev
```

For more information, see the API documentation plug-in in Tanzu Developer Portal.

API Curation (alpha)

This topic tells you how to use API Curation to expose several standalone APIs as one API for API Auto Registration.

Caution

The API Curation feature is in alpha and is intended for evaluation and test purposes only. VMware discourages using API Curation in a production environment.

Overview

To unlock the maximum power of API curation, VMware recommends using a supported route provider. Without this a supported route provider, the generated API specifications do not have a functional server URL set for testing the curated API. You must manually create the routing resources to route traffic to each referenced API to match with the aggregated API specifications. With the route provider integration, these routing concerns are taken care of automatically.

Prerequisites

A successful API curation requires the following prerequisites:

- (Optional) Spring Cloud Gateway for Kubernetes is installed.
- (Optional) `SpringCloudGateway` resources created with the matching `groupId` and `version`.
- One or more `APIDescriptor`s in the ready state.
- Create a `CuratedAPIDescriptor` resource referencing ready `APIDescriptor`s.

You can get the aggregated API specifications from the OpenAPI endpoint from the controller.

(Optional) Install route provider and create gateway resources

You can optionally install a route provider and create gateway resources.

Setup Spring Cloud Gateway integration

Using Spring Cloud Gateway for Kubernetes (SCG) integration as a route provider is optional. To install SCG, see Install Spring Cloud Gateway for Kubernetes.

For SCG v2.1.0 and later, if you enabled TLS on SCG, or installed it in a custom namespace, you must overwrite `route_provider.spring_cloud_gateway.scg_openapi_service_url` in your API Auto Registration values file.

```
route_provider:
  spring_cloud_gateway:
    scg_openapi_service_url: "http://scg-openapi-service.spring-cloud-gateway.svc.clus
ter.local" # default value
```

If you are using an earlier version of SCG, consider upgrading or see the following table to understand the impact:

Capability with SCG v2.1.0 and later	Behavior before SCG v2.1.0
The default value `scg_openapi_service_url` is sufficient if using the default SCG installation	You must overwrite the value `scg_openapi_service_url` with `http://scg-operator.tap-install.svc.cluster.local` if using the default SCG installation.
Matching SCG updates API metadata automatically and the generated OpenAPI specifications reflect the metadata	API metadata annotations are added or updated, but the API specifications exposed from SCG OpenAPI endpoint do not reflect that

Create SpringCloudGateway resource

You can create, using GitOps or manually, an `SpringCloudGateway` CR and apply it in the cluster you choose.

The following is an example SCG resource:

```
apiVersion: "tanzu.vmware.com/v1"
kind: SpringCloudGateway
metadata:
  name: test-api-curation
spec:
  api:
    version: 1.2.3
    groupId: test-api-curation
    serverUrl: https://my-curated-api.mydomain.com
    cors:
      allowedOrigins:
        - "http://api-portal.mydomain.com"
      allowedMethods:
        - "GET"
        - "PUT"
        - "POST"
      allowedHeaders:
        - '*'
```

The `groupId` and `version` matches on SCG when it reconciles for `CuratedAPIDescriptor`. After finding a match, SCG uses `serverUrl` as the baseURL of the curated API.

Create APIDescriptors for curation

To create `APIDescriptor` resources, see API Auto Registration Usage Guide. If any of the referenced `APIDescriptor` are not ready, the `CuratedAPIDescriptor` keeps retrying until all the

referenced `APIDescriptor`s are ready. If the API specifications from any of the `APIDescriptor` update, the controller selects the changes on the next reconciliation loop.

Note By default, the update might take up to 10 minutes, including maximum 5 minutes to refresh the `APIDescriptor`, and maximum 5 minutes to refresh `CuratedAPIDescriptor`. You can shorten the wait time by configuring `sync_period` in the AAR values file.

Create CuratedAPIDescriptor custom resource

Using your GitOps process, or manually, you can create an CuratedAPIDescriptor CR and apply it in the cluster you choose. Specify all the required fields for an CuratedAPIDescriptor CR to reconcile.

For information about CuratedAPIDescriptors, see CuratedAPIDescriptor explained.

You can view the readiness of the applied CuratedAPIDescriptors by running:

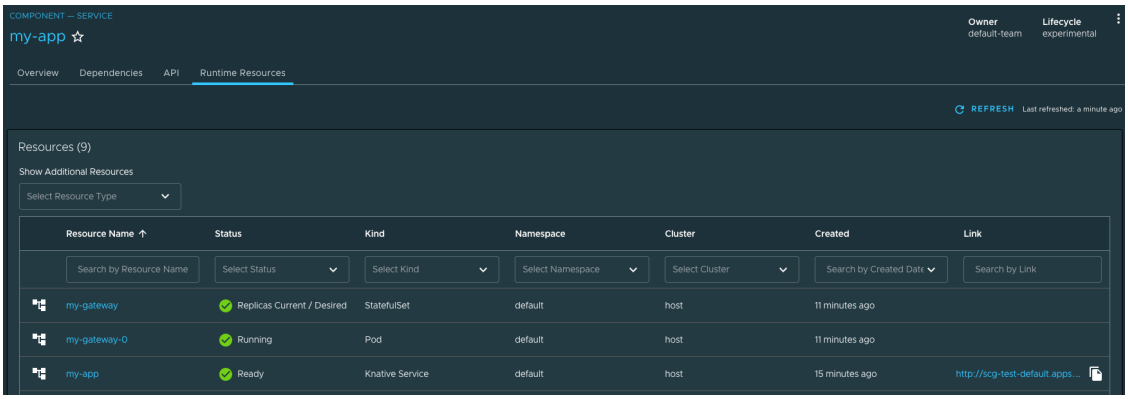
```
kubectl get curatedapidescriptors -A

NAMESPACE           NAME         GROUPID            VERSION   STATUS   CURATED API SPE
C URL
my-apps             petstore     cute-api-group     1.2.3     Ready    http://AAR-CONT
ROLLER-FQDN/openapi/my-apps/petstore
```

View the auto-registered API within Tanzu Developer Portal

After you the CuratedAPIDescriptor you created is in the `Ready` state, navigate to Tanzu Developer Portal to view the automatically registered APIs. You will see one new API for the CuratedAPIDescriptor and the other APIs generated from APIDescriptors.

Additionally, you will see a component registered for the curated API. If you chose to use Spring Cloud Gateway as the route provider in Setup Spring Cloud Gateway integration earlier, this component can show any gateway resources with the matching `app.kubernetes.io/part-of={PART_OF}` label under the **Runtime Resources**. To make this connection, add the `app.kubernetes.io/part-of={PART_OF}` label to the `SpringCloudGateway` instance you create. For more information, see the Spring Cloud Gateway documentation.



Retrieve curated API specifications

The API Auto Registration controller offers an endpoint to retrieve all the generated API specifications for the curated APIs in the cluster.

To retrieve curated API specifications:

1. Find the HTTPProxy that's created to access the endpoint:

```
kubectl get httpproxy api-auto-registration-controller -n api-auto-registration
```

The following is an example output:

```
NAME                                FQDN                                TLS SECRET
STATUS   STATUS DESCRIPTION
api-auto-registration-controller   api-auto-registration.tap.domain  api-auto-r
egistration-cert   valid    Valid HTTPProxy
```

2. To get all the curated API specifications with curl, use FQDN with an http scheme:

   ```
   curl http(s)://AAR-CONTROLLER-FQDN/openapi
   ```

   Where `AAR-CONTROLLER-FQDN` is the AAR FQDN controller you want the specifications for.

3. Retrieve specifications for `CuratedAPIDescriptor` from a specific namespace by specifying the following path:

   ```
   curl http(s)://AAR-CONTROLLER-FQDN/openapi/NAMESPACE
   ```

   Where:

   - `NAMESPACE` is the namespace that you want to retrieve specifications from.

4. Retrieve specifications for a specific `CuratedAPIDescriptor` by `namespace` and `name`:

   ```
   curl http(s)://AAR-CONTROLLER-FQDN/openapi/NAMESPACE/NAME
   ```

   Where:

   - `NAMESPACE` is the namespace of the `CuratedAPIDescriptor` that you want to use.
   - `NAME` is name of the `CuratedAPIDescriptor` that you want to use.

5. Retrieve specifications for a specific `groupId` and `version` combination by specifying query parameters:

   ```
   curl http(s)://AAR-CONTROLLER-FQDN/openapi?groupId=GROUP-ID&version=VERSION
   curl http(s)://AAR-CONTROLLER-FQDN/openapi/NAMESPACE?groupId=GROUP-ID&version=V
   ERSION
   ```

   Where:

   - `NAMESPACE` is the namespace that you want to retrieve specifications from.
   - `VERSION` is the version you want the specifications for.
   - `GROUP-ID` is group ID you want the specifications for.
   - `AAR-CONTROLLER-FQDN` is the AAR-CONTROLLER-FQDN you want to query.

6. Add the curated APIs to an API portal for display by configuring the source URL locations of an existing API portal. You can add all your curated APIs by using the unfiltered URL `http(s)://AAR-CONTROLLER-FQDN/openapi` or the filtered URL with query parameters to add a specific curated API of your choice. See Configuring API portal for VMware Tanzu on Kubernetes.

7. This curated API is not automatically registered in Tanzu Developer Portal. You can do this manually by creating an `api.yaml` and adding it to the catalog. For information about the structure of the definition file for an API entity, see the API documentation plug-in in Tanzu Developer Portal or the Backstage Kind: API documentation.

Troubleshoot API Auto Registration

This topic contains ways that you can troubleshoot API Auto Registration.

Debug API Auto Registration

This section includes commands for debugging or troubleshooting the APIDescriptor Custom Resource (commonly known as CR).

1. Get the details of CRs.

   ```
   kubectl get apidescriptor NAME -n NAMESPACE -owide
   kubectl get curatedapidescriptor NAME -n NAMESPACE -owide
   ```

   Where:

   - `NAME` is the name of the CR you want to debug.
   - `NAMESPACE` is the namespace associated with the CR you want to debug.

2. Find the status of the CRs.

   ```
   kubectl get apidescriptor NAME -n NAMESPACE -o jsonpath='{.status.conditions}'
   kubectl get curatedapidescriptor NAME -n NAMESPACE -o jsonpath='{.status.condit
   ions}'
   ```

   Where:

   - `NAME` is the name of the CR you want to debug.
   - `NAMESPACE` is the namespace associated with the CR you want to debug.

3. Find the generated SpringCloudGatewayRouteConfig (commonly known as SCGRC) and SpringCloudGatewayMapping (commonly known as SCGM) resource associated with a specific APIDescriptor CR from curation.

   The generated Spring Cloud Gateway (commonly known as SCG) resources are placed in the same namespace as the CuratedAPIDescriptor, and the generated name has a prefix with the name of the CuratedAPIDescriptor. To see which APIDescriptor the resource was generated for, you can list generated SCG resources with additional labels by running:

   ```
   kubectl get scgrc -A -L apis.apps.tanzu.vmware.com/api-descriptor-name -L apis.
   apps.tanzu.vmware.com/api-descriptor-namespace
   kubectl get scgm -A -L apis.apps.tanzu.vmware.com/api-descriptor-name -L apis.a
   pps.tanzu.vmware.com/api-descriptor-namespace
   ```

   Sample output:

   ```
   NAMESPACE      NAME                AGE   API-DESCRIPTOR-NAME   API-DESCRIPTOR-N
   AMESPACE
   api-curation   petstore-4a8d2a4f   49s   turtle-api            turtle-ns
   api-curation   petstore-ce551c65   49s   cat-api               cat-ns
   api-curation   petstore-d0243a39   49s   dog-api               dog-ns
   ```

4. Read logs from the `api-auto-registration` controller.

   ```
   kubectl -n api-auto-registration logs deployment.apps/api-auto-registration-con
   troller
   ```

5. Patch an APIDescriptor that is stuck in Deleting mode.

This might happen if the controller package is uninstalled before you clean up the APIDescriptor resources. You can reinstall the package and delete all the APIDescriptor resources first, or run for each stuck APIDescriptor resource.

```
kubectl patch apidescriptor API-DESCRIPTOR-NAME -p '{"metadata":{"finalizers":n
ull}}' --type=merge
```

Where `API-DESCRIPTOR-NAME` is the name of the API descriptor you want to patch.

Note

If you manually remove the finalizers from the APIDescriptor resources, you can have stale API entities within Tanzu Developer Portal that you must manually deregister.

6. Fix a `CuratedAPIDescriptor` that does not match with a SCG.

   This might happen if the `groupId` and version of the `CuratedAPIDescriptor` does not match any available `SpringCloudGateway` resource. You can remove the `"apis.apps.tanzu.vmware.com/route-provider": "spring-cloud-gateway"` annotation from your `CuratedAPIDescriptor` to skip SCG matching, or ensure that you have a matching SCG applied to the cluster.

APIDescriptor CRD shows message of `connection refused` but service is up and running

In Tanzu Application Platform v1.4 and later, if your workloads use ClusterIssuer for the TLS configuration or your API specifications location URL is secured using a custom CA, you might encounter the following message.

Your APIDescription CRD shows a status and message similar to:

```
    Message:               Get "https://spring-petclinic.example.com/v3/api-docs": dia
l tcp 12.34.56.78:443: connect: connection refused
    Reason:                FailedToRetrieve
    Status:                False
    Type:                  APISpecResolved
    Last Transition Time:  2022-11-28T09:59:13Z
```

This might be due to your workloads using a custom Ingress issuer. To solve this issue, either:

- Configure `ca_cert_data` following the instructions in Configure CA Cert Data.
- Deactivate TLS by setting `shared.ingress_issuer: ""`. VMware discourages this method. Deactivating TLS reduces your ability to test plug-in capability and iterate quickly.

Configure CA Cert Data

1. Obtain the PEM Encoded crt file for your ClusterIssuer or TLS setup. You use this to update the `api-auto-registration` package.
2. If you installed the API Auto Registration package through predefined profiles, you must update the `tap-values.yaml` and update the Tanzu Application Platform installation. Place the PEM encoded certificate into the `shared.ca_cert_data` key of the values file. See Install your Tanzu Application Platform profile. Run to update the package:

   ```
   tanzu package installed update tap -p tap.tanzu.vmware.com -v TAP-VERSION  --va
   lues-file tap-values.yaml -n tap-install
   ```

Where `TAP-VERSION` is the version of Tanzu Application Platform installed.

3. If you installed the API Auto Registration package as standalone, you must update the `api-auto-registration-values.yaml` and then update the package. Place the PEM encoded certificate into the `ca_cert_data` key of the values file. Run to update the package.

```
tanzu package installed update api-auto-registration --version API-AUTO-REGISTR
ATION-VERSION --namespace tap-install --values-file api-auto-registration-value
s.yaml
```

Where `API-AUTO-REGISTRATION-VERSION` is the version of API Auto Registration installed.

You can find the available api-auto-registration versions by running:

```
tanzu package available list -n tap-install | grep 'API Auto Registration'
```

APIDescriptor status shows `x509: certificate signed by unknown authority` but service is running

Your APIDescription CR shows a status and message similar to:

```
    Message:               Put "https://tap-gui.tap.my-cluster.tapdemo.vmware.com/api/
catalog/immediate/entities": x509: certificate signed by unknown authority
    Reason:                Error
    Status:                False
    Type:                  Ready
    Last Transition Time:  2022-11-28T09:59:13Z
```

This is the same issue as `connection refused` described earlier.

Unexpected content in generated specification

This issue happens when there are two or more `CuratedAPIDescriptor` with conflicting `groupId` and `version`.

If you create two `CuratedAPIDescriptor`s with the same `groupId` and `version` combination, both reconcile without an error. However, the following undesired behaviors can signal conflict:

- The `/openapi?groupId&version` endpoint returns more than one API specification.
- If you add both specifications to API portal, for example, `/openapi?groupId&version`, only one of them shows up in the API portal UI with a warning indicating that there is a conflict.
- If you add the route provider annotation for both of the `CuratedAPIDescriptor`s to use SCG, the generated API specification includes API routes from both `CuratedAPIDescriptor`s.

You can see the `groupId` and `version` information from all `CuratedAPIDescriptor`s to find conflicts by running:

```
$ kubectl get curatedapidescriptors -A

NAMESPACE           NAME         GROUPID            VERSION   STATUS   CURATED API SPE
C URL
my-apps             petstore     test-api-group     1.2.3     Ready    http://AAR-CONT
ROLLER-FQDN/openapi/my-apps/petstore
default             mystery      test-api-group     1.2.3     Ready    http://AAR-CONT
ROLLER-FQDN/openapi/default/mystery
```

Unsupported OpenAPI version

API Auto Registration only supports OpenAPI v3.0 and v2.0, formerly known as Swagger.

Overview of API portal for VMware Tanzu

This topic tells you how to use API portal for VMware Tanzu to find APIs you can use in your own applications.

Overview

You can view detailed API documentation and try out an API to meet your needs. API portal assembles its dashboard and detailed API documentation views by ingesting OpenAPI documentation from the source URLs. An API portal operator can add any number of OpenAPI source URLs in a single instance.

Getting started

To install the package without the predefined profiles of Tanzu Application Platform, see Install API portal.

For information about API portal for VMware Tanzu, see API portal for VMware Tanzu.

For information about configuring the package, see Configuring API portal for VMware Tanzu on Kubernetes.

API portal for VMware Tanzu supports:

- Authentication through Single Sign-On (SSO)
- API keys configuration and management
- Secure communication by using TLS

Overview of API portal for VMware Tanzu

This topic tells you how to use API portal for VMware Tanzu to find APIs you can use in your own applications.

Overview

You can view detailed API documentation and try out an API to meet your needs. API portal assembles its dashboard and detailed API documentation views by ingesting OpenAPI documentation from the source URLs. An API portal operator can add any number of OpenAPI source URLs in a single instance.

Getting started

To install the package without the predefined profiles of Tanzu Application Platform, see Install API portal.

For information about API portal for VMware Tanzu, see API portal for VMware Tanzu.

For information about configuring the package, see Configuring API portal for VMware Tanzu on Kubernetes.

API portal for VMware Tanzu supports:

- Authentication through Single Sign-On (SSO)
- API keys configuration and management
- Secure communication by using TLS

Install API portal for VMware Tanzu

This topic tells you how to install and update Tanzu API portal for VMware Tanzu from the Tanzu Application Platform (commonly known as TAP) package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install API portal. For more information about profiles, see Components and installation profiles.

Prerequisites

Before installing API portal:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.

Install

To install the API portal package:

1. Confirm what versions of API portal are available to install by running:

   ```
   tanzu package available list -n tap-install api-portal.tanzu.vmware.com
   ```

   For example:

   ```
   $ tanzu package available list api-portal.tanzu.vmware.com --namespace tap-inst
   all
   - Retrieving package versions for api-portal.tanzu.vmware.com...
     NAME                          VERSION  RELEASED-AT
     api-portal.tanzu.vmware.com  1.0.3    2021-10-13T00:00:00Z
   ```

2. (Optional) Gather values schema.

   ```
   tanzu package available get api-portal.tanzu.vmware.com/VERSION-NUMBER --values
   -schema --namespace tap-install
   ```

   Where `VERSION-NUMBER` is the version of the API Portal package listed earlier.

   For example:

   ```
   $ tanzu package available get api-portal.tanzu.vmware.com/1.0.3 --values-schema
   --namespace tap-install

   Retrieving package details for api-portal.tanzu.vmware.com/1.0.3...
   ```

3. (Optional) VMware recommends creating `api-portal-values.yaml`.

   To overwrite the default values when installing the package, create a `api-portal-values.yaml` file by following the values schema.

4. Install API portal by running:

   ```
   tanzu package install api-portal -n tap-install -p api-portal.tanzu.vmware.com
   -v VERSION-NUMBER --values-file api-portal-values.yaml
   ```

   Where `VERSION-NUMBER` is the version of the API Portal package listed earlier.

For example:

```
$ tanzu package install api-portal -n tap-install -p api-portal.tanzu.vmware.co
m -v 1.0.3 --values-file api-portal-values.yaml

/ Installing package 'api-portal.tanzu.vmware.com'
| Getting namespace 'api-portal'
| Getting package metadata for 'api-portal.tanzu.vmware.com'
| Creating service account 'api-portal-api-portal-sa'
| Creating cluster admin role 'api-portal-api-portal-cluster-role'
| Creating cluster role binding 'api-portal-api-portal-cluster-rolebinding'
/ Creating package resource
- Package install status: Reconciling

Added installed package 'api-portal' in namespace 'tap-install'
```

5. Verify the package installation by running:

   ```
   tanzu package installed get api-portal -n tap-install
   ```

   Verify that `STATUS` is `Reconcile succeeded`:

   ```
   kubectl get pods -n api-portal
   ```

Update the installation values for the `api-portal` package

To update the installation values for the `api-portal` package:

1. To overwrite the default values, create new values, or update the existing values, you need an `api-portal-values.yaml` file. If you do not already have an existing values file, you can extract the existing values by running:

   ```
   tanzu package installed get api-portal -n tap-install --values-file-output api-
   portal-values.yaml
   ```

   You can view the schema of the package:

   ```
   tanzu package available get apis.apps.tanzu.vmware.com/VERSION-NUMBER --values-
   schema --namespace tap-install
   ```

   Where `VERSION-NUMBER` is the version of the API Portal package listed in the earlier step.

   For example:

   ```
   tanzu package available get api-portal.tanzu.vmware.com/1.2.5 --values-schema -
   -namespace tap-install
   ```

2. Update the package by using the Tanzu CLI:

   ```
   tanzu package installed update api-auto-registration
   --package apis.apps.tanzu.vmware.com
   --namespace tap-install
   --version VERSION-NUMBER
   --values-file api-portal-values.yaml
   ```

   Where `VERSION-NUMBER` is the version of the API Portal package listed in the earlier step.

3. If you installed the API portal package as part of Tanzu Application Platform, you must update the `tap-values.yaml` and update the installation of Tanzu Application Platform. See Install your Tanzu Application Platform profile.

```
tanzu package installed update tap --package tap.tanzu.vmware.com --version VER
SION-NUMBER --values-file tap-values.yaml -n tap-install
```

Where `VERSION-NUMBER` is the version of the API Portal package listed in the earlier step.

Note

You can update API portal as part of upgrading Tanzu Application Platform. See Upgrading Tanzu Application Platform.

Overview of Application Accelerator

This topic tells you about the Application Accelerator component and architecture in Tanzu Application Platform (commonly known as TAP).

Overview

Application Accelerator for VMware Tanzu helps you bootstrap developing your applications and deploying them in a discoverable and repeatable way.

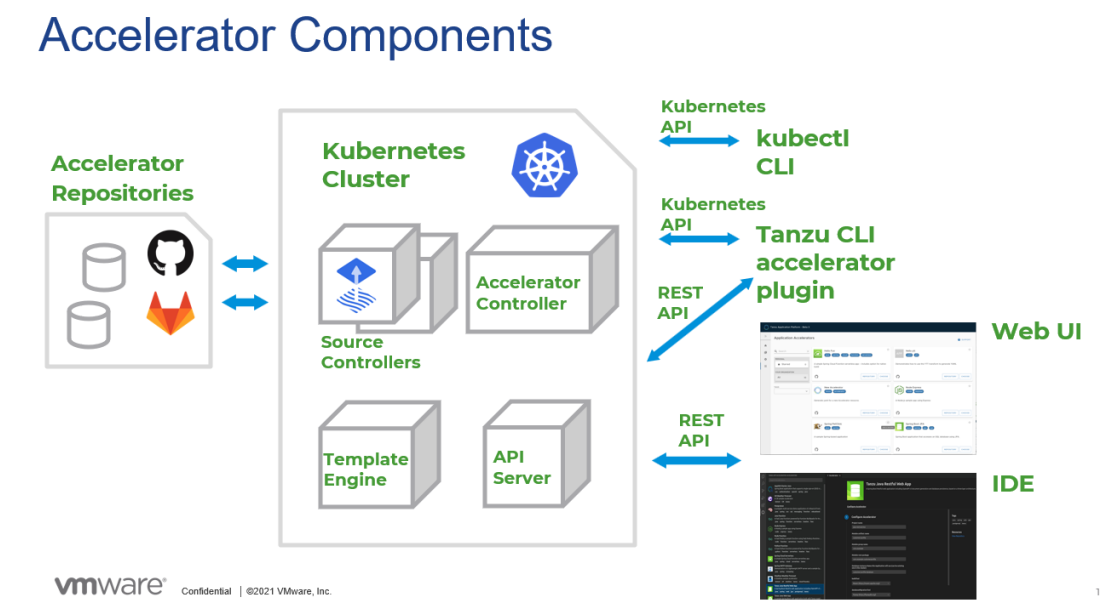
Enterprise Architects author and publish accelerator projects that provide developers and operators in their organization ready-made, conforming code and configurations.

Published accelerator projects are maintained in Git repositories. You can then use Application Accelerator to create new projects based on those accelerator projects.

The Application Accelerator UI enables you to discover available accelerators, configure them, and generate new projects to download.

Architecture

The following diagram of Accelerator components illustrates the Application Accelerator architecture.



How does Application Accelerator work?

Application Accelerator allows you to generate new projects from files in Git repositories. An `accelerator.yaml` file in the repository declares input options for the accelerator. This file also contains instructions for processing the files when you generate a new project.

Accelerator custom resources (CRs) control which repositories appear in both the Tanzu Application Platform Application Accelerator UI and in the Application Accelerator extension for VS Code. You can maintain CRs by using Kubernetes tools such as kubectl or by using the Tanzu CLI accelerator commands. The Accelerator controller reconciles the CRs with a Flux2 Source Controller to fetch files from GitHub or GitLab.

The Application Accelerator web UI gives you a searchable list of accelerators to choose from. After you select an accelerator, the UI presents text boxes for the options that are defined within the `accelerator.yaml` of the selected accelerator.

Application Accelerator sends the input values to the Accelerator Engine for processing. (Optional) The user can choose to have a new Git repository created as part of the project creation process. The Engine then returns the project in a ZIP file. If the project was generated using the Application Accelerator extension for VS Code, the project automatically be extracted to the directory location of your choice on your local machine. You can then open the project in your favorite integrated development environment (IDE) to develop further.

Overview of Application Accelerator

This topic tells you about the Application Accelerator component and architecture in Tanzu Application Platform (commonly known as TAP).

Overview

Application Accelerator for VMware Tanzu helps you bootstrap developing your applications and deploying them in a discoverable and repeatable way.

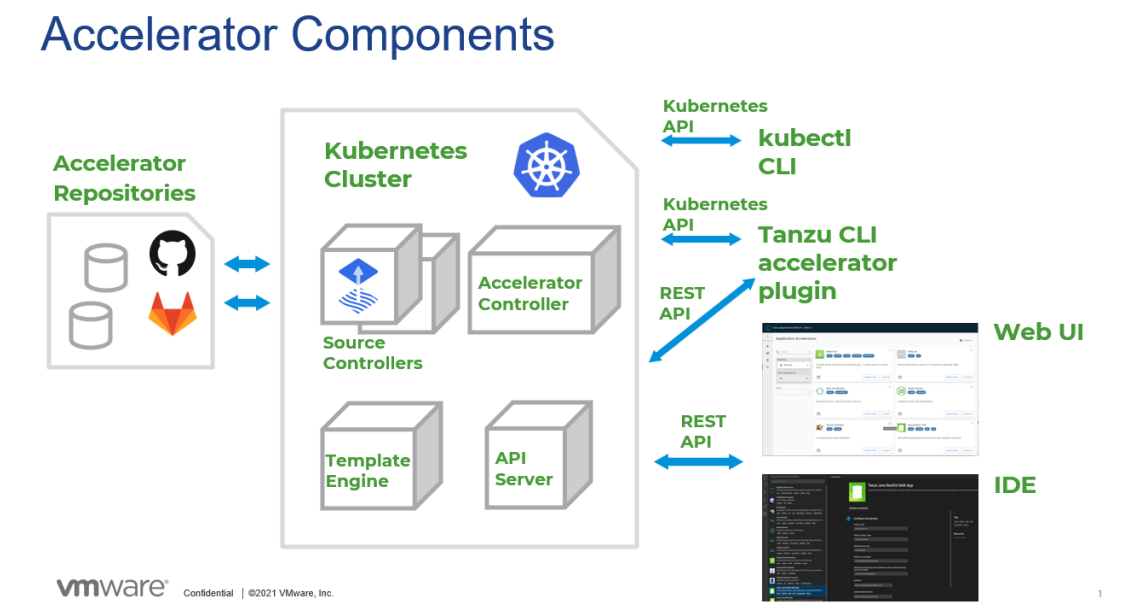
Enterprise Architects author and publish accelerator projects that provide developers and operators in their organization ready-made, conforming code and configurations.

Published accelerator projects are maintained in Git repositories. You can then use Application Accelerator to create new projects based on those accelerator projects.

The Application Accelerator UI enables you to discover available accelerators, configure them, and generate new projects to download.

Architecture

The following diagram of Accelerator components illustrates the Application Accelerator architecture.



How does Application Accelerator work?

Application Accelerator allows you to generate new projects from files in Git repositories. An `accelerator.yaml` file in the repository declares input options for the accelerator. This file also contains instructions for processing the files when you generate a new project.

Accelerator custom resources (CRs) control which repositories appear in both the Tanzu Application Platform Application Accelerator UI and in the Application Accelerator extension for VS Code. You can maintain CRs by using Kubernetes tools such as kubectl or by using the Tanzu CLI accelerator commands. The Accelerator controller reconciles the CRs with a Flux2 Source Controller to fetch files from GitHub or GitLab.

The Application Accelerator web UI gives you a searchable list of accelerators to choose from. After you select an accelerator, the UI presents text boxes for the options that are defined within the `accelerator.yaml` of the selected accelerator.

Application Accelerator sends the input values to the Accelerator Engine for processing. (Optional) The user can choose to have a new Git repository created as part of the project creation process. The Engine then returns the project in a ZIP file. If the project was generated using the Application Accelerator extension for VS Code, the project automatically be extracted to the directory location of your choice on your local machine. You can then open the project in your favorite integrated development environment (IDE) to develop further.

Install Application Accelerator

This topic tells you how to install Application Accelerator from the Tanzu Application Platform (commonly known as TAP) package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install Application Accelerator. For more information about profiles, see About Tanzu Application Platform components and profiles.

Prerequisites

Before installing Application Accelerator:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- Install Flux SourceController on the cluster. See Install Flux CD Source Controller.
- Install Source Controller on the cluster. See Install Source Controller.

Install

To install Application Accelerator:

1. List version information for the package by running:

   ```
   tanzu package available list accelerator.apps.tanzu.vmware.com --namespace tap-install
   ```

   For example:

   ```
   $ tanzu package available list accelerator.apps.tanzu.vmware.com --namespace tap-install

   - Retrieving package versions for accelerator.apps.tanzu.vmware.com...
     NAME                                VERSION  RELEASED-AT
     accelerator.apps.tanzu.vmware.com  1.4.0    2022-12-08 12:00:00 -0500 EST
   ```

2. (Optional) View the changes you can make to the default installation settings by running:

   ```
   tanzu package available get accelerator.apps.tanzu.vmware.com/VERSION-NUMBER \
     --values-schema \
     --namespace tap-install
   ```

   Where `VERSION-NUMBER` is the version of the Application Accelerator package listed earlier.

   For example:

   ```
   $ tanzu package available get accelerator.apps.tanzu.vmware.com/1.4.0 \
       --values-schema \
       --namespace tap-install
   ```

   For more information about values schema options, see the properties listed in Configure properties and resource use later.

3. Create a file named `app-accelerator-values.yaml` using the following example code:

   ```
   server:
     service_type: "LoadBalancer"
     watched_namespace: "accelerator-system"
   samples:
     include: true
   ```

4. Edit the values in your `app-accelerator-values.yaml` if needed, or leave the default values. You can add values you want from Configure properties and resource use.

5. Install the package by running:

```
tanzu package install app-accelerator \
  --package accelerator.apps.tanzu.vmware.com \
  --version VERSION-NUMBER \
  --namespace tap-install \
  --values-file app-accelerator-values.yaml
```

Where `VERSION-NUMBER` is the version of the Application Accelerator package listed earlier.

For example:

```
$ tanzu package install app-accelerator \
    --package accelerator.apps.tanzu.vmware.com \
    --version 1.4.0 \
    --namespace tap-install \
    --values-file app-accelerator-values.yaml

- Installing package 'accelerator.apps.tanzu.vmware.com'
| Getting package metadata for 'accelerator.apps.tanzu.vmware.com'
| Creating service account 'app-accelerator-tap-install-sa'
| Creating cluster admin role 'app-accelerator-tap-install-cluster-role'
| Creating cluster role binding 'app-accelerator-tap-install-cluster-rolebindin
g'
| Creating secret 'app-accelerator-tap-install-values'
- Creating package resource
- Package install status: Reconciling

 Added installed package 'app-accelerator' in namespace 'tap-install'
```

6. Verify the package install by running:

```
tanzu package installed get app-accelerator -n tap-install
```

For example:

```
$ tanzu package installed get app-accelerator -n tap-install

| Retrieving installation details for cc...
NAME:                    app-accelerator
PACKAGE-NAME:            accelerator.apps.tanzu.vmware.com
PACKAGE-VERSION:         1.4.0
STATUS:                  Reconcile succeeded
CONDITIONS:              [{ReconcileSucceeded True  }]
USEFUL-ERROR-MESSAGE:
```

Verify that `STATUS` is `Reconcile succeeded`.

7. To see the IP address for the Application Accelerator API when the `server.service_type` is set to `LoadBalancer`, run:

```
kubectl get service -n accelerator-system
```

This lists an external IP address for use with the `--server-url` Tanzu CLI flag for the Accelerator plug-in `generate` & `generate-from-local` command.

For how to troubleshoot installation issues, see Troubleshoot Application Accelerator.

Configure properties and resource use

When you install the Application Accelerator, you can configure the following optional properties from within your `app-accelerator-values.yaml` configuration file:

Property	Default	Description
registry.secret_ref	registry.tanzu.vmware.com	The secret used for accessing the registry where the App-Accelerator images are located
server.service_type	ClusterIP	The service type for the acc-ui-server service including LoadBalancer, NodePort, or ClusterIP
server.watched_namespace	accelerator-system	The namespace the server watches for accelerator resources
server.engine_invocation_url	http://acc-engine.accelerator-system.svc.cluster.local/invocations	The URL to use for invoking the accelerator engine
engine.service_type	ClusterIP	The service type for the acc-engine service including LoadBalancer, NodePort, or ClusterIP
engine.max_direct_memory_size	32M	The maximum size for the Java -XX:MaxDirectMemorySize setting
samples.include	True	Option to include the bundled sample Accelerators in the installation
ingress.include	False	Option to include the ingress configuration in the installation
ingress.enable_tls	False	Option to include TLS for the ingress configuration
domain	tap.example.com	Top-level domain to use for ingress configuration, default is shared.ingress_domain
tls.secret_name	tls	The name of the secret
tls.namespace	tanzu-system-ingress	The namespace for the secret
telemetry.retain_invocation_events_for_no_days	30	The number of days to retain recorded invocation events resources
telemetry.record_invocation_events	true	The system records each engine invocation when generating files for an accelerator?
git_credentials.secret_name	git-credentials	The name to use for the secret storing Git credentials for accelerators
git_credentials.username	null	The user name to use in secret storing Git credentials for accelerators
git_credentials.password	null	The password to use in secret storing Git credentials for accelerators
git_credentials.ca_file	null	The CA certificate data to use in secret storing Git credentials for accelerators
managed_resources.enable	false	Whether to enable the App used to control managed accelerator resources
managed_resources.git.url	none	Required if managed_resources are enabled. Git repository URL containing manifests for managed accelerator resources
managed_resources.git.ref	origin/main	Required if managed_resources are enabled. Git ref to use for repository containing manifests for managed accelerator resources
managed_resources.git.sub_path	null	Git subPath to use for repository containing manifests for managed accelerator resources

Property	Default	Description
`managed_resources.git.secret_ref`	`git-credentials`	Secret name to use for repository containing manifests for managed accelerator resources

VMware recommends that you do not override the default setting for `registry.secret_ref`, `server.engine_invocation_url`, or `engine.service_type`. These properties are only used to configure non-standard installations.

The following table is the resource use configurations for the components of Application Accelerator.

Component	Resource requests	Resource limits
acc-controller	CPU: 100m memory: 20Mi	CPU: 100m memory: 30Mi
acc-server	CPU: 100m memory:20Mi	CPU: 100m memory: 30Mi
acc-engine	CPU: 500m memory: 1Gi	CPU: 500m memory: 2Gi

Configure Application Accelerator

This topic tells you about advanced configuration options available for Application Accelerator in Tanzu Application Platform (commonly known as TAP). This includes configuring Git-Ops style deployments of accelerators and configurations for use with non-public repositories and in air-gapped environments.

Accelerators are created either using the Tanzu CLI or by applying a YAML manifest using kubectl. Another option is Using a Git-Ops style configuration for deploying a set of managed accelerators.

Application Accelerator pulls content from accelerator source repositories using either the “Flux SourceController” or the “Tanzu Application Platform Source Controller” components. If the repository used is accessible anonymously from a public server, you do not have to configure anything additional. Otherwise, provide authentication as explained in Using non-public repositories. There are also options for making these configurations easier explained in Configuring tap-values.yaml with Git credentials secret

Using a Git-Ops style configuration for deploying a set of managed accelerators

To enable a Git-Ops style of managing resources used for deploying accelerators, there is a new set of properties for the Application Accelerator configuration. The resources are managed using a Carvel kapp-controller App in the `accelerator-system` namespace that watches a Git repository containing the manifests for the accelerators. This means that you can make changes to the manifests, or to the accelerators they point to, and the changes are reconciled and reflected in the deployed resources.

You can specify the following accelerator configuration properties when installing the Application Accelerator. The same properties are provided in the `accelerator` section of the `tap-values.yaml` file:

```
accelerator:
  managed_resources:
    enable: true
    git:
      url: GIT-REPO-URL
```

```
      ref: origin/main
      sub_path: null
      secret_ref: git-credentials
```

Where:

- `GIT-REPO-URL` is the URL of a Git repository that contains manifest YAML files for the accelerators that you want to have managed. The URL must start with `https://` or `git@`. You can specify a `sub_path` if necessary and also a `secret_ref` if the repository requires authentication. If not needed, then leave these additional properties out.

  For more information, see Configure tap-values.yaml with Git credentials secret and Creating a manifest with multiple accelerators and fragments in this topic.

Functional and Organizational Considerations

Any accelerator manifest that is defined under the `GIT-REPO-URL` and optional `sub_path` is selected by the kapp-controller app. If there are multiple manifests at the defined `GIT-REPO-URL`, they are all watched for changes and displayed to the user as a merged catalog.

For example: if you have two manifests containing multiple accelerator or fragment definitions, `manifest-1.yaml`, and `manifest-2.yaml`, on the same path in the organizational considerations. The resulting catalog is (`manifest-1.yaml` + `manifest-2.yaml`).

Examples for creating accelerators

A minimal example for creating an accelerator

A minimal example might look like the following manifest:

`spring-cloud-serverless.yaml`

```
apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
kind: Accelerator
metadata:
  name: spring-cloud-serverless
spec:
  git:
    url: https://github.com/vmware-tanzu/application-accelerator-samples
    subPath: spring-cloud-serverless
    ref:
      branch: main
```

This example creates an accelerator named `spring-cloud-serverless`. The `displayName`, `description`, `iconUrl`, and `tags` text boxes are populated based on the content under the `accelerator` key in the `accelerator.yaml` file found in the `main` branch of the Git repository at Application Accelerator Samples under the sub-path `spring-cloud-serverless`. For example:

`accelerator.yaml`

```
accelerator:
  displayName: Spring Cloud Serverless
  description: A simple Spring Cloud Function serverless app
  iconUrl: https://raw.githubusercontent.com/vmware-tanzu/application-accelerator-samp
les/main/icons/icon-cloud.png
  tags:
  - java
  - spring
  - cloud
  - function
  - serverless
```

```
  - tanzu
...
```

To create this accelerator with kubectl, run:

```
kubectl apply --namespace --accelerator-system --filename spring-cloud-serverless.yaml
```

Or, you can use the Tanzu CLI and run:

```
tanzu accelerator create spring-cloud-serverless --git-repo https://github.com/vmware-
tanzu/application-accelerator-samples.git --git-branch main --git-sub-path spring-clou
d-serverless
```

An example for creating an accelerator with customized properties

You can specify the `displayName`, `description`, `iconUrl`, and `tags` text boxes and this overrides any values provided in the accelerator's Git repository. The following example explicitly sets those text boxes and the `ignore` text box:

`my-spring-cloud-serverless.yaml`

```
apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
kind: Accelerator
metadata:
  name: my-spring-cloud-serverless
spec:
  displayName: My Spring Cloud Serverless
  description: My own Spring Cloud Function serverless app
  iconUrl: https://raw.githubusercontent.com/vmware-tanzu/application-accelerator-samp
les/main/icons/icon-cloud.png
  tags:
    - spring
    - cloud
    - function
    - serverless
  git:
    ignore: ".git/, bin/"
    url: https://github.com/vmware-tanzu/application-accelerator-samples
    subPath: spring-cloud-serverless
    ref:
      branch: test
```

To create this accelerator with kubectl, run:

```
kubectl apply --namespace --accelerator-system --filename my-spring-cloud-serverless.y
aml
```

To use the Tanzu CLI, run:

```
tanzu accelerator create my-spring-cloud-serverless --git-repo https://github.com/vmwa
re-tanzu/application-accelerator-samples --git-branch main --git-sub-path spring-cloud
-serverless \
  --description "My own Spring Cloud Function serverless app" \
  --display-name "My Spring Cloud Serverless" \
  --icon-url https://raw.githubusercontent.com/vmware-tanzu/application-accelerator-sa
mples/main/icons/icon-cloud.png \
  --tags "spring,cloud,function,serverless"
```

Note

It is not possible to provide the `git.ignore` option with the Tanzu CLI.

Creating a manifest with multiple accelerators and fragments

You might have a manifest that contains multiple accelerators or fragments. For example:

`accelerator-collection.yaml`

```
---
apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
kind: Accelerator
metadata:
  name: spring-cloud-serverless
spec:
  git:
    url: https://github.com/vmware-tanzu/application-accelerator-samples
    subPath: spring-cloud-serverless
    ref:
      branch: main
---
apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
kind: Accelerator
metadata:
  name: tanzu-java-web-app
spec:
  git:
    url: https://github.com/vmware-tanzu/application-accelerator-samples.git
    subPath: tanzu-java-web-app
    ref:
      branch: main
```

For a larger example of this, see Sample Accelerators Main. Optionally, use this to create an initial catalog of accelerators and fragments during a fresh Application Accelerator install.

Configure `tap-values.yaml` with Git credentials secret

Note

For how to create a new OAuth Token for optional Git repository creation, see Create an Application Accelerator Git repository during project creation.

When deploying accelerators using Git repositories that requires authentication or are installed with custom CA certificates, you must provide some additional authentication values in a secret. The examples in the next section provide more details. This section describes how to configure a Git credentials secret that is used in later Git-based examples.

You can specify the following accelerator configuration properties when installing Application Accelerator. The same properties are provided in the `accelerator` section of the `tap-values.yaml` file:

```
accelerator:
  git_credentials:
    secret_name: git-credentials
    username: GIT-USER-NAME
    password: GIT-CREDENTIALS
    ca_file: CUSTOM-CA-CERT
```

Where:

- `GIT-USER-NAME` is the user name for authenticating with the Git repository.
- `GIT-CREDENTIALS` is the password or access token used for authenticating with the Git repository. VMware recommends using an access token for this.
- `CUSTOM-CA-CERT` is the certificate data needed when accessing the Git repository.

This is an example of this part of a `tap-values.yaml` configuration:

```
accelerator:
  git_credentials:
    secret_name: git-credentials
    username: testuser
    password: s3cret
    ca_file: |
      -----BEGIN CERTIFICATE-----
      .
      .
      .  < certificate data >
      .
      .
      -----END CERTIFICATE-----
```

You can specify the custom CA certificate data using the shared config value `shared.ca_cert_data` and it propagates to all components that can make use of it, including the App Accelerator configuration. The example earlier produces an output such as this using the shared value:

```
shared:
  ca_cert_data: |
    -----BEGIN CERTIFICATE-----
    .
    .
    .  < certificate data >
    .
    .
    -----END CERTIFICATE-----

accelerator:
  git_credentials:
    secret_name: git-credentials
    username: testuser
    password: s3cret
```

Using non-public repositories

For GitHub repositories that aren't accessible anonymously, you must provide credentials in a Secret.

- For HTTPS repositories the secret must contain user name and password fields. The password field can contain a personal access token instead of an actual password. For more information, see Fluxcd/source-controller basic access authentication.
- For HTTPS with self-signed certificates, you can add a `.data.caFile` value to the secret created for HTTPS authentication. For more information, see fluxcd/source-controller HTTPS Certificate Authority.
- For SSH repositories, the secret must contain identity, identity.pub, and known_hosts text boxes. For more information, see fluxcd/source-controller SSH authentication.
- For Image repositories that aren't publicly available, an image pull secret might be provided. For more information, see Kubernetes documentation on using imagePullSecrets.

Examples for a private Git repository

Example using http credentials

To create an accelerator using a private Git repository, first create a secret with the HTTP credentials.

Note

For better security, use an access token as the password.

```
kubectl create secret generic https-credentials \
    --namespace accelerator-system \
    --from-literal=username=USER \
    --from-literal=password=ACCESS-TOKEN
```

Verify that your secret was created by running:

```
kubectl get secret --namespace accelerator-system https-credentials -o yaml
```

The output is similar to:

```
apiVersion: v1
kind: Secret
metadata:
  name: https-credentials
  namespace: accelerator-system
type: Opaque
data:
  username: <BASE64>
  password: <BASE64>
```

After you created and verified the secret, you can create the accelerator by using the `spec.git.secretRef.name` property:

`private-acc.yaml`

```
apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
kind: Accelerator
metadata:
  name: private-acc
spec:
  displayName: private
  description: Accelerator using a private repository
  git:
    url: REPOSITORY-URL
    ref:
      branch: main
    secretRef:
      name: https-credentials
```

For https credentials, the `REPOSITORY-URL` must use `https://` as the URL scheme.

If you are using the Tanzu CLI, add the `--secret-ref` flag to your `tanzu accelerator create` command and provide the name of the secret for that flag.

Example using http credentials with self-signed certificate

To create an accelerator using a private Git repository with a self-signed certificate, create a secret with the HTTP credentials and the certificate.

Note

For better security, use an access token as the password.

```
kubectl create secret generic https-ca-credentials \
    --namespace accelerator-system \
    --from-literal=username=USER \
    --from-literal=password=ACCESS-TOKEN \
    --from-file=caFile=PATH-TO-CA-FILE
```

Verify that your secret was created by running:

```
kubectl get secret --namespace accelerator-system https-ca-credentials -o yaml
```

The output is similar to:

```
apiVersion: v1
kind: Secret
metadata:
  name: https-ca-credentials
  namespace: accelerator-system
type: Opaque
data:
  username: <BASE64>
  password: <BASE64>
  caFile: <BASE64>
```

After you have the secret created, you can create the accelerator by using the `spec.git.secretRef.name` property:

`private-acc.yaml`

```
apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
kind: Accelerator
metadata:
  name: private-acc
spec:
  displayName: private
  description: Accelerator using a private repository
  git:
    url: REPOSITORY-URL
    ref:
      branch: main
    secretRef:
      name: https-ca-credentials
```

Important

For https credentials, the `REPOSITORY-URL` must use `https://` as the URL scheme.

If you are using the Tanzu CLI, add the `--secret-ref` flag to your `tanzu accelerator create` command and provide the name of the secret for that flag.

Example using SSH credentials

To create an accelerator using a private Git repository, create a secret with the SSH credentials such as this example:

```
ssh-keygen -q -N "" -f ./identity
ssh-keyscan github.com > ./known_hosts
kubectl create secret generic ssh-credentials \
    --namespace accelerator-system \
    --from-file=./identity \
    --from-file=./identity.pub \
    --from-file=./known_hosts
```

If you have a key file already created, skip the `ssh-keygen` and `ssh-keyscan` steps and replace the values for the `kubectl create secret` command. Such as:

- `--from-file=identity=PATH-TO-YOUR-IDENTITY-FILE`
- `--from-file=identity.pub=PATH-TO-YOUR-IDENTITY.PUB-FILE`
- `--from-file=known_hosts=PATH-TO-YOUR-KNOWN-HOSTS-FILE`

Verify that your secret was created by running:

```
kubectl get secret --namespace accelerator-system ssh-credentials -o yaml
```

The output is similar to :

```
apiVersion: v1
kind: Secret
metadata:
  name: ssh-credentials
  namespace: accelerator-system
type: Opaque
data:
  identity: <BASE64>
  identity.pub: <BASE64>
  known_hosts: <BASE64>
```

To use this secret when creating an accelerator, provide the secret name in the `spec.git.secretRef.name` property:

`private-acc-ssh.yaml`

```
apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
kind: Accelerator
metadata:
  name: private-acc
spec:
  displayName: private
  description: Accelerator using a private repository
  git:
    url: REPOSITORY-URL
    ref:
      branch: main
    secretRef:
      name: ssh-credentials
```

When using SSH credentials, the `REPOSITORY-URL` must include the user name as part of the URL. For example: `ssh://user@example.com:22/repository.git`. For more information, see Flux documentation.

If you are using the Tanzu CLI, add the `--secret-ref` flag to your `tanzu accelerator create` command and provide the name of the secret for that flag.

Examples for a private source-image repository

If your registry uses a self-signed certificate then you must add the CA certificate data to the configuration for the “Tanzu Application Platform Source Controller” component. Add it under `source_controller.ca_cert_data` in your `tap-values.yaml` file that is used during installation.

`tap-values.yaml`

```
source_controller:
  ca_cert_data: |-
    -----BEGIN CERTIFICATE-----
    .
    .
    .  < certificate data >
    .
    .
    -----END CERTIFICATE-----
```

Example using image-pull credentials

To create an accelerator using a private source-image repository, create a secret with the image-pull credentials:

```
create secret generic registry-credentials \
    --namespace accelerator-system \
    --from-literal=username=USER \
    --from-literal=password=PASSWORD
```

Verify that your secret was created by running:

```
kubectl get secret --namespace accelerator-system registry-credentials -o yaml
```

The output is similar to:

```
apiVersion: v1
kind: Secret
metadata:
  name: registry-credentials
  namespace: accelerator-system
type: Opaque
data:
  username: <BASE64>
  password: <BASE64>
```

After you have the secret created, you can create the accelerator by using the `spec.git.secretRef.name` property:

`private-acc.yaml`

```
apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
kind: Accelerator
metadata:
  name: private-acc
spec:
  displayName: private
  description: Accelerator using a private repository
  source:
    image: "registry.example.com/test/private-acc-src:latest"
    imagePullSecrets:
    - name: registry-credentials
```

If you are using the Tanzu CLI, add the `--secret-ref` flag to your `tanzu accelerator create` command and provide the name of the secret for that flag.

Configure ingress timeouts when some accelerators take longer to generate

If Tanzu Application Platform is configured to use an ingress for Tanzu Developer Portal and the Accelerator Server, then it might detect a timeout during accelerator generation.

This can happen if the accelerator takes a longer time to generate than the default timeout. When this happens, Tanzu Developer Portal appears to continue to run for an indefinite period. In the IDE extension, it shows a `504` error. To mitigate this, you can increase the timeout value for the HTTPProxy resources used for the ingress by applying secrets with overlays to edit the HTTPProxy resources.

Configure an ingress timeout overlay secret for each HTTPProxy

For Tanzu Developer Portal, create the following overlay secret in the `tap-install` namespace:

```
apiVersion: v1
kind: Secret
metadata:
  name: patch-tap-gui-timeout
  namespace: tap-install
stringData:
  patch.yaml: |
    #@ load("@ytt:overlay", "overlay")
    #@overlay/match by=overlay.subset({"kind": "HTTPProxy", "metadata": {"name": "tap-
gui"}})
    ---
    spec:
      routes:
        #@overlay/match by=overlay.subset({"services": [{"name": "server"}]})
        #@overlay/match-child-defaults missing_ok=True
        - timeoutPolicy:
            idle: 30s
            response: 30s
```

For Accelerator Server (used for IDE extension), create the following overlay secret in the `tap-install` namespace:

```
apiVersion: v1
kind: Secret
metadata:
  name: patch-accelerator-timeout
  namespace: tap-install
stringData:
  patch.yaml: |
    #@ load("@ytt:overlay", "overlay")
    #@overlay/match by=overlay.subset({"kind": "HTTPProxy", "metadata": {"name": "acce
lerator"}})
    ---
    spec:
      routes:
        #@overlay/match by=overlay.subset({"services": [{"name": "acc-server"}]})
        #@overlay/match-child-defaults missing_ok=True
        - timeoutPolicy:
            idle: 30s
            response: 30s
```

Apply the timeout overlay secrets in tap-values.yaml

Add the following `package_overlays` section to `tap-values.yaml` before installing or updating Tanzu Application Platform:

```
package_overlays:
- name: tap-gui
  secrets:
  - name: patch-tap-gui-timeout
- name: accelerator
  secrets:
  - name: patch-accelerator-timeout
```

Configuring skipping TLS verification for access to Source Controller

You can configure the Flux or Tanzu Application Platform Source Controller to use Transport Layer Security (TLS) and use custom certificates. In that case, configure the Accelerator System to skip the TLS verification for calls to access the sources by providing the following property in the `accelerator` section of the `tap-values.yaml` file:

```
sources:
  skip_tls_verify: true
```

Enabling TLS for Accelerator Server

To enable TLS for the Accelerator Server, the following properties must be provided in the `accelerator` section of the `tap-values.yaml` file:

```
server:
  tls:
    enabled: true
    key: SERVER-PRIVATE-KEY
    crt: SERVER-CERTIFICATE
```

Where:

- `SERVER-PRIVATE-KEY` is the pem encoded server private key.
- `SERVER-CERTIFICATE` is the pem encoded server certificate.

Here is a sample `tap-values.yaml` configuration with TLS enabled for Accelerators Server:

```
server:
  tls:
    enabled: true
    key: |
      -----BEGIN PRIVATE KEY-----
      .
      .  < private key data >
      .
      -----END PRIVATE KEY-----
    crt: |
      -----BEGIN CERTIFICATE-----
      .
      .  < certificate data >
      .
      -----END CERTIFICATE-----
```

Configuring skipping TLS verification of Engine calls for Accelerator Server

If you configure the Accelerator Engine to use TLS and use custom certificates, then you can configure the Accelerator Server to skip the TLS verification for calls to the Engine by providing the following property in the `accelerator` section of the `tap-values.yaml` file:

```
server:
  engine_skip_tls_verify: true
```

Enabling TLS for Accelerator Engine

To enable TLS for the Accelerator Engine, the following properties are provided in the `accelerator` section of the `tap-values.yaml` file:

```
engine:
  tls:
    enabled: true
    key: ENGINE-PRIVATE-KEY
    crt: ENGINE-CERTIFICATE
```

Where:

- `ENGINE-PRIVATE-KEY` is the pem encoded acc-engine private key.
- `ENGINE-CERTIFICATE` is the pem encoded acc-engine certificate.

Here is a sample `tap-values.yaml` configuration with TLS enabled for Accelerators Engine:

```
engine:
  tls:
    enabled: true
    key: |
      -----BEGIN PRIVATE KEY-----
      .
      .  < private key data >
      .
      -----END PRIVATE KEY-----
    crt: |
      -----BEGIN CERTIFICATE-----
      .
      .  < certificate data >
      .
      -----END CERTIFICATE-----
```

Next steps

- Creating accelerators

Create accelerators

This topic tells you how to create an accelerator in Tanzu Developer Portal.

An accelerator contains your conforming code and configurations that developers can use to create new projects that by default follow the standards defined in your accelerators.

Prerequisites

The following prerequisites are required to create an accelerator:

- Application Accelerator is installed. For information about installing Application Accelerator, see Installing Application Accelerator for VMware Tanzu.
- You can access Tanzu Developer Portal from a browser or use the Application Accelerator extension for VS Code.
    - For more information about Tanzu Developer Portal, see Overview of Tanzu Developer Portal.
    - For more information about Application Accelerator extension for VS Code, see Application Accelerator Visual Studio Code extension.
- kubectl is installed and authenticated with admin rights for your target cluster.

Getting started

You can use any Git repository to create an accelerator. You need the URL of the repository to create an accelerator.

For this example, the Git repository is `public` and contains a `README.md` file. These are options available when you create repositories on GitHub.

Use the following procedure to create an accelerator based on this Git repository:

1. Clone your Git repository.
2. Create a file named `accelerator.yaml` in the root directory of this Git repository.
3. Add the following content to the `accelerator.yaml` file:

    ```
    accelerator:
      displayName: Simple Accelerator
      description: Contains just a README
      iconUrl: https://images.freecreatives.com/wp-content/uploads/2015/05/smiley-5
    59124_640.jpg
      tags:
      - simple
      - getting-started
    ```

    Feel free to use a different icon if it uses a reachable URL.
4. Add the new `accelerator.yaml` file, commit this change and push to your Git repository.

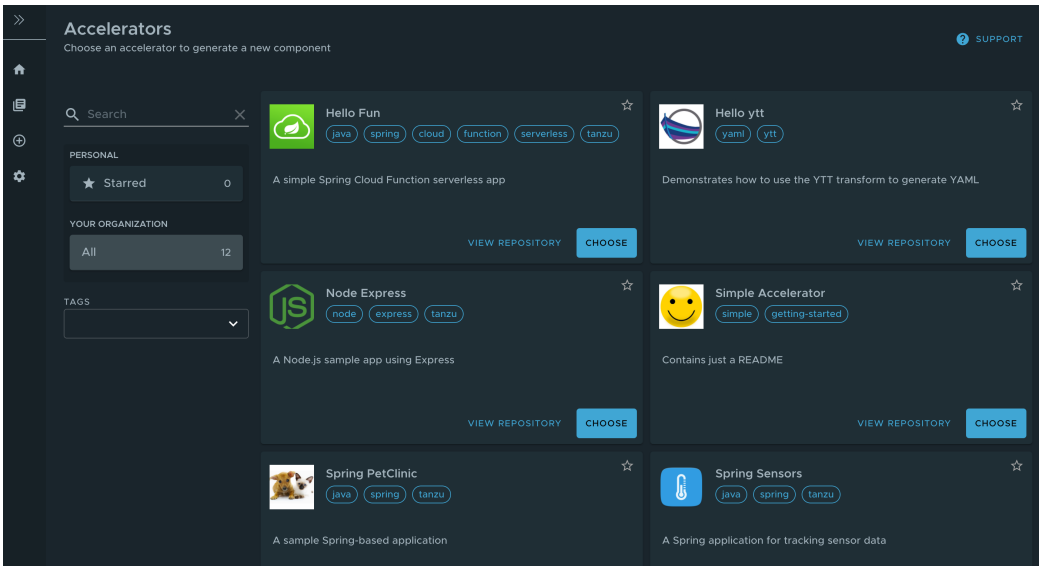
Publishing the new accelerator

1. To publish your new accelerator, run:

    ```
    tanzu accelerator create simple --git-repository ${GIT_REPOSITORY_URL} --git-br
    anch ${GIT_REPOSITORY_BRANCH}
    ```

    Where:

    - `GIT-REPOSITORY-URL` is the URL for your Git repository where the accelerator is located.
    - `GIT-REPOSITORY-BRANCH` is the name of the branch where you pushed the new `accelerator.yaml` file.
2. Refresh Tanzu Developer Portal or the Application Accelerator extension in VS Code to reveal the newly published accelerator. It might take a few seconds to refresh the catalog and add an entry for your new accelerator.



Alternatively, use the Tanzu CLI to create a separate manifest file and apply it to the cluster.

1. Create a `simple-manifest.yaml` file and add the following content, filling in with your Git repository and branch values.

   ```
   apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
   kind: Accelerator
   metadata:
     name: simple
     namespace: accelerator-system
   spec:
     git:
       url: YOUR-GIT-REPOSITORY-URL
       ref:
         branch: YOUR-GIT-BRANCH
   ```

2. To apply the `simple-manifest.yaml`, run this command in your terminal in the directory where you created this file:

   ```
   tanzu accelerator apply -f simple-manifest.yaml
   ```

Using accelerator fragments

Accelerator fragments are reusable accelerator components that can provide options, files, or transforms. They can be imported from accelerators using an `import` entry and the transforms from the fragment can be referenced in an `InvokeFragment` transform in the accelerator that is declaring the import. For additional details see InvokeFragment transform.

The accelerator samples include three fragments - `java-version`, `tap-initialize`, and `live-update`. See vmware-tanzu/application-accelerator-samples/fragments Git repository for the content of these fragments.

To discover what fragments are available to use, run:

```
tanzu accelerator fragment list
```

Look a the `java-version` fragment as an example. It contains the following `accelerator.yaml` file:

```
accelerator:
  options:
  - name: javaVersion
    inputType: select
```

```
    label: Java version to use
    choices:
    - value: "1.8"
      text: Java 8
    - value: "11"
      text: Java 11
    - value: "17"
      text: Java 17
    defaultValue: "11"
    required: true

engine:
  merge:
    - include: [ "pom.xml" ]
      chain:
      - type: ReplaceText
        regex:
          pattern: "<java.version>.*<"
          with: "'<java.version>' + #javaVersion + '<'"
    - include: [ "build.gradle" ]
      chain:
      - type: ReplaceText
        regex:
          pattern: "sourceCompatibility = .*"
          with: "'sourceCompatibility = ''' + #javaVersion + '''\n'"
    - include: [ "config/workload.yaml" ]
      chain:
      - type: ReplaceText
        condition: "#javaVersion == '17'"
        substitutions:
          - text: "spec:"
            with: "'spec:\n  build:\n    env:\n    - name: BP_JVM_VERSION\n      valu
e: \"17\"\n'"
```

This fragment contributes the following to any accelerator that imports it:

1. An option named `javaVersion` with three choices `Java 8`, `Java 11`, and `Java 17`
2. Three `ReplaceText` transforms:
    - If the accelerator has a `pom.xml` file, then what is specified for `<java.version>` is replaced with the chosen version.
    - If the accelerator has a `build.gradle` file, then what is specified for `sourceCompatibility` is replaced with the chosen version.
    - If the accelerator has a `config/workload.yaml` file, and the user selected “Java 17” then a build environment entry of BP_JVM_VERSION is inserted into the `spec:` section.

Deploying accelerator fragments

To deploy new fragments to the accelerator system, use the new `tanzu accelerator fragment create` CLI command or apply a custom resource manifest file with either `kubectl apply` or the `tanzu accelerator apply` commands.

The resource manifest for the `java-version` fragment looks like this:

```
apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
kind: Fragment
metadata:
  name: java-version
  namespace: accelerator-system
spec:
  displayName: Select Java Version
```

```
  git:
    ref:
      tag: GIT_TAG_VERSION
    url: https://github.com/vmware-tanzu/application-accelerator-samples.git
    subPath: fragments/java-version
```

Where `GIT-TAG-VERSION` is the Git tag of the `java-version` fragment. For example, `tap-1.4.0` is a valid Git tag for the `java-version` fragment.

To create the fragment, save the above manifest in a `java-version.yaml` file) and run:

```
tanzu accelerator apply -f ./java-version.yaml
```

Note

The `accelerator apply` command can be used to apply both Accelerator and Fragment resources.

To avoid having to create a separate manifest file, run:

```
tanzu accelerator fragment create java-version \
  --git-repo https://github.com/vmware-tanzu/application-accelerator-samples.git \
  --git-tag ${GIT_TAG_VERSION} \
  --git-sub-path fragments/java-version
```

Where `GIT-TAG-VERSION` is the Git tag of the `java-version` fragment. For example,`tap-1.4.0` is a valid Git tag for the `java-version` fragment.

Now you can use this `java-version` fragment in an accelerator:

```
accelerator:
  displayName: Hello Fragment
  description: A sample app
  tags:
  - java
  - spring
  - cloud
  - tanzu

  imports:
  - name: java-version

engine:
  merge:
    - include: ["**/*"]
    - type: InvokeFragment
      reference: java-version
```

The earlier accelerator imports the `java-version` which, as seen earlier, provides an option to select the Java version to use for the project. It then instructs the engine to run the transforms provided in the fragment that updates the Java version used in `pom.xml` or `build.gradle` files from the accelerator.

For more detail on the use of fragments, see InvokeFragment transform.

Next steps

Learn how to:

- Write an accelerator.yaml.

- Configure accelerators with Accelerator Custom Resources.
- Manipulate files using Transforms.
- Use SpEL in the accelerator.yaml file.

Create accelerators

This topic tells you how to create an accelerator in Tanzu Developer Portal.

An accelerator contains your conforming code and configurations that developers can use to create new projects that by default follow the standards defined in your accelerators.

Prerequisites

The following prerequisites are required to create an accelerator:

- Application Accelerator is installed. For information about installing Application Accelerator, see Installing Application Accelerator for VMware Tanzu.
- You can access Tanzu Developer Portal from a browser or use the Application Accelerator extension for VS Code.
    - For more information about Tanzu Developer Portal, see Overview of Tanzu Developer Portal.
    - For more information about Application Accelerator extension for VS Code, see Application Accelerator Visual Studio Code extension.
- kubectl is installed and authenticated with admin rights for your target cluster.

Getting started

You can use any Git repository to create an accelerator. You need the URL of the repository to create an accelerator.

For this example, the Git repository is `public` and contains a `README.md` file. These are options available when you create repositories on GitHub.

Use the following procedure to create an accelerator based on this Git repository:

1. Clone your Git repository.
2. Create a file named `accelerator.yaml` in the root directory of this Git repository.
3. Add the following content to the `accelerator.yaml` file:

    ```
    accelerator:
      displayName: Simple Accelerator
      description: Contains just a README
      iconUrl: https://images.freecreatives.com/wp-content/uploads/2015/05/smiley-5
    59124_640.jpg
      tags:
      - simple
      - getting-started
    ```

    Feel free to use a different icon if it uses a reachable URL.
4. Add the new `accelerator.yaml` file, commit this change and push to your Git repository.

Publishing the new accelerator

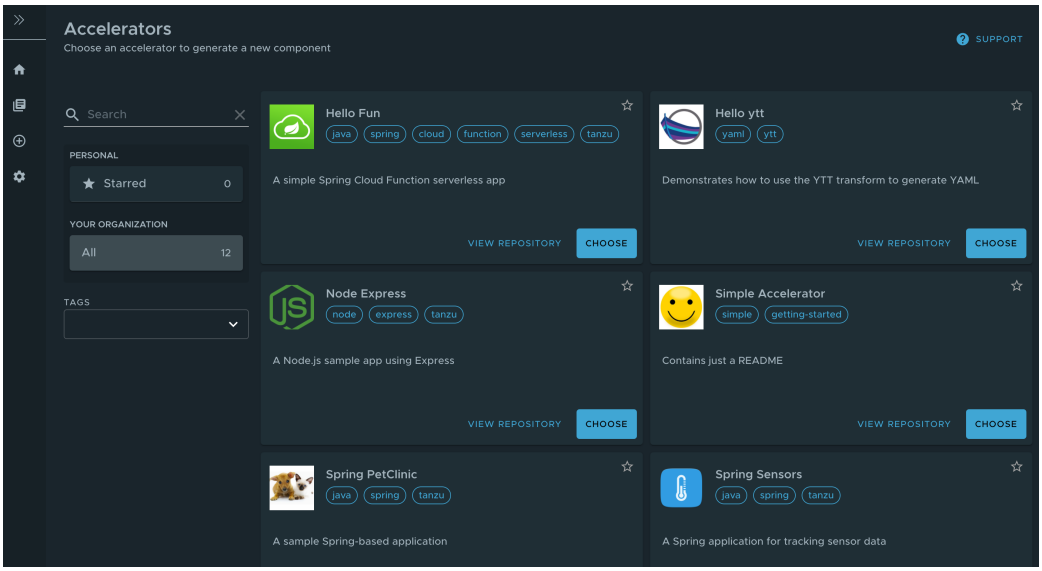
1. To publish your new accelerator, run:

```
tanzu accelerator create simple --git-repository ${GIT_REPOSITORY_URL} --git-br
anch ${GIT_REPOSITORY_BRANCH}
```

Where:

- `GIT-REPOSITORY-URL` is the URL for your Git repository where the accelerator is located.
- `GIT-REPOSITORY-BRANCH` is the name of the branch where you pushed the new `accelerator.yaml` file.

2. Refresh Tanzu Developer Portal or the Application Accelerator extension in VS Code to reveal the newly published accelerator. It might take a few seconds to refresh the catalog and add an entry for your new accelerator.



Alternatively, use the Tanzu CLI to create a separate manifest file and apply it to the cluster.

1. Create a `simple-manifest.yaml` file and add the following content, filling in with your Git repository and branch values.

```
apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
kind: Accelerator
metadata:
  name: simple
  namespace: accelerator-system
spec:
  git:
    url: YOUR-GIT-REPOSITORY-URL
    ref:
      branch: YOUR-GIT-BRANCH
```

2. To apply the `simple-manifest.yaml`, run this command in your terminal in the directory where you created this file:

```
tanzu accelerator apply -f simple-manifest.yaml
```

Using accelerator fragments

Accelerator fragments are reusable accelerator components that can provide options, files, or transforms. They can be imported from accelerators using an `import` entry and the transforms from the fragment can be referenced in an `InvokeFragment` transform in the accelerator that is declaring the import. For additional details see InvokeFragment transform.

The accelerator samples include three fragments - `java-version`, `tap-initialize`, and `live-update`. See vmware-tanzu/application-accelerator-samples/fragments Git repository for the content of these fragments.

To discover what fragments are available to use, run:

```
tanzu accelerator fragment list
```

Look a the `java-version` fragment as an example. It contains the following `accelerator.yaml` file:

```
accelerator:
  options:
  - name: javaVersion
    inputType: select
    label: Java version to use
    choices:
    - value: "1.8"
      text: Java 8
    - value: "11"
      text: Java 11
    - value: "17"
      text: Java 17
    defaultValue: "11"
    required: true

engine:
  merge:
    - include: [ "pom.xml" ]
      chain:
      - type: ReplaceText
        regex:
          pattern: "<java.version>.*<"
          with: "'<java.version>' + #javaVersion + '<'"
    - include: [ "build.gradle" ]
      chain:
      - type: ReplaceText
        regex:
          pattern: "sourceCompatibility = .*"
          with: "'sourceCompatibility = ''' + #javaVersion + '''\n'"
    - include: [ "config/workload.yaml" ]
      chain:
      - type: ReplaceText
        condition: "#javaVersion == '17'"
        substitutions:
          - text: "spec:"
            with: "'spec:\n  build:\n    env:\n    - name: BP_JVM_VERSION\n      valu
e: \"17\"'"
```

This fragment contributes the following to any accelerator that imports it:

1. An option named `javaVersion` with three choices `Java 8`, `Java 11`, and `Java 17`
2. Three `ReplaceText` transforms:
    - If the accelerator has a `pom.xml` file, then what is specified for `<java.version>` is replaced with the chosen version.
    - If the accelerator has a `build.gradle` file, then what is specified for `sourceCompatibility` is replaced with the chosen version.
    - If the accelerator has a `config/workload.yaml` file, and the user selected “Java 17” then a build environment entry of BP_JVM_VERSION is inserted into the `spec:` section.

Deploying accelerator fragments

To deploy new fragments to the accelerator system, use the new `tanzu accelerator fragment create` CLI command or apply a custom resource manifest file with either `kubectl apply` or the `tanzu accelerator apply` commands.

The resource manifest for the `java-version` fragment looks like this:

```
apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
kind: Fragment
metadata:
  name: java-version
  namespace: accelerator-system
spec:
  displayName: Select Java Version
  git:
    ref:
      tag: GIT_TAG_VERSION
    url: https://github.com/vmware-tanzu/application-accelerator-samples.git
    subPath: fragments/java-version
```

Where `GIT-TAG-VERSION` is the Git tag of the `java-version` fragment. For example, `tap-1.4.0` is a valid Git tag for the `java-version` fragment.

To create the fragment, save the above manifest in a `java-version.yaml` file) and run:

```
tanzu accelerator apply -f ./java-version.yaml
```

Note

The `accelerator apply` command can be used to apply both Accelerator and Fragment resources.

To avoid having to create a separate manifest file, run:

```
tanzu accelerator fragment create java-version \
  --git-repo https://github.com/vmware-tanzu/application-accelerator-samples.git \
  --git-tag ${GIT_TAG_VERSION} \
  --git-sub-path fragments/java-version
```

Where `GIT-TAG-VERSION` is the Git tag of the `java-version` fragment. For example,`tap-1.4.0` is a valid Git tag for the `java-version` fragment.

Now you can use this `java-version` fragment in an accelerator:

```
accelerator:
  displayName: Hello Fragment
  description: A sample app
  tags:
  - java
  - spring
  - cloud
  - tanzu

  imports:
  - name: java-version

engine:
  merge:
    - include: ["**/*"]
```

```
    - type: InvokeFragment
      reference: java-version
```

The earlier accelerator imports the `java-version` which, as seen earlier, provides an option to select the Java version to use for the project. It then instructs the engine to run the transforms provided in the fragment that updates the Java version used in `pom.xml` or `build.gradle` files from the accelerator.

For more detail on the use of fragments, see InvokeFragment transform.

Next steps

Learn how to:

- Write an accelerator.yaml.
- Configure accelerators with Accelerator Custom Resources.
- Manipulate files using Transforms.
- Use SpEL in the accelerator.yaml file.

Create an accelerator.yaml file in Application Accelerator

This topic tells you how to use Application Accelerator to create an `accelerator.yaml` file in Tanzu Application Platform (commonly known as TAP).

By including an `accelerator.yaml` file in your Accelerator repository, you can declare input options that users fill in using a form in the UI. Those option values control processing by the template engine before it returns the zipped output files. For more information, see the Sample accelerator.

When there is no `accelerator.yaml`, the repository still works as an accelerator but the files are passed unmodified to users.

`accelerator.yaml` has two top-level sections: `accelerator` and `engine`.

Accelerator

This section documents how an accelerator is presented to users in the web UI. For example:

```
accelerator:
  displayName: Hello Fun
  description: A simple Spring Cloud Function serverless app
  iconUrl: https://raw.githubusercontent.com/vmware-tanzu/application-accelerator-samp
les/main/icons/icon-cloud.png
  tags:
  - java
  - spring

  options:
  - name: deploymentType
    inputType: select
    choices:
    - value: none
      text: Skip Kubernetes deployment
    - value: k8s-simple
      text: Kubernetes deployment and service
    - value: knative
      text: Knative service
    defaultValue: k8s-simple
    required: true
```

Accelerator metadata

These properties are in accelerator listings such as the web UI:

- **displayName**: A human-readable name.
- **description**: A more detailed description.
- **iconUrl**: A URL pointing to an icon image.
- **tags**: A list of tags used to filter accelerators.

Accelerator options

The list of options is passed to the UI to create input text boxes for each option.

The following option properties are used by both the UI and the engine.

- **name**: Each option must have a unique, camelCase name. The option value entered by a user is made available as a SPeL variable name. For example, `#deploymentType`.

  You can specify your own default name by including:

  ```
  options:
  - name: projectName
  label: Name
  inputType: text
  defaultValue: myname
  required: true
  ```

- **dataType**: Data types that work with the UI are:

  - `string`
  - `boolean`
  - `number`
  - Custom types defined in the accelerator `types` section
  - Arrays of these such as `[string]`, `[number]`, and so on.

  Most input types return a string, which is the default. Use Boolean values with `checkbox`.

- **defaultValue**: This literal value pre-populates the option. Ensure that it's type matches the dataType. For example, use `["text 1", "text 2"]` for the dataType `[string]`. Options without a `defaultValue` can trigger a processing error if the user doesn't provide a value for that option.

- **validationRegex**: When present, a regex validates the string representation of the option value *when set*. It doesn't apply when the value is blank. As a consequence, don't use the regex to enforce prerequisites. See **required** for that purpose.

  This regex is used in several layers in Application Accelerator, built using several technologies, for example, JavaScript and Java. So refrain from using "exotic" regex features. Also, the regex applies to portions of the value by default. That is, `[a-z ]+` matches `Hello world` despite the capital `H`. To apply it to the whole value (or just start/end), anchor it using `^` and `$`.

  Finally, backslashes in a YAML string using double quotes must be escaped, so to match a number, write `validationRegex: "\\d+"` or use another string style.

The following option properties are for UI purposes only.

- **label**: A human-readable version of the `name` identifying the option.
- **description**: A tooltip to accompany the input.

- **inputType**:
  - `text`: The default input type.
  - `textarea`: Single text value with larger input allowing line breaks.
  - `checkbox`: Ideal for Boolean values or multi-value selection from choices.
  - `select`: Single-value selection from choices using a drop-down menu.
  - `radio`: Alternative single-value selection from choices using buttons.
- **choices**: This is a list of predefined choices. Users can select from the list in the UI. Choices are supported by `checkbox`, `select`, and `radio`. Each choice must have a `text` property for the displayed text, and a `value` property for the value that the form returns for that choice. The list is presented in the UI in the same order as it is declared in `accelerator.yaml`.
- **required**: `true` forces users to enter a value in the UI.
- **dependsOn**: This is a way to control visibility by specifying the `name` and optional `value` of another input option. When the other option has a value exactly equal to `value`, or `true` if no `value` is specified, then the option with `dependsOn` is visible. Otherwise, it is hidden. Ensure that the value matches the dataType of the `dependsOn` option. For example, a multi-value option (`dataType = [string]`) such as a `checkbox` uses `[matched-value]` to trigger another option when `matched-value` (and only `matched-value`) is selected. See the following section for more information about `dependsOn`.

DependsOn and multi-value dataType

`dependsOn` tests for strict equality, even for multi-valued options. This means that a multi-valued option must not be used to trigger several other options unfolding, one for each value. Instead, use several single-valued options:

Instead of

```
options:
  - name: toppings
    dataType: [string]
    inputType: checkbox
    choices:
      - value: vegetables
        text: Vegetables
      - value: meat
        text: Meat
        ...
  - name: vegType
    dependsOn:
      name: toppings
      value: [vegetables] # or vegetables, this won't do what you want either
  - name: meatType
    dependsOn:
      name: toppings
      value: [meat]
  ...
```

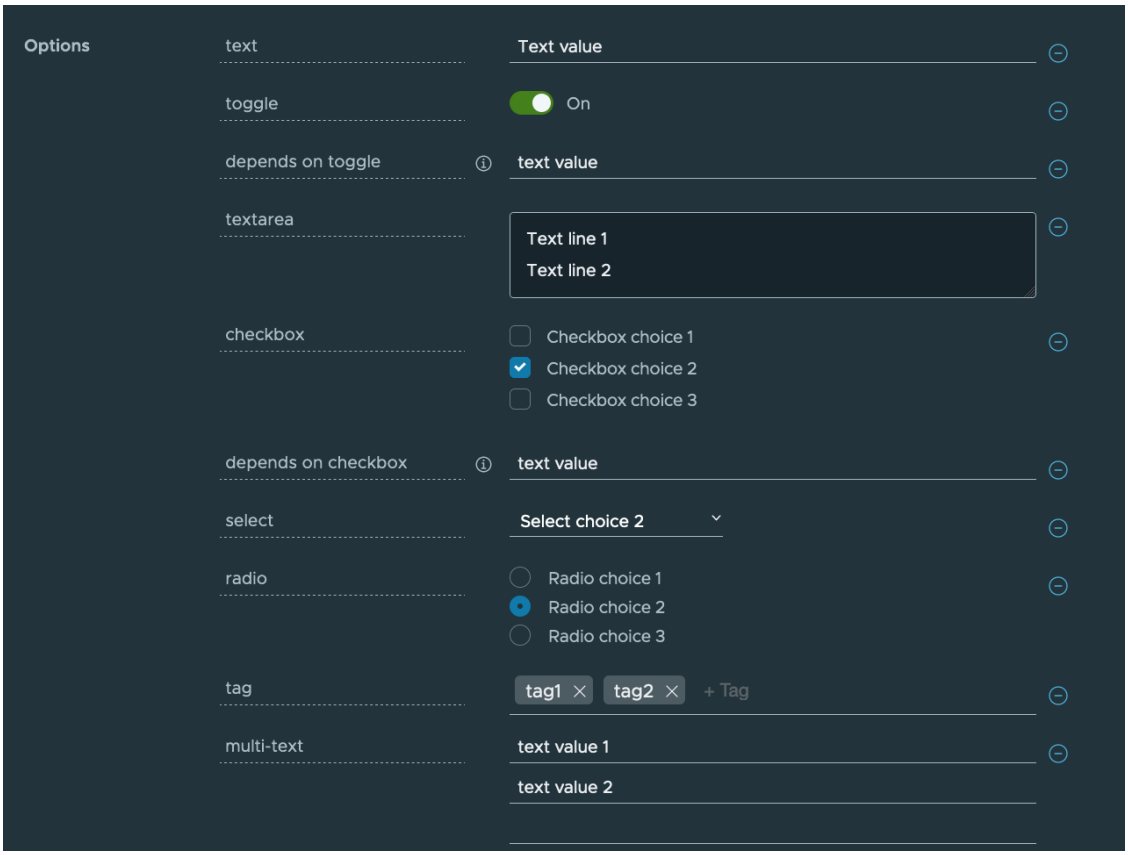
do this:

```
options:
  - name: useVeggies
    dataType: boolean
    inputType: checkbox
    label: Vegetables
  - name: useMeat
    dataType: boolean
```

```
    inputType: checkbox
    label: Meat
  - name: vegType
    dependsOn:
      name: useVeggies
      value: true
  - name: meatType
    dependsOn:
      name: useMeat
      value: true
  ...
```

Examples

The later screenshot and `accelerator.yaml` file snippet that follows demonstrates each `inputType`. You can also see the GitHub sample demo-input-types.



```
accelerator:
  displayName: Demo Input Types
  description: "Accelerator with options for each inputType"
  iconUrl: https://raw.githubusercontent.com/vmware-tanzu/application-accelerator-samp
les/main/icons/icon-cloud.png
  tags: ["demo", "options"]

  options:

  - name: text
    display: true
    defaultValue: Text value

  - name: toggle
    display: true
    dataType: boolean
    defaultValue: true
```

```
  - name: dependsOnToggle
    label: 'depends on toggle'
    description: Visibility depends on the value of the toggle option being true.
    dependsOn:
      name: toggle
    defaultValue: text value

  - name: textarea
    inputType: textarea
    display: true
    defaultValue: |
      Text line 1
      Text line 2

  - name: checkbox
    inputType: checkbox
    display: true
    dataType: [string]
    defaultValue:
      - value-2
    choices:
      - text: Checkbox choice 1
        value: value-1
      - text: Checkbox choice 2
        value: value-2
      - text: Checkbox choice 3
        value: value-3

  - name: dependsOnCheckbox

engine:
  type: YTT
```

Engine

The engine section describes how to take the files from the accelerator root directory and transform them into the contents of a generated project file.

The YAML notation here defines what is called a transform. A transform is a function on a set of files. It uses a set of files as input. It produces a modified set of files as output derived from this input.

Different types of transforms do different tasks:

- Filtering the set of files: that is, removing, or keeping files that match certain criteria.
- Changing the contents of files. For example, replacing some strings in the files.
- Renaming or moving files: that is, changing the paths of the files.

The notation also provides the composition operators `merge` and `chain`, which enable you to create more complex transforms by composing simpler transforms together.

The following is an example of what is possible. To learn the notation, see Introduction to transforms.

Engine example

```
engine:
  include:
    ["**/*.md", "**/*.xml", "**/*.gradle", "**/*.java"]
  exclude:
    ["**/secret/**"]
  let:
    - name: includePoms
      expression:
        "#buildType == 'Maven'"
    - name: includeGradle
      expression: "#buildType == 'Gradle'"
  merge:
    - condition:
        "#includeGradle"
      include: ["*.gradle"]
    - condition: "#includePoms"
      include: ["pom.xml"]
    - include: ["**/*.java", "README.md"]
      chain:
        - type: ReplaceText
          substitutions:
            - text: "Hello World!"
              with: "#greeting"
  chain:
    - type: RewritePath
      regex: (.*)simpleboot(.*)
      rewriteTo: "#g1 + #packageName + #g2"
    - type: ReplaceText
      substitutions:
        - text: simpleboot
          with: "#packageName"
  onConflict:
    Fail
```

Engine notation descriptions

This section describes the notations in the preceding example.

`engine` is the global transformation node. It produces the final set of files to be zipped and returned from the accelerator. As input, it receives all the files from the accelerator repository root. The properties in this node dictate how this set of files is transformed into a final set of files zipped as the accelerator result.

`engine.include` filters the set of files, retaining only those matching a list of path patterns. This ensures that that the accelerator only detects files in the repository that match the list of patterns.

`engine.exclude` further restricts which files are detected. The example ensures files in any directory called `secret` are never detected.

`engine.let` defines additional variables and assigns them values. These derived symbols function such as options, but instead of being supplied from a UI widget, they are computed by the accelerator itself.

`engine.merge` executes each of its children in parallel. Each child receives a copy of the current set of input files. These are files remaining after applying the `include` and `exclude` filters. Each of the children therefore produces a set of files. All the files from all the children are then combined, as if overlaid on top of each other in the same directory. If more than one child produces a file with the same path, the transform resolves the conflict by dropping the file contents from the earlier child and keeping the contents from the later child.

`engine.merge.chain` specifies additional transformations to apply to the set of files produced by this child. In the example, `ReplaceText` is only applied to Java files and `README.md`.

`engine.chain` applies transformation to all files globally. The chain has a list of child transformations. These transformations are applied after everything else in the same node. This is the global node. The children in a chain are applied sequentially.

`engine.onConflict` specifies how conflict is handled when an operation, such as merging, produces multiple files at the same path: - `Fail` raises an error when there is a conflict. - `UseFirst` keeps the contents of the first file. - `UseLast` keeps the contents of the last file. - `Append` keeps both by using `cat <first-file> <second-file>`.

Advanced accelerator use

Additional advanced features can be leveraged when writing an `accelerator.yaml`. For more information see, Creating dynamic parameters using custom types

Application Accelerator sample accelerator.yaml file

This topic provides you with a sample accelerator file to get you started writing your own accelerators in Tanzu Application Platform (commonly known as TAP).

```
accelerator:
  # The `accelerator` section serves to document how an accelerator is presented to th
e
  # user in the accelerator web UI.

  # displayName: a descriptive human-readable name. Make this short so as to look nice
  #              in a list of many accelerators shown to a user.
  displayName: Hello Spring Boot

  # description: a more detailed description that a user can see if they took a closer
  #              look at a particular accelerator.
  description: Simple Hello World Rest Service based on Spring Boot

  # iconUrl: Optional, a nice colorful, icon for your accelerator to make it stand out
visually.
  iconUrl: https://raw.githubusercontent.com/vmware-tanzu/application-accelerator-samp
les/main/icons/icon-cloud.png
```

```
  # tags: A list of classification tags. The UI allows users to search for accelerator
s based on tags
  tags:
    - Java
    - Spring
    - Function

  # options are parameters that can affect how the accelerator behaves.
  # The purpose of the options section is
  #   - to list all applicable options
  #   - describe each option in enough detail so that the UI can create
  #     a suitable input widget for it.
  options: # a list of options
    # a first option
    - name:
        greeting
        # name: each option must have a name.
        # This must be
        #   - camelCase
        #   - unique (i.e. no two options can have the same name)
        # This is like a variable used by the accelerator to refer to
        # and use the value during its execution.
        # This name is internal to your accelerator and is not shown to
        # the user.
      label:
        Greeting Message
        # A human readable version of the `name`. This is used to identify an
        # option to the user in the UI.
        # This should be short (so as not to look ugly in a ui with limited
        # space available for labeling the input widgets).
        # There are no limits on what characters can be used in the label (so spaces
        # are allowed).
      description:
        Greeting message displayed by the Hello World app.
        # An optional more detailed description / explanation that can be shown to
        # to the user in the UI when the short label alone might not be enough to unde
rstand
        # its purpose.
      dataType:
        string
        # type of data the accelerator expects during execution (this is
        # like the type of the 'variable'.
        # possible dataTypes are string, boolean, number or [string] (the latter meani
ng a
        # list of strings
      inputType:
        text
        # Related to the dataType but somewhat independent, this identifies the type
        # of widget shown in the ui. Available types are:
        # - text - the default
        # - textarea (single text value with larger input that allows linebreaks)
        # - checkbox - multivalue selection from choices
        # - select - single value selection from choices
        # - radio - alternative single value selection from choices
        # - tag - multivalue input ui for entering single-word tags
      required: true
      defaultValue: Hello Accelerator
    # second option:
    - name: packageName
      label: "Package Name"
      description: Name of Java package
      dataType: string
      inputType: text
      defaultValue: somepackage
    # another option:
```

```
    - name: buildType
      label: Build Type
      description: Choose whether to use Maven or Gradle to build the project.
      dataType: string
      inputType: select
      choices:
        - value: Maven
          text: Maven (pom.xml)
        - value: Gradle
          text: Gradle (build.gradle)

# The 'engine' section describes how to take the files from the accelerator
# repo root folder and 'transform' them into the contents of a generated project / zi
p.
# transformation operate on the files as a set and can do things like:
# - filtering the set of files (i.e. removing / keeping only files that match certain
criteria)
# - changing the contents of a file (e.g. replacing some strings in them)
# - renaming or moving files (changing the paths of the files)
engine:
  # this is the 'global' transformation node. It produces the final set of
  # files to be zipped and returned from the accelerator.
  # As input it receives all the files from the accelerator repo root.

  # The properties in this node dictate how this set of files is
  # transformed into a final set of files to zip up as the accelerator
  # result.

  include:
    ["**/*.md", "**/*.xml", "**/*.gradle", "**/*.java"]
    # This globally defined `include` filters the set of files
    # retaining only those matching a given list of path patterns.
    # This can ensure that only files in the repo matching the list of
    # patterns will be seen / considered by the accelerator.

  exclude:
    ["**/secret/**"]
    # This globally defined `exclude` further restricts what files are considered.
    # This example ensures files in any directory called `secret` are never considere
d.

  # Under 'let' you can define additional variables and assign them values
  # These 'derived symbols' function much like options, but instead of
  # being supplied from a UI widget, they are computed by the accelerator itself.
  let:
    - name: includePoms # name of a symbol, must be camelCase
      expression:
        "#buildType == 'Maven'" # <- SpEL expression given as a string. You must take
care to use
        # proper quotes to avoid yaml treating '#' as starting a comment.
    - name: includeGradle
      expression: "#buildType == 'Gradle'"
  merge: # This merge section executes each of its children 'in parallel'.
    # Each child receives a copy of the current set of input files.
    # (i.e. the files that are remaining after considering the `include` and `exclude
`.
    # Each of the children thus produces a set of files.
    # Merge then combines all the files from all the children, as if by overlaying the
m on top of each other
    # in the same directory. If more than one child produces a file with the same pat
h,
    # this 'conflict' is resolved by dropping the file contents from the earlier child
    # and keeping only the later one.
    # merge child 1: this child node wants to contribute 'gradle' files to the final r
esult
    - condition:
```

```
        "#includeGradle" # this child is deactivated if the Gradle option was not sele
cted by the user
        # A deactivated child doesn't contribute anything to the final result.
      include: ["*.gradle"] # this child only focusses on gradle files (ignoring all o
ther files)
    # merge child 2: this child wants to contribute 'pom' files to the final result
    - condition: "#includePoms"
      include: ["pom.xml"]
    # merge child 3: this child wants to contribute Java code and README.md to the fin
al result
    - include: ["**/*.java", "README.md"]
      # Using: chain you can specify additional transformations to be applied to the s
et
      # of files produced by this child (i.e. the `ReplaceText` below is only applied
to .java files and README.md)
      chain:
        - type: ReplaceText
          substitutions:
            - text: "Hello World!"
              with: "#greeting"
  chain:
    # Globally specified chain, works like the one `from merge child 3`. But because i
t is global, it
    # applies transformation to all files globally.
    #
    # The chain has a list of child transformations. These transformation are applied
after everything else
    # in the same node (here we are in the 'global node').
    #
    # The children in a chain are applied sequentially.
    - type: RewritePath
      regex: (.*)simpleboot(.*)
      rewriteTo: "#g1 + #packageName + #g2" # SpEL expression. You can use '#g1' and
'#g2' to reference 'match groups'
    - type: ReplaceText
      substitutions:
        - text: simpleboot
          with: "#packageName"
  onConflict:
    Fail # other values are `UseFirst`, `UseLast`, or `Append`
    # when merging (or really any operation) produces multiple files at the same path
    # this defines how that conflict is handled.
    # Fail: raise an error when conflict happens
    # UseFirst: keep the contents of the first file
    # UseLast: keep the contents of the last file
    # Append: keep both as by using `cat <first-file> <second-file>`).
```

Use transforms in Application Accelerator

This topic tells you about using transforms with Application Accelerator.

When the accelerator engine executes the accelerator, it produces a ZIP file containing a set of files. The purpose of the `engine` section is to describe precisely how the contents of that ZIP file is created.

```
accelerator:
  ...
engine:
  <transform-definition>
```

Why transforms?

When you run an accelerator, the contents of the accelerator produce the result. It is made up of subsets of the files taken from the accelerator `<root>` directory and its subdirectories. You can copy the files as is, or transform them in a number of ways before adding them to the result.

The YAML notation in the `engine` section defines a transformation that takes as input a set of files (in the `<root>` directory of the accelerator) and produces as output another set of files, which are put into the ZIP file.

Every transform has a `type`. Different types of transform have different behaviors and different YAML properties that control precisely what they do.

In the following example, a transform of type `Include` is a filter. It takes as input a set of files and produces as output a subset of those files, retaining only those files whose path matches any one of a list of `patterns`.

If the accelerator has something like this:

```
engine:
  type: Include
  patterns: ['**/*.java']
```

This accelerator produces a ZIP file containing all the `.java` files from the accelerator `<root>` or its subdirectories but nothing else.

Transforms can also operate on the contents of a file, instead of merely selecting it for inclusion.

For example:

```
type: ReplaceText
substitutions:
- text: hello-fun
  with: "#artifactId"
```

This transform looks for all instances of a string `hello-fun` in all its input files and replaces them with an `artifactId`, which is the result of evaluating a SpEL expression.

Combining transforms

From the preceding examples, you can see that transforms such as `ReplaceText` and `Include` are too primitive to be useful by themselves. They are meant to be the building blocks of more complex accelerators.

To combine transforms, provide two operators called `Chain` and `Merge`. These operators are recursive in the sense that they compose a number of child transforms to create a more complex transform. This allows building arbitrarily deep and complex trees of nested transform definitions.

The following example shows what each of these two operators does and how they are used together.

Chain

Because transforms are functions whose input and output are of the same type (a set of files), you can take the output of one function and feed it as input to another. This is what `Chain` does. In mathematical terms, `Chain` is function composition.

You might, for example, want to do this with the `ReplaceText` transform. Used by itself, it replaces text strings in all the accelerator input files. What if you wanted to apply this replacement to only a subset of the files? You can use an `Include` filter to select only a subset of files of interest and chain that subset into `ReplaceText`.

For example:

```
type: Chain
transformations:
- type: Include
  patterns: ['**/pom.xml']
- type: ReplaceText
  substitutions:
  - text: hello-fun
    with: "#artifactId"
```

Merge

Chaining `Include` into `ReplaceText` limits the scope of `ReplaceText` to a subset of the input files. It also eliminates all other files from the result.

For example:

```
engine:
  type: Chain
  transformations:
  - type: Include
    patterns: ['**/pom.xml']
  - type: ReplaceText
    substitutions:
    - text: hello-fun
      with: "#artifactId"
```

The preceding accelerator produces a ZIP file that only contains `pom.xml` files and nothing else.

What if you also wanted other files in that ZIP? Perhaps you want to include some Java files as well, but don't want to apply the same text replacement to them.

You might be tempted to write something such as:

```
engine:
  type: Chain
  transformations:
  - type: Include
    patterns: ['**/pom.xml']
  - type: ReplaceText
    ...
  - type: Include
    patterns: ['**/*.java']
```

However, that doesn't work. If you chain non-overlapping includes together like this, the result is an empty result set. The reason is that the first include retains only `pom.xml` files. These files are fed to the next transform in the chain. The second include only retains `.java` files, but because there are only `pom.xml` files left in the input, the result is an empty set.

This is where `Merge` comes in. A `Merge` takes the outputs of several transforms executed independently on the same input sourceset and combines or merges them together into a single sourceset.

For example:

```
engine:
  type: Merge
  sources:
  - type: Chain
    - type: Include
      patterns: ['**/pom.xml']
    - type: ReplaceText
      ...
```

```
  - type: Include
    patterns: ['**/*.java']
```

The preceding accelerator produces a result that includes both:

- The `pom.xml` files with some text replacements applied to them.
- Verbatim copies of all the `.java` files.

Shortened notation

It becomes cumbersome and verbose to combine transforms such as `Include`, `Exclude`, and `ReplaceText` with explicit `Chain` and `Merge` operators. Also, there is a common composition pattern to using them. Specifically, select an interesting subset using includes and excludes, apply a chain of additional transformations to the subset, and merge the result with the results of other transforms. That is why there is a transform known the `Combo` transform that combines `Include`, `Exclude`, `Merge`, and `Chain`.

For example:

```
type: Combo
include: ['**/*.txt', '**/*.md']
exclude: ['**/secret/*']
merge:
- <transform-definition>
- ...
chain:
- <transform-definition>
- ...
```

Each of the properties in this `Combo` transform is optional if you specify at least one.

Notice how each of the properties `include`, `exclude`, `merge`, and `chain` corresponds to the name of a type of transform, only spelled with lowercase letters.

If you specify only one of the properties, the `Combo` transform behaves exactly as if you used that type of transformation by itself.

For example:

```
merge: ...
```

Behaves the same as:

```
type: Merge
sources: ...
```

When you do specify multiple properties at the same time, the `Combo` transform composes them together and combines `Merge` and `Chain`.

For example:

```
include: ['**/*.txt', '**.md']
chain:
- type: ReplaceText
  ...
```

Is the same as:

```
type: Chain
transformations:
- type: Include
```

```
  patterns: ['**/*.txt', '**.md']
- type: Chain
  transformations:
  - type: ReplaceText
    ...
```

When you use all of the properties of `Combo` at once:

```
include: I
exclude: E
merge:
- S1
- S2
chain:
- T1
- T2
```

This is equivalent to:

```
type: Chain
transformations:
- type: Include
  patterns: I
- type: Exclude
  patterns: E
- type: Merge
  sources:
  - S1
  - S2
- T1
- T2
```

A Combo of one?

You can use the `Combo` as a convenient shorthand for a single type of annotation. However, though you can use it to combine multiple types, and though that is its main purpose, that doesn't mean you have to.

For example:

```
include: ["**/*.java"]
```

This is a `Combo` transform (remember, `type: Combo` is optional), but rather than combining multiple types of transforms, it only defines the `include` property. This makes it behaves exactly as an `Include` transform:

```
type: Include
patterns: ["**/*.java"]
```

It is usually more convenient to use a `Combo` transform to denote a single `Include`, `Exclude`, `Chain`, or `Merge` transform, because it is slightly shorter to write it as a `Combo` than writing it with an explicit `type:` property.

A common pattern with merge transforms

It is a common and useful pattern to use merges with overlapping contents to apply a transformation to a subset of files and then replace these changed files within a bigger context.

For example:

```
engine:
  merge:
  - include: ["**/*"]
  - include: ["**/pom.xml"]
    chain:
    - type: ReplaceText
        subsitutions: ...
```

The preceding accelerator copies all files from accelerator `<root>` while applying some text replacements only to `pom.xml` files. Other files are copied verbatim.

Here in more detail is how this works:

- **Transform A** is applied to the files from accelerator `<root>`. It selects all files, including `pom.xml` files.
- **Transform B** is *also* applied to the files from accelerator `<root>`. Again, `Merge` passes the same input independently to each of its child transforms. Transform B selects `pom.xml` files and replaces some text in them.

So both **Transform A** and **Transform B** output `pom.xml` files. The fact that both result sets contain the same file, and with different contents in them in this case, is a conflict that has to be resolved. By default, `Combo` follows a simple rule to resolve such conflicts: take the contents from the last child. Essentially, it behaves as if you overlaid both result sets one after another into the same location. The contents of the latter overwrite any previous files placed there by the earlier.

In the preceding example, this means that while both **Transform A** and **Transform B** produce contents for `pom.xml`, the contents from **Transform B** “wins.” So you get the version of the `pom.xml` that has text replacements applied to it rather than the verbatim copy from **Transform A**.

Conditional transforms

Every `<transform-definition>` can have a `condition` attribute.

```
  - condition: "#k8sConfig == 'k8s-resource-simple'"
    include: [ "kubernetes/app/*.yaml" ]
    chain:
      - type: ReplaceText
        substitutions:
        - text: hello-fun
          with: "#artifactId"
```

When a transform’s condition is `false`, that transform is deactivated. This means it is replaced by a transform that does nothing. However, doing nothing can have different meanings depending on the context:

- When in the context of a `Merge`, a deactivated transform behaves like something that returns an empty set. A `Merge` adds things together using a kind of union; adding an empty set to union essentially does nothing.
- When in the context of a `'Chain` however, a deactivated transform behaves like the `identity` function instead (that is, `lambda (x) => x`). When you chain functions together, a value is passed through all functions in succession. So each function in the chain has the chance to do something by returning a different modified value. If you are a function in a chain, to do nothing means to return the input you received unchanged as your output.

If a transform is deactivated in the context of your accelerator definition, it evaluates to false and is ignored. Your accelerator behaves as if you deleted or commented out that transform’s YAML text from the accelerator definition file.

The following examples illustrate both cases.

Conditional 'Merge' transform

This example, **transform A**, has a conditional transform in a `Merge` context:

```
merge:
  - condition: "#k8sConfig == 'k8s-resource-simple'"
    include: [ "kubernetes/app/*.yaml" ]
    chain:
      ...
  - include: [ "pom.xml" ]
    chain:
      ...
```

If the condition of **transform A** is `false`, it is replaced with an empty set because it is used in a `Merge` context. This has the same effect as if the whole of **transform A** was deleted or commented out:

```
merge:
  - include: [ "pom.xml" ]
    chain:
      ...
```

In this example, if the condition is `false`, only `pom.xml` file is in the result.

Conditional 'Chain' transform

In the following example, some conditional transforms are used in a `Chain` context:

```
merge:
- include: [ '**/*.json' ]
  chain:
  - type: ReplaceText
    condition: '#customizeJson'
    substitutions: ...
  - type: JsonPrettyPrint
    condition: '#prettyJson'
    indent: '#jsonIndent'
```

In the preceding example, both **transform A** and **transform B** are conditional and used in a `Chain` context. **Transform A** is chained after the `include` transform. Whereas **transform B** is chained after **transform A**. When either of these conditions is `false`, the corresponding transform behaves like the identity function. Namely, whatever set of files it receives as input is exactly what it returns as output.

For example, if **transform A**'s condition is `false`, it behaves as if **transform A** isn't there. **Transform A** is chained after `include` so it receives the `include`'s result, returns it unchanged, and this is passed to **transform B**. In other words, the result of the `include` is passed as is to **transform B**.

A small gotcha with using conditionals in merge transforms

As mentioned earlier, it is a useful pattern to use merges with overlapping contents. But you must be careful using this in combination with conditional transforms.

For example:

```
engine:
  merge:
  - include: ["**/*"]
  - include: ["**/pom.xml"]
    chain:
```

```
    - type: ReplaceText
      subsitutions: ...
```

If you only want to include pom files, if you select a `useMaven` option, when you add a 'condition' to **transform B** to deactivate it, the final result still contains `pom.xml` files.:

```
engine:
  merge:
  - include: "**/*"
  - condition: '#useMaven'
    include: ["**/pom.xml"]
    chain:
    - type: ReplaceText
      subsitutions: ...
```

This is because if a transform is deactivated in the context of your accelerator definition, it evaluates to false and is ignored. So when `#useMaven` is `false`, the example reduces to:

```
engine:
  merge:
  - include: ["**/*"]
```

This accelerator copies all files from accelerator `<root>`, including `pom.xml`.

There are several ways to avoid this. One is to ensure the `pom.xml` files are not included in **transform A** by explicitly excluding them:

```
  ...
  - include: ["**/*"]
    exclude: ["**/pom.xml"]
  ...
```

Another way is to apply the exclusion of `pom.xml` conditionally in a `Chain` after the main transform:

```
engine:
  merge:
  - include: ["**/*"]
  - include: ["**/pom.xml"]
    chain:
    - type: ReplaceText
        subsitutions: ...
  chain:
  - condition: '!#useMaven'
    exclude: ['**/pom.xml']
```

Merge conflict

The representation of the set of files upon which transforms operate is richer than what you can physically store on a file system. A key difference is that in this case, the set of files allows for multiple files with the same path to exist at the same time. When files are initially read from a physical file system, or a ZIP file, this situation does not arise. However, as transforms are applied to this input, it can produce results that have more than one file with the same path and yet different contents.

Earlier examples illustrated this happening through a `merge` operation. For example:

```
merge:
- include: ["**/*"]
- include: ["**/pom.xml"]
  chain:
```

```
  - type: ReplaceText
    subsitutions: ...
```

The result of the preceding `merge` is two files with path `pom.xml`, assuming there was a `pom.xml` file in the input. **Transform A** produces a `pom.xml` that is a verbatim copy of the input file. **Transform B** produces a modified copy with some text replaced in it.

It is impossible to have two files on a disk with the same path. Therefore, this conflict must be resolved before you can write the result to disk or pack it into a ZIP file.

As the example shows, merges are likely to give rise to these conflicts, so you might call this a "merge conflict." However, such conflicts can also arise from other operations. For example, `RewritePath`:

```
type: RewritePath
regex: '.*.md'
rewriteTo: "'docs/README.md'"
```

This example renames any `.md` file to `docs/README.md`. Assuming the input contains more than one `.md` file, the output contains multiple files with path `docs/README.md`. Again, this is a conflict, because there can only be one such file in a physical file system or ZIP file.

Resolving merge conflicts

By default, when a conflict arises, the engine doesn't do anything with it. Our internal representation for a set of files allows for multiple files with the same path. The engine carries on manipulating the files as is. This isn't a problem until the files must be written to disk or a ZIP file. If a conflict is still present at that time, an error is raised.

If your accelerator produces such conflicts, they must be resolved before writing files to disk. VMware provides the UniquePath transform. This transform allows you to specify what to do when more than one file has the same path. For example:

```
chain:
- type: RewritePath
  regex: '.*.md'
  rewriteTo: "'docs/README.md'"
- type: UniquePath
  strategy: Append
```

The result of the above transform is that all `.md` files are gathered up and concatenated into a single file at path `docs/README.md`. Another possible resolution strategy is to keep only the contents of one of the files. See Conflict Resolution.

Combo transform includes some convenient built-in support for conflict resolution. It automatically selects the `UseLast` strategy if none is explicitly supplied. You rarely, if ever, need to specify a conflict resolution strategy.

File ordering

As mentioned earlier, our set of files representation is richer than the files on a typical file system in that it allows for multiple files with the same path. Another way in which it is richer is that the files in the set are ordered. That is, a `FileSet` is more like an ordered list than an unordered set.

In most situations, the order of files in a `FileSet` doesn't matter. However, in conflict resolution it is significant. If you look at the preceding `RewritePath` example again, you might wonder about the order in which the various `.md` files are appended to each other. This ordering is determined by the order of the files in the input set.

So what is that order? In general, when files are read from disk to create a `FileSet`, you cannot assume a specific order. Yes, the files are read and processed in a sequential order, but the actual order is not well defined. It depends on implementation details of the underlying file system. The accelerator engine therefore does not ensure a specific order in this case. It only ensures that it preserves whatever ordering it receives from the file system, and processes files in accord with that order.

If you do not want the file order produced from reading directly from a file system and want to control the order of the sections in the `README.md` file, change the order of the merge children. `Merge` processes its children in order and reflects this order in the resulting output

For example:

```
chain:
  - merge:
      - include: ['README.md']
      - include: ['DEPLOYMENT.md']
        chain:
          - type: RewritePath
            rewriteTo: "'README.md'"
  - type: UniquePath
    strategy: Append
```

In this example, `README.md` from the first child of `merge` comes before `DEPLOYMENT.md` from the second child of `merge`.

Next steps

This introduction focused on an intuitive understanding of the `<transform-definition>` notation. This notation defines precisely how the accelerator engine generates new project content from the files in the accelerator root.

For more information, see:

- An exhaustive Reference of all built-in transform types
- A sample, commented accelerator.yaml to learn from a concrete example

Use custom types in Application Accelerator

This topic tells you how to declare new `types` in `accelerator.yaml`

Use these types for options declaration, in addition to the built-in types `string`, `number`, and `boolean`.

In `accelerator.yaml`, use the `types` entry (inside the top-level `accelerator` section) to define custom types.

The name must be an initial capital letter.

In the following example, the `struct` type definition is syntactically equivalent to a sequence of option definitions:

```
accelerator:
  options:
    ...
  types:
    - name: Task
      struct:
        - name: title
          dataType: string
          label: Title
```

```
          description: A sample title
        - name: details
          label: Task details
          description: Enter the task details
        - name: done
          dataType: boolean
          label: Done?
          defaultValue: false
```

This example creates a new *type* that is available for the `dataType` property of any option. For example,

```
accelerator:
  options:
    - name: myTask
      dataType: Task
  types:
    ...
```

UIs render similar to the following:

and associate the entered values to the `myTask` top-level name, resulting in the following example values submission (here represented using JSON notation):

```
{
  "myTask": { // Note the use of a nested object here
    "title": "Get job done!",
    "details": "Needs this asap",
    "done": false
  }
}
```

The type of the `myTask` value is `object` (in Javascript/JSON parlance) and `Map<String, ?>` when seen from the Java engine side.

The earlier example is technically possible with the custom types feature, but brings little benefit over having three options named to achieve the same result, for example, `myTaskTitle`, `myTaskDetails`, and `myTaskDone`. The value of custom types is when they are used in sequence types, allowing you to enter an unbounded list of structured data:

```
accelerator:
  options:
    - name: myTasks
      dataType: [Task]
  types:
    ...
```

Which might result in the following example submission (JSON):

```
{
  "myTasks": [ // Note the use of JSON array
    {  // with elem 0 being an object
      "details": "something",
      "done": true,
      "title": "The Title"
    },
    {  // and elem 1 as well, etc
      "details": "something else",
      "done": false,
      "title": "The other Title"
    }
  ]
}
```

Limitations

A `struct` custom type declaration is made of an ordered series of option definitions. The support and semantics for individual text boxes of option-definition-like elements when used in the type *declaration* are stated in the following example.

When *referencing* a custom type in an option definition, some previously valid properties of an option definition might become irrelevant or unsupported. This is stated in the following example:

```
accelerator:
  types:
    - name: MyType
      struct:
        - name: someField   # the "option name" will become a 'property' of the newly
created type
          dataType: string  # is the type of this single property. Typically, will be
a simple
                            # scalar type like string or number
          defaultValue: foo # supported and is the default if not overridden at usage
point by the option's defaultValue
          description: something # will become the description for the field's widget
          choices:              # supported
            - value: v
              text:  t
          validationRegex:      # validates that single property
          label:                # will become the "title" of the widget
          inputType:            # supported
          required:             # supported
          dependsOn:            # supported against other properties of THIS struct
    .. other fields
  options:
    - name: anOptionThatUsesACustomType
      dataType: MyType
      defaultValue: # supported, should then be an object (or array thereof)
      description:  # supported, is the description of the whole option (as opposed to
individual fields)
      label:        # supported, idem
      choices:      # NOT supported
        - value: v
          text:  t
      validationRegex: # NOT supported
      inputType:       # NOT supported
      required:        # technically supported, useless in practice
      dependsOn:       # OK to depend on another option
```

Interaction with SpEL

Everywhere that SpEL is used in the engine syntax, accelerator authors might use SpEL syntax for accessing properties or array elements:

```
#myTasks[2]['done']
```

Do not use array indexing either with a literal number or a variable, as the purpose of the list of the custom types feature is that you don't know the data length in advance. For more information about idiomatic uses of repeated structured data, see Loop Transform.

Interaction with Composition

Using composition alongside custom types has the following advantages/disadvantages:

- You might want to **leverage** types declared in an imported fragment
- There might be a type **name clash** between a host accelerator/fragment and an imported fragment, because the imported fragment author is unaware of how the fragment is to be used.

For more information about the syntax to customize the imported types names, see Use fragments in Application Accelerator.

Use fragments in Application Accelerator

This topic tells you how to use fragments in Application Accelerator.

Introduction

Despite their benefits, writing and maintaining, accelerators can become repetitive and verbose as new accelerators are added. Some create a project different from the next with similar aspects, requiring some form of copy-paste.

To alleviate this concern, Application Accelerators support a feature named Composition that allows the re-use of parts of an accelerator, called **fragments**.

Introducing fragments

A **fragment** looks exactly the same as an accelerator:

- It is made of a set of files.
- It contains an `accelerator.yaml` descriptor with options, declarations, and a root transform.

There are differences however. Namely:

- Fragments are declared to the system differently. They are filed as **fragment** custom resources.
- They deal with files differently. Because fragments deal with their own files and files from the accelerator using them, they use dedicated conflict resolution strategies (more on this later).

Fragments may be thought of as "functions" in programming languages. After being defined and referenced, they are "called" at various points in the main accelerator. The composition feature is designed with ease of use and "common use first" in mind, so these "functions" are typically called with as little noise as possible. You can also call them complex or different values.

Composition relies on two building blocks that play hand in hand:

- The `imports` section at the top of an accelerator manifest.
- The, `InvokeFragment` transform, to be used alongside any other transform.

| The `imports` section explained

To be usable in composition, a fragment MUST be *imported* into the dedicated section of an accelerator manifest:

```
accelerator:
  name: my-awesome-accelerator
  options:
    - name: flavor
      dataType: string
      defaultValue: Strawberry
  imports:
    - name: my-first-fragment
    - name: another-fragment
engine:
  ...
```

The effect of importing a fragment this way is twofold:

- It makes its files available to the engine (therefore importing a fragment is required).
- It exposes all of its options as options of the accelerator as if they were defined by the accelerator itself.

So in the earlier example, if the `my-first-fragment` fragment had the following `accelerator.yaml` file:

```
accelerator
  name: my-first-fragment
  options:
    - name: optionFromFragment
      dataType: boolean
      description: this option comes from the fragment
...
```

Then it is as if the `my-awesome-accelerator` accelerator defined it:

```
accelerator:
  name: my-awesome-accelerator
  options:
    - name: flavor
      dataType: string
      defaultValue: Strawberry
    - name: optionFromFragment
      dataType: boolean
      description: this option comes from the fragment
  imports:
    - name: my-first-fragment
    - name: another-fragment
engine:
  ...
```

All the metadata about options (type, default value, description, choices if applicable, *etc.*) come along when imported.

Because of this, users are prompted for a value for those options that come from fragments, as if they were options of the accelerator.

Using the `InvokeFragment` Transform

The second part at play in the composition is the `InvokeFragment` Transform.

As with any other transform, it may be used anywhere in the `engine` tree and receives files that are "visible" at that point. Those files, alongside those that make up the fragment, are made available to the fragment logic. If the fragment wants to choose between two versions of a file for a path, two new conflict resolution strategies are available: `FavorForeign` and `FavorOwn`.

The behavior of the `InvokeFragment` transform is very straightforward: after having validated options that the fragment expects (and maybe after having set default values for options that support one), it executes the whole transform of the fragment *as if it was written in place of* `InvokeFragment`.

See the `InvokeFragment` reference page for more explanations, examples, and configuration options. This topic now focuses on additional features of the `imports` section that are seldom used but still available to cover more complex use cases.

Back to the `imports` section

The complete definition of the `imports` section is as follows, with features in increasing order of "complexity":

```
accelerator:
  name: ...
  options:
    - name: ...
    ...
  imports:
    - name: some-fragment

    - name: another-fragment
      expose:
        - name: "*"
      exposeTypes:
        - name: "*"

    - name: yet-another-fragment
      expose:
        - name: someOption

        - name: someOtherOption
          as: aDifferentName
      exposeType:
        - name: SomeType

        - name: SomeOtherType
          as: ADifferentName
engine:
  ...
```

As shown earlier, the `imports` section calls a list of fragments to import. By default, all their options and types become options/type of the accelerator. Those options appear *after* the options defined by the accelerator, in the order the fragments are imported in.

It is even possible for a fragment to import another fragment, the semantics being the same as when an accelerator imports a fragment. This is a way to break apart a fragment even further if needed.

When importing a fragment, you can select which options of the fragment to make available as options of the accelerator. **This feature should only be used when a name clash arises in option names.**

The semantics of the `expose` block are as follows:

- For every `name`/`as` pair, don't use the original (`name`) of the option but instead, use the alias (`as`). Other metadata about the option is left unchanged.
- If the special `name: "*"` (which is NOT a legit option name usually) appears, all imported option names that are not remapped (the index at which the `*` appears in the YAML list is irrelevant) might be exposed with their original name.
- The default value for `expose` is `[{name: "*"}]`, that is, by default exposes all options with their original name.
- As soon as a single remap rule appears, the default is overridden. For example, to override some names AND expose the others unchanged, the `*` must be explicitly re-added.
- To explicitly un-expose ALL options from an imported fragment, an empty array may be used and overrides the default: `expose: []`.

Similarly, you can also select which custom types of the fragment to make available as types of the accelerator. **This feature should only be used when a name clash arises in types names.**

The semantics of the `exposeTypes` block are as follows:

- For every `name`/`as` pair, don't use the original (`name`) of the type but instead, use the alias (`as`). Options that used the original name are automatically "rewritten" to use the new name.
- If the special `name: "*"` appears, which is NOT usually a legit type name, all imported other type names that are not remapped are exposed with their original name. The index at which the `*` appears in the YAML list is irrelevant.
- The default value for `exposeTypes` is `[{name: "*"}]`, that is, by default exposes all types with their original name.
- As soon as a single remap rule appears, the default is overridden. For example, to override some names AND expose the others unchanged, the `*` must be explicitly re-added.
- To explicitly un-expose ALL types from an imported fragment, an empty array may be used, which overrides the default: `exposeTypes: []`.

Using `dependsOn` in the `imports` section

Lastly, as a convenience for the conditional use of fragments, you can make an exposed imported option *depend on* another option, as in the following example:

```
imports:
  - name: tap-initialize
    expose:
      - name: gitRepository
        as: gitRepository
        dependsOn:
          name: deploymentType
          value: workload
      - name: gitBranch
        as: gitBranch
        dependsOn:
          name: deploymentType
          value: workload
```

This plays well with the use of `condition`, as in the following example:

```
...
engine:
  ...
```

```
    type: InvokeFragment
    condition: "#deploymentType == 'workload'"
    reference: tap-initialize```
```

Discovering fragments using Tanzu CLI accelerator plug-in

Using the accelerator plug-in for Tanzu CLI, you can view a list of available fragments. Run:

```
tanzu accelerator fragment list
```

To see a list of available accelerator fragments. For example:

```
NAME                                READY   REPOSITORY
app-sso-client                      true    source-image: dev.registry.tanzu.vmware.c
om/app-accelerator/fragments/app-sso-client@sha256:ed5cf5544477d52d4c7baf3a76f71a11298

```

The `tanzu accelerator fragment get <fragment-name>` command shows all the options defined for the fragment and also any accelerators or other fragments that import this fragment. Run:

```
tanzu accelerator fragment get java-version
```

The following output is displayed:

```
name: java-version
namespace: accelerator-system
displayName: Select Java Version
ready: true
options:
- choices:
  - text: Java 8
    value: "1.8"
  - text: Java 11
    value: "11"
  - text: Java 17
    value: "17"
  defaultValue: "11"
  inputType: select
  label: Java version to use
  name: javaVersion
  required: true
artifact:
  message: Resolved revision: dev.registry.tanzu.vmware.com/app-accelerator/fragments/
java-version@sha256:df99a5ace9513dc8d083fb5547e2a24770dfb08ec111b6591e98497a329b969d
  ready: true
  url: http://source-controller-manager-artifact-service.source-system.svc.cluster.loc
al./imagerepository/accelerator-system/java-version-frag-97nwp/df99a5ace9513dc8d083fb5
```

```
547e2a24770dfb08ec111b6591e98497a329b969d.tar.gz
imports:
  None
importedBy:
  accelerator/java-rest-service
  accelerator/java-server-side-ui
  accelerator/spring-cloud-serverless
```

This shows the `options` and `importedBy` with a list of three accelerators that import this fragment.

Correspondingly, the `tanzu accelerator get <accelerator-name>` shows the fragments that an accelerator imports. Run:

```
tanzu accelerator get java-rest-service
```

The following output is shown:

```
name: java-rest-service
namespace: accelerator-system
description: A Spring Boot Restful web application including OpenAPI v3 document gener
ation and database persistence, based on a three-layer architecture.
displayName: Tanzu Java Restful Web App

imports:
  java-version
  live-update
  tap-workload
```

The `imports` section at the end shows the fragments that this accelerator imports. The `options` section shows all options defined for this accelerator. This includes all options defined in the imported fragments, for example, the options for the Java version imported from the `java-version` fragment.

Transforms reference

This topic provides you with a list and brief description of the available Application Accelerator transforms in Tanzu Application Platform (commonly known as TAP).

Available transforms

You can use:

- Combo as a shortcut notation for many common operations. It combines the behaviors of many of the other transforms.
- Include to select files to operate on.
- Exclude to select files to operate on.
- Merge to work on subsets of inputs and to gather the results at the end.
- Chain to apply several transforms in sequence using function composition.
- Let to introduce new scoped variables to the model.
- InvokeFragment allows re-using various fragments across accelerators.
- ReplaceText to perform simple token replacement in text files.
- RewritePath to move files around using regular expression (regex) rules.
- OpenRewriteRecipe to apply Rewrite recipes, such as package rename.
- YTT to run the `ytt` tool on its input files and gather the result.
- UseEncoding to set the encoding to use when handling files as text.
- UniquePath to decide what to do when several files end up on the same path.
- Loop to iterate over a list and apply a transform for each element.
- Provenance to generate a manifest of the accelerator run.

Transforms reference

This topic provides you with a list and brief description of the available Application Accelerator transforms in Tanzu Application Platform (commonly known as TAP).

Available transforms

You can use:

- Combo as a shortcut notation for many common operations. It combines the behaviors of many of the other transforms.
- Include to select files to operate on.
- Exclude to select files to operate on.
- Merge to work on subsets of inputs and to gather the results at the end.
- Chain to apply several transforms in sequence using function composition.
- Let to introduce new scoped variables to the model.
- InvokeFragment allows re-using various fragments across accelerators.
- ReplaceText to perform simple token replacement in text files.
- RewritePath to move files around using regular expression (regex) rules.
- OpenRewriteRecipe to apply Rewrite recipes, such as package rename.
- YTT to run the `ytt` tool on its input files and gather the result.
- UseEncoding to set the encoding to use when handling files as text.
- UniquePath to decide what to do when several files end up on the same path.
- Loop to iterate over a list and apply a transform for each element.
- Provenance to generate a manifest of the accelerator run.

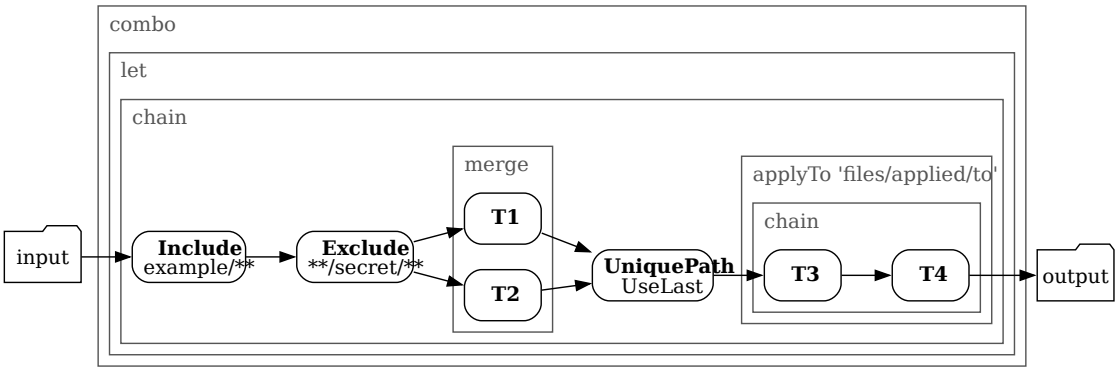
- Conflict Resolution

Combo transform

This topic tells you about the Application Accelerator `Combo` transform in Tanzu Application Platform (commonly known as TAP).

The `Combo` transform combines the behaviors of Include, Exclude, Merge, Chain, UniquePath, and Let.



Syntax reference

Here is the full syntax of `Combo`:

```
type: Combo                    # This can be omitted, because Combo is the default trans
form type.
let:                          # See Let.
```

```
  - name: <string>
    expression: <SpEL expression>
  - name: <string>
    expression: <SpEL expression>
condition: <SpEL expression>
include: [<ant pattern>]    # See Include.
exclude: [<ant pattern>]    # See Exclude.
merge:                      # See Merge.
  - <m1-transform>
  - <m2-transform>
  - ...
chain:                    # See Chain.
  - <c1-transform>
  - <c2-transform>
  - ...
applyTo: [<ant pattern>]   # See Chain
onConflict: <conflict resolution> # See UniquePath.
```

Behavior

The `Combo` transform properties have default values, are optional, and you must use at least one property.

When you configure the `Combo` transform with all properties, it behaves as follows:

1. Applies the `include` as if it were the first element of a Chain. The default value is `['**']`; if not present, all files are retained.
2. Applies the `exclude` as if it were the second element of the chain. The default value is `[]`; if not present, no files are excluded. Only files that match the `include`, but are not excluded by the `exclude`, remain.
3. Feeds all those files as input to all transforms declared in the `merge` property, exactly as Merge does. The result of that `Merge`, which is the third transform in the big chain, is another set of files. If there are no elements in `merge`, the previous result is directly fed to the next step.
4. The result of the merge step is prone to generate duplicate entries for the same `path`. It's implicitly forwarded to a UniquePath check, configured with the `onConflict` strategy. The default policy is to retain files appearing later. The results of the transforms that appear later in the `merge` block "win" against results appearing earlier.
5. Passes that result as the input to the chain defined by the `chain` property. The combo chain is prolonged with the elements defined in `chain`. If there are no elements in `chain`, it's as if the previous result was used directly. If the `applyTo` property is set, it applies to the sub-chain (and that sub-chain only).
6. If the `let` property is defined in the `Combo`, the whole execution is wrapped inside a Let that exposes its derived symbols.

To recap in pseudo code, a giant `Combo` behaves like this:

```
Let(symbols, in:
    Chain(
        include,
        exclude,
        Chain(Merge(<m1-transform>, <m2-transform>, ...), UniquePath(onConflict)),
        Chain(<applyTo>, <c1-transform>, <c2-transform>, ...)
    )
)
```

You rarely use at any one time all the features that `Combo` offers. Yet `Combo` is a good way to author other common building blocks without having to write their `type: x` in full.

For example, this:

```
include: ['**/*.txt']
```

is a perfectly valid way to achieve the same effect as this:

```
type: Include
patterns: ['**/*.txt']
```

Similarly, this:

```
chain:
  - type: T1
    ...
  - type: T2
    ...
```

is often preferred over the more verbose:

```
type: Chain
transformations:
  - type: T1
    ...
  - type: T2
    ...
```

As with other transforms, the order of declaration of properties has no impact. For clarity, a convention that mimics the actual behavior is used, but the following applies **T1** and **T2** on all `.yaml` files even though it places the `include` section after the `merge` section.

```
merge:
  - type: T1
  - type: T2
include: ["*.yaml"]
```

In other words, `Combo` applies `include` filters before `merge` irrespective of the physical order of the keys in the YAML text. It's a good practice to place the `include` key before the `merge` key. This makes the accelerator definition more readable, but has no effect on its execution order.

Examples

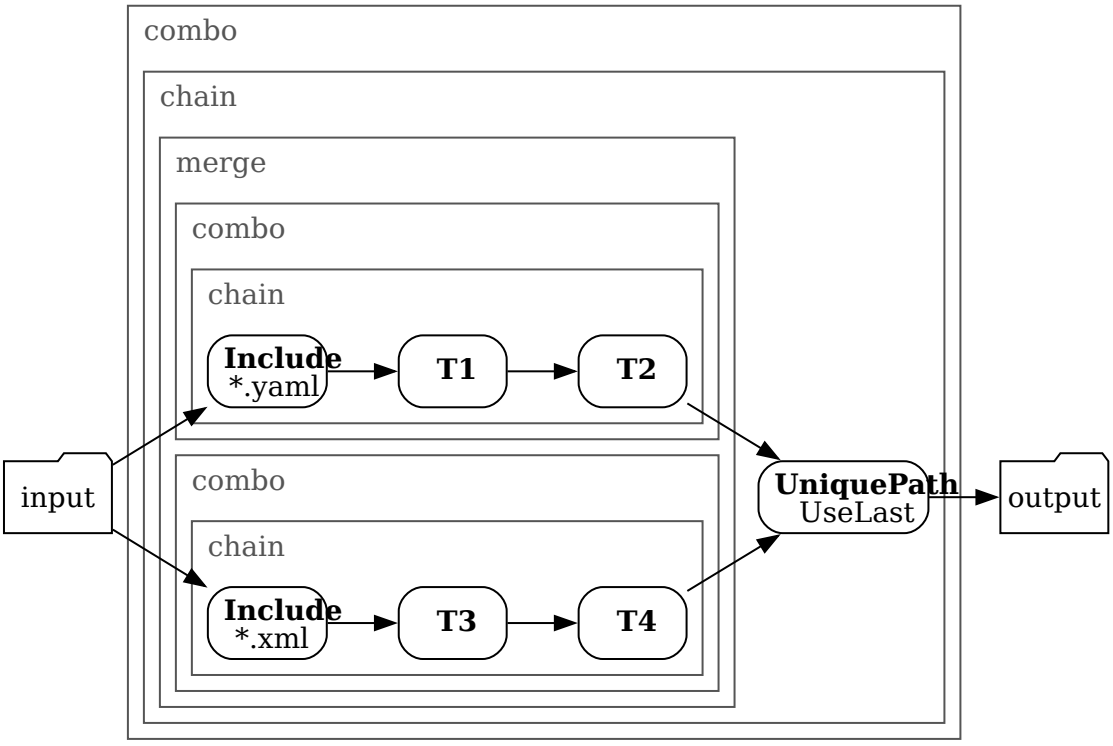
The following are typical use cases for `Combo`.

Example 1

To apply separate transformations to separate sets of files. For example, to all `.yaml` files and to all `.xml` files:

```
merge:                   # This uses the Merge syntax in a first Combo.
  - include: ['*.yaml']      # This actually nests a second Combo inside the first.
    chain:
      - type: T1
      - type: T2
  - include: ['*.xml']      # Here comes a third Combo, used as the 2nd child inside t
he first
    chain:
```

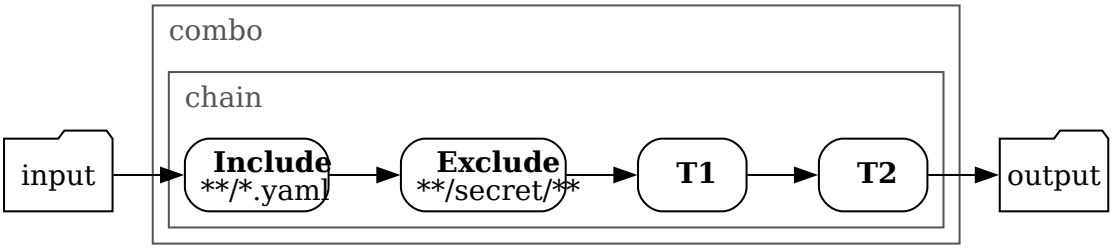
```
      - type: T3
      - type: T4
```



Example 2

To apply **T1** then **T2** on all `.yaml` files that are not in any `secret` directory:

```
include: ['**/*.yaml']
exclude: ['**/secret/**']
chain:
  - type: T1
    ..
  - type: T2
    ..
```



Include transform

This topic tells you about the Application Accelerator `Include` transform in Tanzu Application Platform (commonly known as TAP).

The `Include` transform retains files based on their `path`, letting in *only* those files whose path matches at least one of the configured `patterns`. The contents of files, and any of their other characteristics, are unaffected.

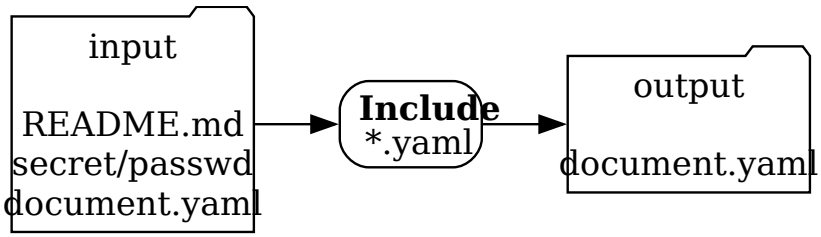
`Include` is a basic building block seldom used as is, which makes sense if composed inside a Chain or a Merge. It is often more convenient to leverage the shorthand notation offered by Combo.

Syntax reference

```
type: Include
patterns: [<ant pattern>]
condition: <SpEL expression>
```

Examples

```
type: Chain
transformations:
  - type: Include
    patterns: ["**/*.yaml"]
  - type: # At this point, only yaml files are affected
```



See also

- Exclude
- Combo

Exclude transform

This topic tells you about the Application Accelerator `Exclude` transform in Tanzu Application Platform (commonly known as TAP).

The `Exclude` transform retains files based on their `path`, allowing all files except ones with a path that matches at least one of the configured `patterns`. The contents of files, and any of their other characteristics are unaffected.

`Exclude` is a basic building block seldom used *as is*, which makes sense if composed inside a Chain or a Merge. It is often more convenient to leverage the shorthand notation offered by Combo.

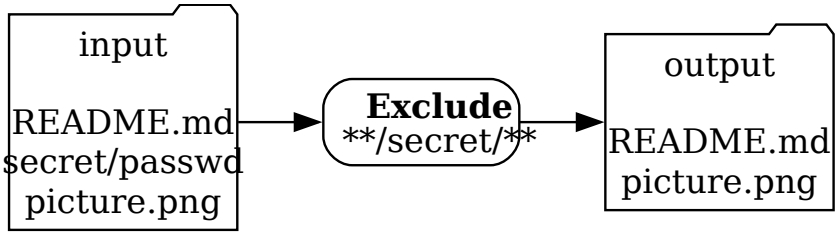
Syntax reference

```
type: Exclude
patterns: [<ant pattern>]
condition: <SpEL expression>
```

Examples

```
type: Chain
transformations:
  - type: Exclude
```

```
    patterns: ["**/secret/**"]
  - type: # At this point, no file matching **/secret/** is affected.
```



See also

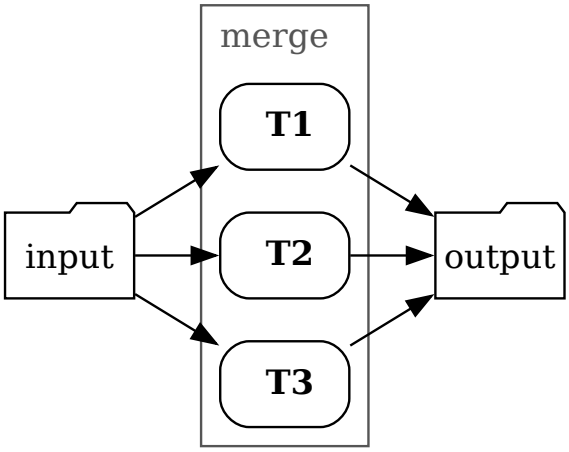
- Include
- Combo

Merge transform

This topic tells you about the Application Accelerator `Merge` transform in Tanzu Application Platform (commonly known as TAP).

The `Merge` transform feeds a copy of its input to several other transforms and merges the results together using set union.

A `Merge` of **T1**, **T2**, and **T3** applied to input **I** results in **T1(I)** ∪ **T2(I)** ∪ **T3(I)**.



An empty merge produces nothing (∅).

Syntax reference

```
type: Merge
sources:
  - <transform>
  - <transform>
  - <transform>
  - ...
condition: <SpEL expression>
```

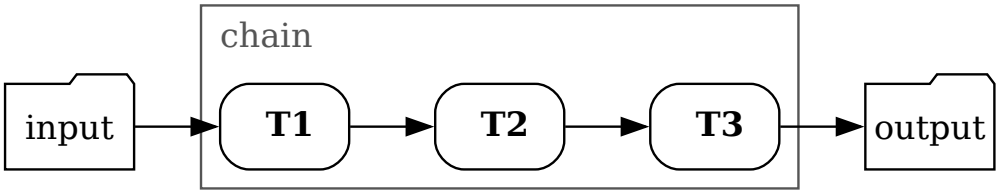
See also

- Combo is often used to express a `Merge` **and** other transformations in a shorthand syntax.

Chain transform

This topic tells you about the Application Accelerator `Chain` transform in Tanzu Application Platform (commonly known as TAP).

The `Chain` transform uses function composition to produce its final output.



Syntax reference

```
type: Chain
transformations:
  - <transform>
  - <transform>
  - <transform>
  - ...
applyTo: [<ant pattern>]
condition: <SpEL expression>
```

Behavior

A chain of **T1** then **T2** then **T3** first applies transform **T1**. It then applies **T2** to the output of **T1**, and finally applies **T3** to the output of that. In other words, **T3** to **T2** to **T1**.

An empty chain acts as function identity.

If the optional `applyTo` property is set, then the chained transformations are only applied to files with paths that match the `applyTo` patterns. Files with paths that don't match are left untouched and merged back with the other results to form the final result of the `Chain` transform.

Let transform

This topic tells you about the Application Accelerator `Let` transform in Tanzu Application Platform (commonly known as TAP).

The `Let` transform wraps another transform, creating a new scope that extends the existing scope.

SpEL expressions inside the `Let` can access variables from both the existing scope and the new scope.

Variables defined by the `Let` should not shadow existing variables. If they do, those existing variables won't be accessible.

Syntax reference

```
type: Let
symbols:
- name: <string>
  expression: <SpEL expression>
- ...
in: <transform> # <- new symbols are visible in here
```

Execution

The `Let` adds variables to the new scope by computation of SpEL expressions.

```
engine:
  let:
  - name: <string>
    expression: <SpEL expression>
  - ...
```

Both a `name` and an `expression` must define each symbol where:

- `name` must be a camelCase string name. If a let *symbol* happens to have the same name as a symbol already defined in the surrounding scope, then the local symbol shadows the symbol from the surrounding scope. This makes the variable from the surrounding scope inaccessible in the remainder of the `Let` but doesn't alter its original value.
- `expression` must be a valid SpEL expression expressed as a YAML string. Be careful when using the `#` symbol for variable evaluation, because this is the comment marker in YAML. So SpEL expressions in YAML must enclose strings in quotes or rely on block style. For more information about block style, see Block Style Productions.

Symbols defined in the `Let` are evaluated in the new scope in the order they are defined. This means that symbols lower in the list can make use of the variables defined higher in the list but not the other way around.

See also

- Combo provides a way to declare a `Let` scope and other transforms in a short syntax.

Loop transform

This topic tells you about the Application Accelerator `Loop` transform in Tanzu Application Platform (commonly known as TAP).

The `Loop` transform iterates over elements in a list and applies the provided transform for every element in that list.

When `doAsMerge` is used, a copy of the `Loop` transform's input is passed to each transform and the outputs from each transform are merged using a set union.

When `doAsChain` is used, each transform is executed sequentially, receiving the previous transform's output as its input. The first transform is to receive the `Loop` transform's input as its input.

Syntax reference

```
type: Loop
on: <SpEL expression>
var: <string>
index: <string>
doAsChain: <transform>
doAsMerge: <transform>
```

- `on` must be a SpEL expression that evaluates a list. This is the list of elements to be iterated over.
- `var` is the name of the variable to be assigned to the current element on each iteration. (optional)

- `index` is the variable's name to be assigned to the index of the current element on each iteration. (optional)
- `doAsMerge` is the transform to be executed for every element in the list, on a copy of the `Loop` transform's input.
- `doAsChain` is the transform to be executed for every element in the list, passing the output of the transform as input to the next transform.

Both `var` and `index` are optional.

Only one of the `doAsMerge` or `doAsChain` variables is to be used in a `Loop` transform.

Behavior

Consider the following when choosing `doAsMerge` or `doAsChain`:

`doAsMerge` executes the transform on the same input files for every iteration and merges the resulting outputs. It is best suited when a transform is executed multiple times on the same input and does not have conflicts.

`doAsChain` executes the transform on the initial input files once and then passes the resulting output to the second iteration and so on. It is best suited when a transform must detect any changes that occurred in the previous iteration.

Examples

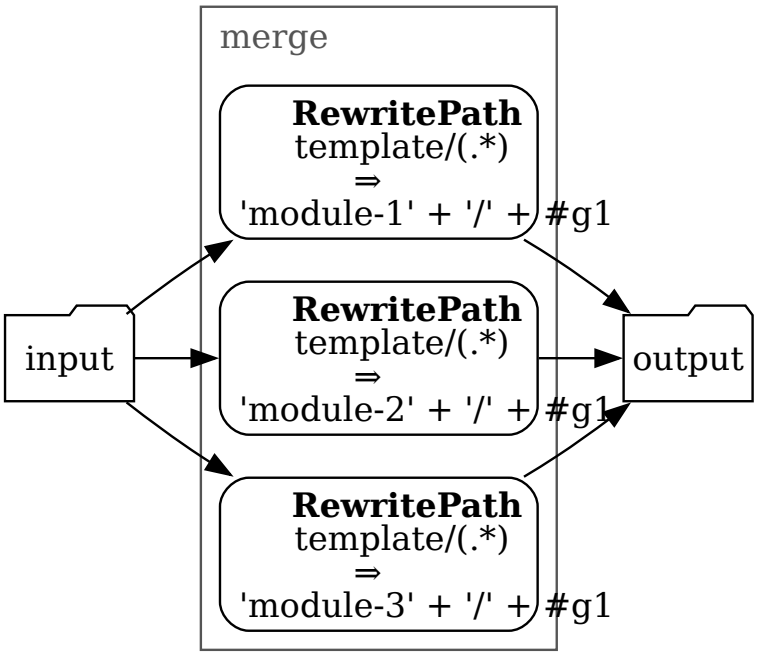
See the following examples using the `Loop` transform.

Example 1

Create a new directory for every module in `modules` (a list of strings) based on the contents of the "template" directory.

```
type: Loop
on: "#modules"
var: m
doAsMerge:
  type: RewritePath
  regex: "template/(.*)"
  rewriteTo: "#m + '/' + #g1"
```

The following diagram shows how this example behaves:

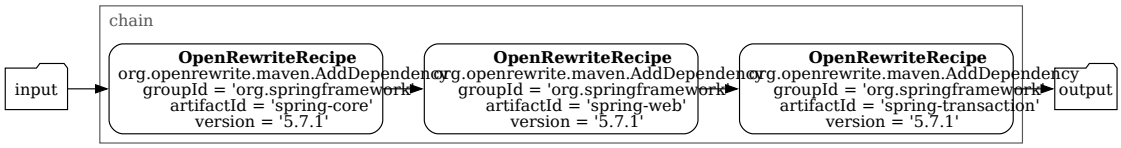


Example 2

Add every artifactId in `artifacts` (a list of strings) as a Spring dependency.

```
type: Loop
on: "#artifacts"
var: a
doAsChain:
  type: OpenRewriteRecipe
  recipe: org.openrewrite.maven.AddDependency
  options:
    groupId: "'org.springframework'"
    artifactId: "#a"
    version: "'5.7.1'"
```

The following diagram shows how this example behaves:



Example 3

You can use `Loop` in combination with custom types, for example:

```
accelerator:
  types:
    - name: MavenPlugin
      struct:
        - name: groupId
        - name: artifactId
        - name: version
  options:
    - name: pluginsToAdd
      dataType: [MavenPlugin] # End users will be able to enter a collection of GAV tu
ples
engine:
```

```
  include: [pom.xml]
  chain:
    - type: Loop
      on: pluginsToAdd # Iterate on the pluginsToAdd collection
      var: p           # The variable "p" will contain each tuple in turn
      doAsChain:       # Will apply the second execution to the result of the first, a
nd so on...
        type: OpenRewriteRecipe
        recipe: org.openrewrite.maven.AddPlugin
        options:
          groupId:    "#p['groupId']"
          artifactId: "#p['artifactId']"
          version:    "#p['version']"
```

For more information, see Using Custom Types.

InvokeFragment transform

This topic tells you about the Application Accelerator `InvokeFragment` transform in Tanzu Application Platform (commonly known as TAP).

The `InvokeFragment` performs transformations defined in an imported Fragment, allowing re-use across accelerators.

Syntax reference

```
type: InvokeFragment
reference: <imported-fragment>
let:  # See Let
  - name: <string>
    expression: <SpEL expression>
  ...
anchor: [<file path>]
```

Behavior

Assuming some fragment `my-fragment` has been imported in the accelerator (thus exposing the options it defines as options of the current accelerator), the following construct invokes `my-fragment`:

```
type: InvokeFragment
reference: my-fragment
```

This passes all input files (depending where this invocation sits in the “tree”) to the invoked fragment, which can then manipulate them alongside its own files. The result of the invocation becomes the result of this transform.

Variables

At the point of invocation, all currently defined variables are made visible to the invoked fragment. Therefore, if it was `import`-ed in the most straightforward manner, a fragment defining an option `myOption` is defining an option named `myOption` at the accelerator level, and the value provided by the user is visible at the time of invocation.

To override a value, or if an imported option has been exposed under a different name, or not at all, you can use a `let` construct when using `InvokeFragment`. This behaves as the Let transform: for the duration of the fragment invocation, the variables defined by `let` now have their newly defined values. Outside the scope of the invocation, the regular model applies.

Files

The set of files coming from the invoking accelerator and made visible to the fragment is the set of files that “reach” the point of invocation. For example, in the following case:

```
include: ["somedir/**"]
chain:
  - type: InvokeFragment
    reference: my-fragment
```

All files that the fragment invocation “sees” are files in the `somedir/` subdirectory. If the `my-fragment` has not been written accordingly, this can be problematic. Chances are that this re-usable fragment expects files to be present at the root of the project tree and work on them.

To better cope with this typical situation, the `InvokeFragment` transform exposes the optional `anchor` configuration property. Continuing with the earlier example, by using `anchor: somedir`, then all files coming from the current accelerator are exposed as if their `path` had the `somedir/` prefix removed. When it comes to gathering the result of the invocation though, all resulting files are re-introduced with a prefix prepended to their `path` (this applies to **all** files produced by the fragment, not just the ones originating from the accelerator).

The value of the `anchor` property must not start nor end with a slash (`/`) character.

Examples

The following is a full-featured example showcasing the interaction between the `imports` section and `InvokeFragment`:

```
accelerator:
  name: my-accelerator
  options:
    - name: someOption
      dataType: number
  imports:
    - name: my-fragment

engine:
  merge:
    - include: ["..."]
    - ...
    - chain:
        - include: ["**/pom.xml"]
        - type: InvokeFragment
          reference: my-fragment
```

Assuming `my-fragment` is defined as follows:

```
accelerator:
  name: my-fragment
  options:
    - name: indentationLevel
      dataType: number
      defaultValue: 2
transform:
  chain:
    - include: ["**/*.xml"]
    - type: SomeTransform
      ...
```

Then users will be presented with two options: `someOption` and `indentationLevel`, as if `indentationLevel` was defined in the host accelerator.

Moreover, the behavior of the calling accelerator is exactly as if the body of the fragment transform was inserted in-place of `InvokeFragment`:

```
accelerator:
  name: my-accelerator
  options:
    - name: someOption
      dataType: number
    - name: indentationLevel
      dataType: number
      defaultValue: 2

engine:
  merge:
    - include: ["..."]
    - ...
    - chain:
        - include: ["**/pom.xml"]
        - chain:
          - include: ["**/*.xml"]
          - type: SomeTransform
            ...
```

Now you can imagine some scenarios to better clarify all configuration properties.

If, for some reason, you don't want to use the value entered in the `indentationLevel` option for the fragment, but twice the value provided for `someOption`. The `InvokeFragment` block can be rewritten as follows:

```
    type: InvokeFragment
    reference: my-fragment
    let:
      - name: indentationLevel
        value: '2 * #someOption'
```

Finally, if the invocation in the accelerator looks like this:

```
engine:
  merge:
    - include: ["..."]
    - ...
    - chain:
        - include: ["**/README.md"]
        - type: InvokeFragment
          reference: my-fragment
```

Then there is zero visible effect, because this is forwarding only `README.md` files to the fragment and the fragment is itself using a filter on `*.xml` files.

- Let
- RewritePath

ReplaceText transform

This topic tells you about the Application Accelerator `ReplaceText` transform in Tanzu Application Platform (commonly known as TAP).

The `ReplaceText` transform allows replacing one or several text tokens in files as they are being copied to their destination. The replacement values are the result of dynamic evaluation of SpEL expressions.

This transform is text-oriented and requires knowledge of how to interpret the stream of bytes that make up the file contents into text. All files are assumed to use `UTF-8` encoding by default, but you can use the UseEncoding transform upfront to specify a different charset to use on some files.

You can use `ReplaceText` transform in one of two ways:

- To replace several literal text tokens.
- To define the replacement behavior using a single regular expression, in which case the replacement SpEL expression can leverage the regex capturing group syntax.

Syntax reference

Syntax reference for replacing several literal text tokens:

```
type: ReplaceText
substitutions:
  - text: STRING
    with: SPEL-EXPRESSION
  - text: STRING
    with: SPEL-EXPRESSION
  - ..
condition: SPEL-EXPRESSION
```

Syntax reference for defining the replacement behavior using a *single* regular expression:

Regex is used to match the entire document. To match on a per line basis, enable multiline mode by including `(?m)` in the regex.

```
type: ReplaceText
regex:
  pattern: REGULAR-EXPRESSION
  with: SPEL-EXPRESSION
condition: SPEL-EXPRESSION
```

In both cases, the SpEL expression can use the special `#files` helper object. This enables the replacement string to consist of the contents of an accelerator file. See the following example.

Another set of helper objects are functions of the form `xxx2Yyyy()` where `xxx` and `yyy` can take the value `camel`, `kebab`, `pascal`, or `snake`. For example, `camel2Snake()` enables changing from camelCase to snake_case.

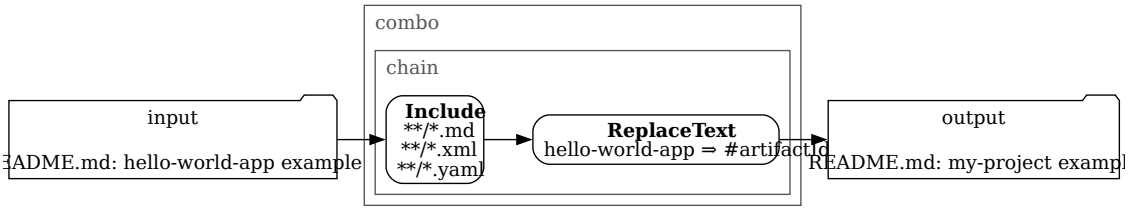
Examples

See the following examples using The `ReplaceText` transform.

Example 1

Replacing the hardcoded string `"hello-world-app"` with the value of variable `#artifactId` in all `.md`, `.xml`, and `.yaml` files.

```
include: ['**/*.md', '**/*.xml', '**/*.yaml']
chain:
  - type: ReplaceText
    substitutions:
      - text: "hello-world-app"
        with: "#artifactId"
```



Example 2

Replacing the hardcoded string `"hello-world-app"` with the value of variable `#artifactId` in the `README-fr.md` and `README-de.md` files, which are encoded using the `ISO-8859-1` charset:

```
include: ['README-fr.md', 'README-de.md']
chain:
  - type: UseEncoding
    encoding: 'ISO-8859-1'
  - type: ReplaceText
    substitutions:
      - text: "hello-world-app"
        with: "#artifactId"
```

Example 3

Similar to the preceding example, but making sure the value appears as kebab case, while the entered `#artifactId` is using camel case:

```
include: ['**/*.md', '**/*.xml', '**/*.yaml']
chain:
  - type: ReplaceText
    substitutions:
      - text: "hello-world-app"
        with: "#camel2Kebab(#artifactId)"
```

Example 4

Replacing the hardcoded string `"REPLACE-ME"` with the contents of file named after the value of the `#platform` option in `README.md`:

```
include: ['README.md']
chain:
  - type: ReplaceText
    substitutions:
      - text: "REPLACE-ME"
        with: "#files.contentsOf('snippets/install-' + #platform + '.md')"
```

Example 5

Replacing all occurrences of `apple` or `orange`, singular or plural, with the value of the accelerator option `#vegetable`, for example `'banana'`, keeping the trailing `'s'` when there was one.

```
include: ['README.md']
chain:
  - type: ReplaceText
    regex:
      pattern: "(apple|orange)(s)?"
      # This constructs a SpEL string containing eg 'banana$2' where $2
      # refers to the second capturing group (the optional 's')
      with: "#vegetable + '$2'"
```

See also

- UseEncoding

RewritePath transform

This topic tells you about the Application Accelerator `RewritePath` transform in Tanzu Application Platform (commonly known as TAP).

The `RewritePath` transform allows you to change the name and path of files without affecting their content.

Syntax reference

```
type: RewritePath
regex: <string>
rewriteTo: <SpEL expression>
matchOrFail: <boolean>
```

For each input file, `RewritePath` attempts to match its `path` by using the regular expression (regex) defined by the `regex` property. If the regex matches, `RewritePath` changes the `path` of the file to the evaluation result of `rewriteTo`.

`rewriteTo` is an expression that has access to the overall engine model and to variables defined by capturing groups of the regular expression. Both *named capturing groups* `(?<example>[a-z]*)` and regular *index-based* capturing groups are supported. `g0` contains the whole match, `g1` contains the first capturing group, and so on.

If the regex doesn't match, the behavior depends on the `matchOrFail` property:

- If set to `false`, which is the default, the file is left untouched.
- If set to `true`, an error occurs. This prevents misconfiguration if you expect all files coming in to match the regex. For more information about typical interactions between `RewritePath` and `Chain + Include`, see the following section, Interaction with Chain and Include.

The default value for `regex` is the following regular expression, which provides convenient access to some named capturing groups:

```
^(?<folder>.*/)?(?<filename>([^/]+?|)(?=(?<ext>\.[^/.]*)?)$)
```

Using `some/deep/nested/file.xml` as an example, the preceding regular expression captures:

- **folder:** The full folder path the file is in. In this example, `some/deep/nested/`.
- **filename:** The full name of the file, including extension *if present*. In this example, `file.xml`.
- **ext:** The last dot and extension in the filename, *if present*. In this example, `.xml`.

The default value for `rewriteTo` is the expression `#folder + #filename`, which doesn't rewrite paths.

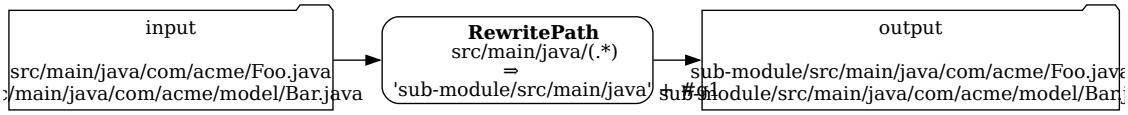
Examples

See the following examples using the `RewritePath` transform.

Example 1

The following moves all files from `src/main/java` to `sub-module/src/main/java`:

```
type: RewritePath
regex: src/main/java/(.*)
rewriteTo: "'sub-module/src/main/java' + #g1"   # 'sub-module/' + #g0 works too
```



Example 2

The following flattens all files found inside the `sub-path` directory and its subdirectories, and puts them into the `flattened` folder:

```
type: RewritePath
regex: sub-path/(.*/)*(?<filename>[^/]+)
rewriteTo: "'flattened' + #filename"   # 'flattened' + #g2 would work too
```

Example 3

The following turns all paths into lowercase:

```
type: RewritePath
rewriteTo: "#g0.toLowerCase()"
```

Interaction with Chain and Include

It's common to define pipelines that perform a `Chain` of transformations on a subset of files, typically selected by `Include/Exclude`:

```
- include: ["**/*.java"]
- chain:
    - # do something here
    - # and then here
```

If one of the transformations in the chain is a `RewritePath` operation, chances are you want the rewrite to apply to *all* files matched by the `Include`. For those typical configurations, you can set the `matchOrFail` guard to `true` to ensure the `regex` you provide indeed matches all files coming in.

- Use UniquePath to ensure rewritten paths don't clash with other files, or to decide which path to select if they do clash.

OpenRewriteRecipe transform

This topic tells you about the Application Accelerator `OpenRewriteRecipe` transform in Tanzu Application Platform (commonly known as TAP).

The `OpenRewriteRecipe` transform allows you to apply any Open Rewrite **Recipe** to a set of files and gather the results.

The engine leverages v8.7.4 of Open Rewrite and parses Java files using the grammar for Java 17.

The following Open Rewrite Recipes are supported:

- Java recipes (v8.7.4)
- Maven recipes (v8.7.4)

- XML recipes (v8.7.4)
- YAML recipes (v8.7.4)
- JSON recipes (v8.7.4)
- Properties recipes (v8.7.4)
- Kubernetes recipes (v1.18.0)
- Python recipes (v1.1.2)
- Terraform recipes (v2.0.5)

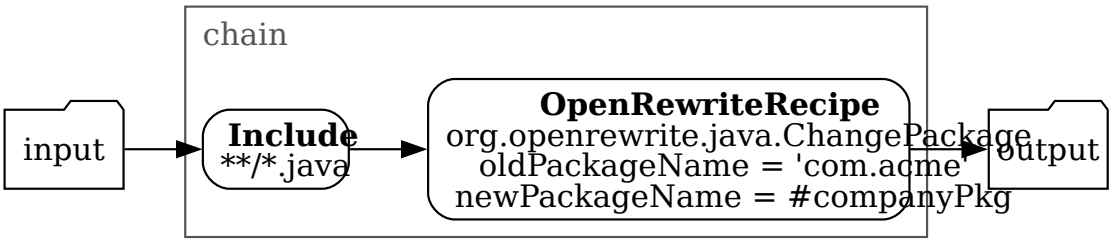
Syntax reference

```
type: OpenRewriteRecipe
recipe: <string>                  # Full qualified classname of the recipe
options:
  <string>: <SpEL expression>      # Keys and values depend on the class of the recipe
  <string>: <SpEL expression>      # Refer to the documentation of said recipe
  ...
```

Example

The following example applies the ChangePackage Recipe to a set of Java files in the `com.acme` package and moves them to the value of `#companyPkg`. This is more powerful than using RewritePath and ReplaceText, as it reads the syntax of files and correctly deals with imports, fully compared to non-fully qualified names, and so on.

```
chain:
  - include: ["**/*.java"]
  - type: OpenRewriteRecipe
    recipe: org.openrewrite.java.ChangePackage
    options:
      oldPackageName: "'com.acme'"
      newPackageName: "#companyPkg"
```



YTT transform

This topic tells you about the Application Accelerator `YTT` transform in Tanzu Application Platform (commonly known as TAP).

The `YTT` transform starts the YTT template engine as an external process.

Syntax reference

```
type: YTT
extraArgs: # optional
  - <SPEL-EXPRESSION-1>
```

```
  - <SPEL-EXPRESSION-2>
  - ...
```

The `YTT` transform's YAML notation does not require any parameters. When invoked without parameters, which is the typical use case, the YTT transform's input is determined entirely by two things only:

1. The input files fed into the transform.
2. The current values for options and derived symbols.

Execution

YTT is invoked as an external process with the following command line:

```
ytt -f <input-folder> \
    --data-values-file <symbols.json> \
    --output-files <output-folder> \
    <extra-args>
```

The `<input-folder>` is a temporary directory into which the input files are "materialized." That is, the set of files passed to the YTT transform as input is written out into this directory to allow the YTT process to read them.

The `<symbols.json>` file is a temporary JSON file, which the current option values and derived symbols are materialized in the form of a JSON map. This allows YTT templates in the `<input-folder>` to make use of these symbols during processing.

The `<output-folder>` is a fresh temporary directory that is empty at the time of invocation. In a typical scenario, upon completion, the output directory contains files generated by YTT.

The `<extra-args>` are additional command line arguments obtained by evaluating the SPEL expressions from the `extraArgs` attribute.

When the `ytt` process completes with a 0 exit code, this is considered a successful execution and the contents of the output directory is taken to be the result of the YTT transform.

When the `ytt` process completes with a non 0 exit code, the execution of the `YTT` transform is considered to have failed and an exception is raised.

Examples

See the following examples using the `YTT` transform.

Basic invocation

When you want to execute `ytt` on the contents of the entire accelerator repository, use the YTT transform as your only transform in the engine declaration.

```
accelerator:
  ...
engine:
  type: YTT
```

To do anything beyond calling YTT, compose YTT into your accelerator flow using merge or chain combinators. This is exactly the same as composing any other type of transform.

For example, when you want to define some derived symbols as well as merge the results from YTT with results from other parts of your accelerator transform, you can reference this example:

```
engine:
  let: # Define derived symbols visible to all transforms (including YTT)
  - name: theAnswer
    expression: "41 + 1"
  merge:
  - include: ["deploy/**.yml"] # select some yaml files to process with YTT
    chain: # Chain selected yaml files to YTT
    - type: YTT
  - ... include/generate other stuff to be merged alongside yaml generated by YTT...
```

The preceding example uses a combination of Chain and Merge. You can use either `Merge` or `Chain` or both to compose YTT into your accelerator flow. Which one you choose depends on how you want to use YTT as part of your larger accelerator.

Using `extraArgs`

The `extraArgs` passes additional command line arguments to YTT. This adds file marks. See File Marks in the Carvel documentation.

For example, the following runs YTT and renames the `foo/demo.yml` file in its output to `bar/demo.yml`.

```
engine:
  type: YTT
  extraArgs: ["'--file-mark'",  "'foo/demo.yml:path=bar/demo.yml'"]
```

The `extraArgs` attribute expects SPEL expressions. Take care to use proper escaping of literal strings using double and single quotes (that is, `“‘LITERAL-STRING’”).

UseEncoding transform

This topic tells you about the Application Accelerator `UseEncoding` transform in Tanzu Application Platform (commonly known as TAP).

When considering files in textual form, for example, when doing text replacement with the ReplaceText transform, the engine must decide which encoding to use.

By default, `UTF-8` is assumed. If any files must be handled differently, use the `UseEncoding` transform to annotate them with an explicit encoding.

`UseEncoding` returns an error if you apply encoding to files that have already been explicitly configured with a particular encoding.

Syntax reference

```
type: UseEncoding
encoding: <encoding>    # As recognized by the java java.nio.charset.Charset class
condition: <SpEL expression>
```

Supported encoding names include, for example, `UTF-8`, `US-ASCII`, and `ISO-8859-1`.

Example use

`UseEncoding` is typically used as an upfront transform to, for example, ReplaceText in a chain:

```
type: Chain   # Or using "Combo"
transformations:
  - type: UseEncoding
    encoding: ISO-8859-1
```

```
  - type: ReplaceText
    substitutions:
      - text: "hello"
        with: "#howToSayHello"
```

See also

- ReplaceText

UniquePath transform

This topic tells you about the Application Accelerator `UniquePath` transform in Tanzu Application Platform (commonly known as TAP).

You can use the `UniquePath` transform to ensure there are no `path` conflicts between files transformed. You can often use this at the tail of a Chain.

Syntax reference

```
type: UniquePath
strategy: <conflict resolution>
condition: <SpEL expression>
```

Examples

The following example concatenates the file that was originally named `DEPLOYMENT.md` to the file `README.md`:

```
chain:
  - merge:
      - include: ['README.md']
      - include: ['DEPLOYMENT.md']
        chain:
          - type: RewritePath
            rewriteTo: "'README.md'"
  - type: UniquePath
    strategy: Append
```

See also

- `UniquePath` uses a Conflict Resolution strategy to decide what to do when several input files use the same `path`.
- Combo implicitly embeds a `UniquePath` after the Merge defined by its `merge` property.

Conflict resolution

This topic tells you how to resolve conflicts that Application Accelerator transforms in Tanzu Application Platform (commonly known as TAP) might produce.

For example, if you're using Merge (or Combo's `merge` syntax) or RewritePath, a transform can produce several files at the same `path`. The engine then must take an action: Should it keep the last file? Report an error? Concatenate the files together?

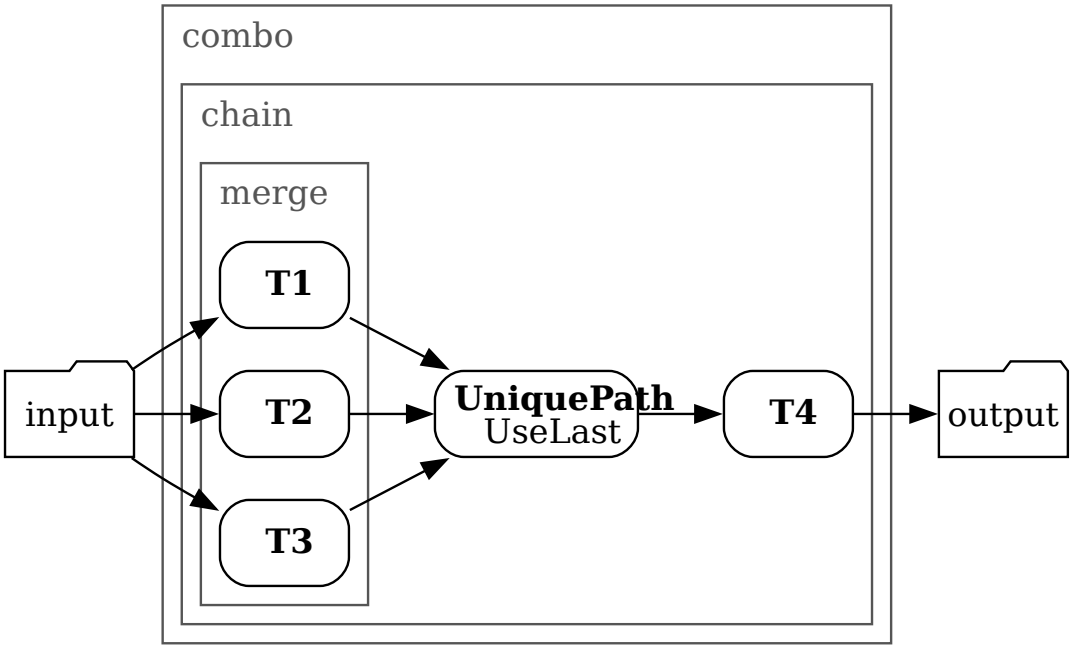
Syntax reference

Conflicts can arise for a number of reasons. You can avoid or resolve them by configuring transforms with a conflict resolution. For example:

- Combo uses UseLast by default, but you can configure it to do otherwise.
- You can explicitly end a transform Chain with a UniquePath, which by default uses Fail. This is customizable.

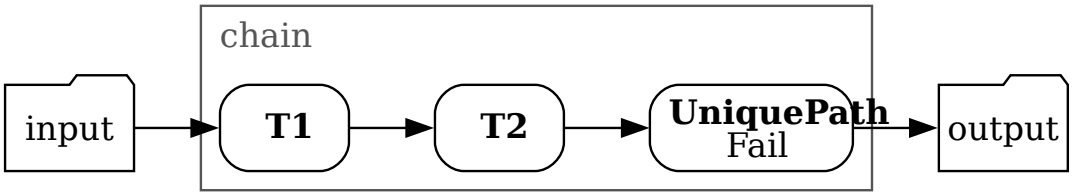
Combo

```
type: Combo      # often omitted
merge:
  - <transform>
  - <transform>
  - <transform>
chain:
  - <transform>
  - ...
onConflict: <conflict resolution>  # defaults to 'UseLast'
```



Chain

```
type: Chain      # or implicitly using Combo
transformations:
  - <transform>
  - <transform>
  - type: UniquePath
    strategy: <conflict resolution>  # defaults to 'Fail'
```



Available strategies

The following values and behaviors are available:

- `Fail`: Stop processing on the first file that exhibits `path` conflicts.
- `UseFirst`: For each conflicting file, the file produced first (typically by a transform appearing earlier in the YAML definition) is retained.
- `UseLast`: For each conflicting file, the file produced last (typically by a transform appearing later in the YAML definition) is retained.
- `Append`: The conflicting versions of files are concatenated (as if using `cat file1 file2 ...`), with files produced first appearing first.
- `FavorOwn`: Only makes sense in the context of composition. Selects the version of the file that comes from the current executing fragment if possible, falls back to the caller version otherwise.
- `FavorForeign`: Only makes sense in the context of composition. Selects the version of the file that was provided by the caller if present, falls back to the file originating from this fragment's fileset otherwise.
- `NWayDiff`: Try to merge the conflicting resources by applying patches computed against a common ancestor. The resulting resource has the attributes of the first conflicting resource.

See also

- Combo
- UniquePath

Provenance transform

This topic tells you about the Application Accelerator `Provenance` transform in Tanzu Application Platform (commonly known as TAP).

The `Provenance` transform is a special transform used to generate a file that provides details of the accelerator engine transform.

Syntax reference

```
type: Provenance
condition: <SpEL expression>
```

The `Provenance` transform is added as a child to the top-most transform, which is usually a `Merge` or a `Chain`, using a `Combo`.

Behavior

The `Provenance` transform ignores its input and outputs a single resource named `accelerator-info.yaml`. For example:

```
id: <unique GUID of invocation>
timestamp: <timestamp in RFC3339 format>
username: <captured username of user triggering the run>
source: <client environment from which accelerator was run>
accelerator:
  name: <name of registered accelerator>
  git:
```

```
    url: <git repository location>
    ref:
      branch: <branch name> or
      tag: <tag name> or
      commit: <specific requested commit>
    subPath: <optional subpath inside the repo>
    commit: <actual SHA the branch or tag pointed to>
fragments:
  - name: <name of registered fragment 1>
    git:
      url: <git repository location>
      ref:
        branch: <branch name> or
        tag: <tag name> or
        commit: <specific requested commit>
      subPath: <optional subpath inside the repo>
      commit: <actual SHA the branch or tag pointed to>
  - name: <name of registered fragment 2>
    git:
      url: <git repository location>
      ref:
        branch: <branch name> or
        tag: <tag name> or
        commit: <specific requested commit>
      subPath: <optional subpath inside the repo>
      commit: <actual SHA the branch or tag pointed to>
  - ...
options:
  - name: <option name>
    value: <option value>
  - name: <option name>
    value: <option value>
```

Note

Depending on the invocation scenario, some pieces of data might not be present.

Use SpEL with Application Accelerator

This topic tells you about some common Spring Expression Language (SpEL) use cases for the `accelerator.yaml` file in Application Accelerator.

For more information, see Spring Expression Language documentation.

Variables

You can reference all the values added as options in the `accelerator` section from the YAML file as variables in the `engine` section. You can access the value using the syntax `#<option name>`:

```
options:
  - name: foo
    dataType: string
    inputType: text
...
engine:
  - include: ["some/file.txt"]
    chain:
    - type: ReplaceText
      substitutions:
```

```
      - text: bar
        with: "#foo"
```

This sample replaces every occurrence of the text `bar` in the file `some/file.txt` with the contents of the `foo` option.

Implicit variables

Some variables are made available to the model by the engine, including:

- `artifactId` is a built-in value derived from the `projectName` passed in from the UI with spaces replaced by "_". If that value is empty, it is set to `app`.
- `files` is a helper object that currently exposes the `contentsOf(<path>)` method. For more information, see ReplaceText.
- `camel2Kebab` and other variations of the form `xxx2Yyyy` is a series of helper functions for dealing with changing case of words. For more information, see ReplaceText.

Conditionals

You can use Boolean options for conditionals in your transformations.

```
options:
  - name: numbers
    inputType: select
    choices:
    - text: First Option
      value: first
    - text: Seconf Option
      value: second
    defaultValue: first
...
engine:
  - include: ["some/file.txt"]
    condition: "#numbers == 'first'"
    chain:
    - type: ReplaceText
      substitutions:
      - text: bar
        with: "#foo"
```

This replaces the text only if the selected option is the first one.

Rewrite path concatenation

```
options:
  - name: renameTo
    dataType: string
    inputType: text
...
engine:
  - include: ["some/file.txt"]
    chain:
    - type: RewritePath
      rewriteTo: "'somewhere/' + #renameTo + '.txt'"
```

Regular expressions

Regular expressions allow you to use patterns as a matcher for strings. Here is a small example of what you can do with them:

```
options:
  - name: foo
    dataType: string
    inputType: text
    defaultValue: abcZ123
...
engine:
  - include: ["some/file.txt"]
    condition: "#foo.matches('[a-z]+Z\d+')"
    chain:
    - type: ReplaceText
      substitutions:
      - text: bar
        with: "#foo"
```

This example uses RegEx to match a string of letters that ends with a capital Z and any number of digits. If this condition is fulfilled, the text is replaced in the file, `file.txt`.

Dealing with string arrays

Options with a `dataType` of `[string]` come out as an array of strings.

To use them and for example format the result as a bulleted list, you can use the Java static String.join() method. For example:

```
accelerator:
  options:
    - name: meals
      dataType: [string]
      inputType: checkbox
      choices:
        - value: fish
        - value: chips
        - value: BLT
...
engine:
  type: ReplaceText
  substitutions:
  - text: recipe
    with: "' * ' + T(java.lang.String).join('\n * ', #meals)"
```

Accelerator custom resource definition

This topic tells you about the Application Accelerator custom resource definition.

Overview

The `Accelerator` custom resource definition (CRD) defines any accelerator resources to be made available to the Application Accelerator for VMware Tanzu system. It is a namespaced CRD, meaning that any resources created belong to a namespace. For the resource to be available to the Application Accelerator system, it must be created in the namespace that the Application Accelerator UI server is configured to watch.

The `Fragment` custom resource definition (CRD) defines any accelerator fragment resources to be made available to the Application Accelerator for VMware Tanzu system. It is a namespaced CRD, meaning that any resources created belong to a namespace. For the resource to be available to

the Application Accelerator system, it must be created in the namespace that the Application Accelerator UI server is configured to watch.

API definitions

The `Accelerator` CRD is defined with the following properties:

Property	Value
Name	Accelerator
Group	accelerator.apps.tanzu.vmware.com
Version	v1alpha1
ShortName	acc

Accelerator CRD Spec

The `Accelerator` CRD *spec* defined in the `AcceleratorSpec` type has the following fields:

Field	Description	Required/Optional
displayName	A short descriptive name used for an Accelerator.	Optional (*)
description	A longer description of an Accelerator.	Optional (*)
iconUrl	A URL for an image to represent the Accelerator in a UI.	Optional (*)
tags	An array of strings defining attributes of the Accelerator that can be used in a search.	Optional (*)
git	Defines the accelerator source Git repository.	Optional (***)
git.url	The repository URL, can be a HTTP/S or SSH address.	Optional (***)
git.gitImplementation	Determines which git client library to use. The default setting is to go-git. Valid values are (‘go-git’).	Optional (**)
git.ignore	Overrides the set of excluded patterns in the .sourceignore format (which is the same as .gitignore). If not provided, a default of `.git/` is used.	Optional (**)
git.interval	The interval at which to inquire for repository updates. If not provided the default setting is 10 minuets. There is an additional refresh interval (currently 10s) involved before accelerators can appear in the UI. There might be a 10s delay before changes are reflected in the UI.*	Optional (**)
git.ref	Git reference to checkout and monitor for changes, the default is main branch.	Optional (**)
git.ref.branch	The Git branch to checkout, the default is main.	Optional (**)
git.ref.commit	The Git commit SHA to checkout, if specified tag filters are ignored.	Optional (**)
git.ref.semver	The Git tag semver expression, takes precedence over tag.	Optional (**)
git.ref.tag	The Git tag to checkout, takes precedence over branch.	Optional (**)
git.secretRef	The secret name containing the Git credentials. For HTTPS repositories, the secret must contain user name and password fields. For SSH repositories, the secret must contain identity, identity.pub, and known_hosts fields.	Optional (**)
git.subPath	SubPath is the folder inside the git repository to consider as the root of the accelerator or fragment. Defaults at the root of the repository.	Optional

Field	Description	Required/Optional
source	Defines the source image repository.	Optional (***)
source.image	Image is a reference to an image in a remote registry.	Optional (***)
source.imagePullSecrets	ImagePullSecrets contains the names of the Kubernetes Secrets containing registry login information to resolve image metadata	Optional
source.interval	The interval at which to check for repository updates.	Optional
source.serviceAccountName	ServiceAccountName is the name of the Kubernetes ServiceAccount used to authenticate the image pull if the service account has attached pull secrets	Optional

The `Fragment` CRD is defined with the following properties:

Property	Value
Name	Fragment
Group	accelerator.apps.tanzu.vmware.com
Version	v1alpha1
ShortName	frag

Fragment CRD Spec

The `Fragment` CRD *spec* defined in the `FragmentSpec` type has the following fields:

Field	Description	Required/Optional
displayName	DisplayName is a short descriptive name used for a Fragment.	Optional
git	Defines the fragment source Git repository.	Required
git.url	The repository URL, can be a HTTP/S or SSH address.	Required
git.gitImplementation	Determines which git client library to use. The default setting is to go-git. Valid values are ('go-git', 'libgit2'). Deprecated: gitImplementation is deprecated. go-git is the only supported implementation.	Optional (**)
git.ignore	Overrides the set of excluded patterns in the .sourceignore format (which is the same as .gitignore). If not provided, a default of `.git/` is used.	Optional (**)
git.interval	The interval at which to inquire for repository updates. If not provided the default is 10 min.	Optional (**)
git.ref	Git reference to checkout and monitor for changes, the default is main branch.	Optional (**)
git.ref.branch	The Git branch to checkout, defaults to main.	Optional (**)
git.ref.commit	The Git commit SHA to checkout, if specified tag filters are ignored.	Optional (**)
git.ref.semver	The Git tag semver expression, takes precedence over tag.	Optional (**)
git.ref.tag	The Git tag to checkout, takes precedence over branch.	Optional (**)

Field	Description	Required/Optional
git.secretRef	The secret name containing the Git credentials. For HTTPS repositories, the secret must contain user name and password fields. For SSH repositories, the secret must contain identity, identity.pub, and known_hosts fields.	Optional (**)
git.subPath	SubPath is the directory inside the Git repository to consider as the root of the accelerator or fragment. Defaults at the root of the repository.	Optional

* Any optional text boxes marked with an asterisk (*) are populated from a text box of the same name in the `accelerator` definition in the `accelerator.yaml` file if that is present in the Git repository for the accelerator.

** Any fields marked with a double asterisk (**) are part of the Flux GitRepository CRD that is documented in the Flux Source Controller Git Repositories documentation.

*** Any fields marked with a triple asterisk (`***`) are optional but either `git` or `source` is required to specify the repository to use. If `git` is specified, the `git.url` is required, and if `source` is specified, `source.image` is required.

Excluding files

The `git.ignore` field defaults to `.git/`, which is different from the defaults provided by the Flux Source Controller GitRepository implementation. You can override this, and provide your own exclusions. For more information, see fluxcd/source-controller Excluding files.

Use a local Application Accelerator engine server

This topic tells you how to run a local Application Accelerator engine server that you can use for testing accelerators that you are authoring.

About running a local engine server

When you are authoring your accelerator, it might be convenient to generate a project based on the local files. This enables you to verify that the accelerator provides the defined options and generates the correct set of files.

With the local engine server, you can serve your accelerators with their fragments on `localhost`, including any changes you have locally. You can use the Visual Studio Code (VS Code) Tanzu App Accelerator extension or the Tanzu CLI Accelerator plug-in to generate new projects based on these local files. After you are satisfied with the new or modified accelerators and fragments, you can commit them to a Git repository and then publish them to a cluster to give others access.

Install the local engine server

To install the local engine server:

1. Sign in to VMware Tanzu Network.
2. Go to the Tanzu Application Platform product page.
3. Select your Tanzu Application Platform version from the release drop-down menu.
4. From the list of resources, select the file group named `Application Accelerator Engine Server-v1.9.0`. It contains four different ZIP archives, `macos-aarch64`, `macos-amd64`, `windows`, and `linux`. Download the ZIP file for your operating system and architecture.

   The ZIP file contains the local engine server and a Java runtime for running the server.

5. Extract the ZIP file to a local directory by using the `unzip` command or any other extraction tool.
6. For macOS users, you must give permission to open an app from an unidentified developer:
    1. In the Finder on your Mac, locate the directory where you extracted the downloaded ZIP file and expand the `acc-engine` directory.
    2. Control-open the following files:
        - Control-click `acc-engine/app/bin/ytt` and then click **Open**. This runs it in a terminal that you can close.
        - Control-click `acc-engine/app/bin/java` and then click **Open**. This runs it in a terminal that you can close.

    The app files you control-opened are saved as exceptions to your security settings. You can now run them without getting a verification message.

    > **Note**
    >
    > VMware plans to have these artifacts signed using an Apple developer account to avoid these extra steps.

7. Open a terminal window and change directory to `acc-engine` located inside the directory where you extracted the ZIP file.
8. Set an environment variable named `ACC_LOCAL_FILES` that points to a directory that contains the fragments and accelerators you want to use with the local engine server. There must be a directory named `accelerators` and one named `fragments`. Under these directories, you can provide your local accelerators and fragments. For example:

    ```
    workspace
    ├── accelerators
    │   └── hello-world
    │       ├── accelerator.yaml
    │       ├── ...
    └── fragments
        ├── build-wrapper-maven
        │   ├── accelerator.yaml
        │   ├── ...
        ├── java-version
        │   ├── accelerator.yaml
        │   ├── ...
    ```

    For more examples, see application-accelerator-samples in GitHub.

    - **For macOS and Linux:** Set the environment variable, for example:

        ```
        $ export ACC_LOCAL_FILES="$HOME/workspace"
        ```

    - **For Windows Powershell:** Set the environment variable, for example:

        ```
        $ $Env:ACC_LOCAL_FILES="$HOME\workspace"
        ```

Use the local engine server to generate projects

To use the local engine server:

1. Start the local engine server by running the `engine` script from the terminal:

```
./engine
```

2. The latest versions of the VS Code Tanzu App Accelerator extension, Tanzu Application Accelerator plug-in for IntelliJ, and the Tanzu CLI Accelerator plug-in have settings to use the local engine server instead of the regular cluster endpoints.

    - **For the VS Code Tanzu App Accelerator extension:**

      Under **Settings** > **Extensions** > **Tanzu Application Accelerator**, select the **Use Local Server instead of Developer Portal** check box.

      The extension can then show accelerators from the local engine server that you started. Use them in the same way that you use accelerators loaded from Tanzu Developer Portal. For more information, see Use the extension.

    - **For the Tanzu Application Accelerator plug-in for IntelliJ:**

      Under **IntelliJ IDEA** > **Preferences** > **Tools** > **Tanzu Application Accelerator**, select the **Use Local Server instead of Developer Portal** check box.

      The plug-in can then show accelerators from the local engine server that you started. Use them in the same way that you use accelerators loaded from Tanzu Developer Portal. For more information, see Use the plug-in.

    - **For the Tanzu CLI Accelerator plug-in:**

      For the `list`, `get`, and `generate` commands, use the `--local-server` flag instead of `--server-url`.

Test accelerators in Application Accelerator

This topic tells you how to test an updated accelerator, or fragment that is not registered in your Tanzu Application Platform (commonly known as TAP) cluster.

Generating a project from local sources

When you are authoring your accelerator, you can test it before committing any changes.

With the `tanzu accelerator generate-from-local` command, you can run your accelerator (or fragment), including any changes you have locally, specify a set of options and view the generated project.

You can run the accelerator using the components on your Tanzu Application Platform cluster, without impacting the state of the Tanzu Application Platform cluster.

To do so, ensure that you have the following prerequisites:

- The Tanzu CLI is installed, with the Application Accelerator plug-in. For details about installing the Tanzu CLI and plug-ins, see Tanzu CLI.
- The server URL is pointing to the Tanzu Application Platform cluster you want to test with. For details about setting the server URL, see Application Accelerator CLI plug-in overview.

For example, to use the accelerator that is located at the path `workspace/java-rest`:

```
tanzu accelerator generate-from-local --accelerator-path java-rest=workspace/java-rest
--fragment-names tap-workload,java-version --options '{"projectName":"test"}' --output
-dir generated-project
```

This generates the project in the local directory `generated-project`, using the accelerator located at `workspace/java-rest`, the fragments `tap-workload` and `java-version` which are assumed to be already registered in the Tanzu Application Platform cluster and the option `projectName` set to `test`.

For example, to use the fragment named `java-version` that is located at the path `workspace/version`:

```
tanzu accelerator generate-from-local --accelerator-name java-rest --fragment-paths ja
va-version=workspace/version --fragment-names tap-workload --options '{"projectNam
e":"test"}' --output-dir generated-project
```

This generates the project in the local directory `generated-project`, using the accelerator `java-rest` and the fragment `tap-workload` which are assumed to be already registered in the Tanzu Application Platform cluster, the fragment named `java-version` located at `workspace/version`, and the option `projectName` set to `test`.

For more information about the `generate-from-local` command, see the Tanzu CLI Command Reference documentation.

No changes are made to the Tanzu Application Platform cluster that is provided with the server URL. No new accelerators/fragments are registered or modified. A Tanzu Application Platform cluster is required to ensure that there is consistency between the version that is used for testing and the version that is used when the accelerator is registered. Furthermore, it allows using registered fragments and accelerators as dependencies for the local accelerator/fragment.

CI/CD Pipeline

As you iterate on an accelerator, you can have some automated assertions run before any changes to the accelerator are accepted.

The process for generating a project from the committed source files is the same as described earlier.

When the generated project is available, you can run various assertions on it:

```
cd generated-project
test -f build.gradle
./gradlew test
```

If you have multiple assertions, you might choose to run a predefined script:

```
cd generated-project
../assertions/validate-generate-project.sh
```

You might choose to generate multiple projects from the same accelerator, providing different options for each and running different assertions on each generated project.

(Optional) Getting the Tanzu CLI in a CI/CD pipeline

If the Tanzu CLI is already available in your CI/CD pipeline you can skip this section.

VMware provides an example script that is agnostic to the CI/CD system it is running on. The script requires a variable named `TANZU_REFRESH_TOKEN` which holds a personal VMware Tanzu Network refresh token. To generate such a token see How to Authenticate. The script also uses `curl` and `jq`.

The script downloads artifacts compatible with Tanzu Application Platform version v1.4 and a Linux operating system. Update the script to suit the Tanzu Application Platform version and OS that you are using.

```
#!/bin/bash

# Get access token using personal Tanzu Network refresh token
# See https://network.tanzu.vmware.com/docs/api#how-to-authenticate
```

```
ACCESS_TOKEN=$(curl -X POST https://network.tanzu.vmware.com/api/v2/authentication/acc
ess_tokens -d '{"refresh_token":"'"$TANZU_REFRESH_TOKEN"'"}' | jq -r ".access_token")

# Download bundle
# See https://docs.vmware.com/en/VMware-Tanzu-Application-Platform/1.7/tap/install-tan
zu-cli.html#cli-and-plugin
# Update url to download desired version
mkdir -p $HOME/tanzu
curl -L -X GET https://network.tanzu.vmware.com/api/v2/products/tanzu-application-plat
form/releases/1205491/product_files/1352407/download -H "Authorization: Bearer $ACCESS
_TOKEN" --output bundle.tar

# Unpack bundle
export TANZU_CLI_NO_INIT=true
export VERSION=v0.25.0 # Update to desired version
tar -xvf bundle.tar -C $HOME/tanzu
cd $HOME/tanzu

# Install CLI
# Update to use desired OS
sudo install cli/core/$VERSION/tanzu-core-linux_amd64 /usr/local/bin/tanzu

# Install plugins
tanzu plugin install --local cli accelerator
```

Track life cycle using Provenance transform

This topic tells you about the Application Accelerator `Provenance` transform in Tanzu Application Platform, commonly known as TAP.

Overview

Use the `Provenance` transform to track the life cycle of generated projects.

The `Provenance` transform generates a file that provides details of the accelerator engine transform.

The `Provenance` transform provides traceability and visibility for the generation of an application from an accelerator. The following information is embedded into a file that is part of the generated project:

- Which accelerator was used to bootstrap the project
- Which version of the accelerator was used
- When the application was bootstrapped
- Who bootstrapped the application

For more information about the structure of the file and how to enable application bootstrapping provenance, see Provenance transform.

Integration with AMR

Application Accelerator integrates with Artifact Metadata Repository (AMR).

When you generate an application with an accelerator, an event that contains the same information captured by the `Provenance` transform is sent to the AMR store. The relevant data saved to AMR is `AppAcceleratorRuns` (alpha) and `AppAcceleratorFragments` (alpha).

AppAcceleratorRuns (alpha)

The `AppAcceleratorRuns` data model represents a generation of a project from an accelerator. An `accelerator.yaml` file in the repository declares input options for the accelerator. This file contains instructions for processing the files when you generate a new project. This information is sent to the CloudEvent Handler to store `AppAcceleratorRuns`.

There is one `AppAcceleratorRuns` for each invocation of an accelerator, including version information about which accelerator was used. Each `AppAcceleratorRuns` data entry has a unique `guid`. The `AppAcceleratorRuns` data entry contains information about the Git repository including, `AppAcceleratorRepoURL`, `AppAcceleratorRevision`, and `AppAcceleratorSubpath`. Multiple `AppAcceleratorFragments` entries can point to the same `AppAcceleratorRuns` entry. `AppAcceleratorRuns` are associated with one `AppAcceleratorSource`, also known as `Commit`.

AppAcceleratorFragments (alpha)

The `AppAcceleratorFragments` Accelerator fragments are reusable accelerator components that can provide options, files, or transforms. You can import accelerators using an `import` entry. An `InvokeFragment` transform references the transforms from the fragment in the accelerator that declares the import. The `AppAcceleratorFragments` data model represents the information of a fragment in the accelerator app. The Observer sends this information to the Cloud Event Handler to store `AppAcceleratorFragments`.

Each `AppAcceleratorFragment` data entry stores information about source Git repository: `AppAcceleratorFragmentSourceRepoURL`, `AppAcceleratorFragmentSourceRevision`, and `AppAcceleratorFragmentSourceSubpath`. You can associate an `AppAcceleratorFragment` to an `AppAcceleratorRuns`. You can point a `AppAcceleratorFragmentSource` (also known as `Commit`) to one `AppAcceleratorFragment`.

There is one instance of AppAcceleratorFragment for each named fragment used by the running accelerator.

Querying the data

When invocations are recorded, use the GraphQL capability to query the system about accelerator use and gain insights about generated applications. For more information, see Run query with GraphQL

For more information about how to use the Artifact Metadata Repository, and some sample queries relevant to `AppAcceleratorRuns`, see the Artifact Metadata Repository.

Use the Application Accelerator Visual Studio Code extension

This topic describes how to use the Application Accelerator Visual Studio Code extension to explore and generate projects from the defined accelerators in Tanzu Application Platform (commonly known as TAP) using VS Code.

The Application Accelerator Visual Studio Code extension lets you explore and generate projects from the defined accelerators in Tanzu Application Platform using VS Code.

Dependencies

- To use the VS Code extension, the extension must access the Tanzu Developer Portal URL. For information about how to retrieve the Tanzu Developer Portal URL, see Retrieving the URL for the Tanzu Developer Portal.
- (Optionally) To use Git repository provisioning during project creation in the VS Code extension, you must enable GitHub repository creation in the Application Accelerator plug-

in. For more information, see Create an Application Accelerator Git repository during project creation.

Install the extension

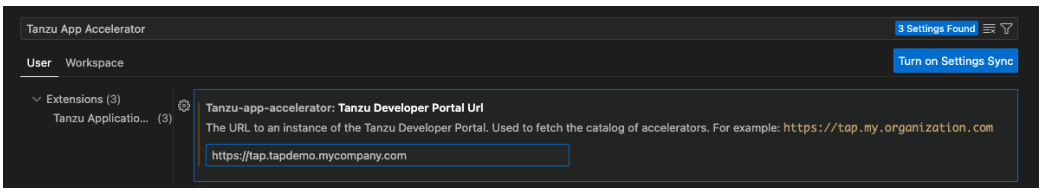
Use the following steps to install the Application Accelerator Visual Studio Code extension:

1. Open Visual Studio Code.
2. Open the command palette and enter `Extensions`.
3. Click **Extensions: Install Extensions**.
4. The **Extensions** view opens on the left side of your screen. In the search box, enter `Tanzu`.
5. Click **Tanzu App Accelerator**.
6. Click **Install**.

Configure the extension

Before using the extension, you need follow the next steps:

1. Go to VS Code settings - click **Code > Preferences > Settings > Extensions > Tanzu App Accelerator**.
2. Look for the setting `Tap Gui Url`.
3. Add the Tanzu Application Platform GUI URL.



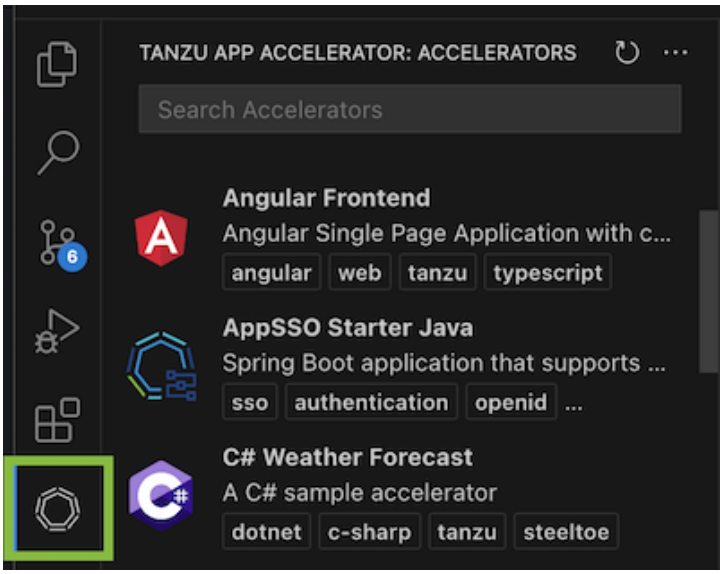
An example URL: `https://tap-gui.myclusterdomain.myorg.com`. If you have access to the Tanzu Application Platform cluster that is running the Tanzu Developer Portal, you can run the following command to determine the fully-qualified domain name:

```
kubectl get httpproxy tap-gui -n tap-gui
```

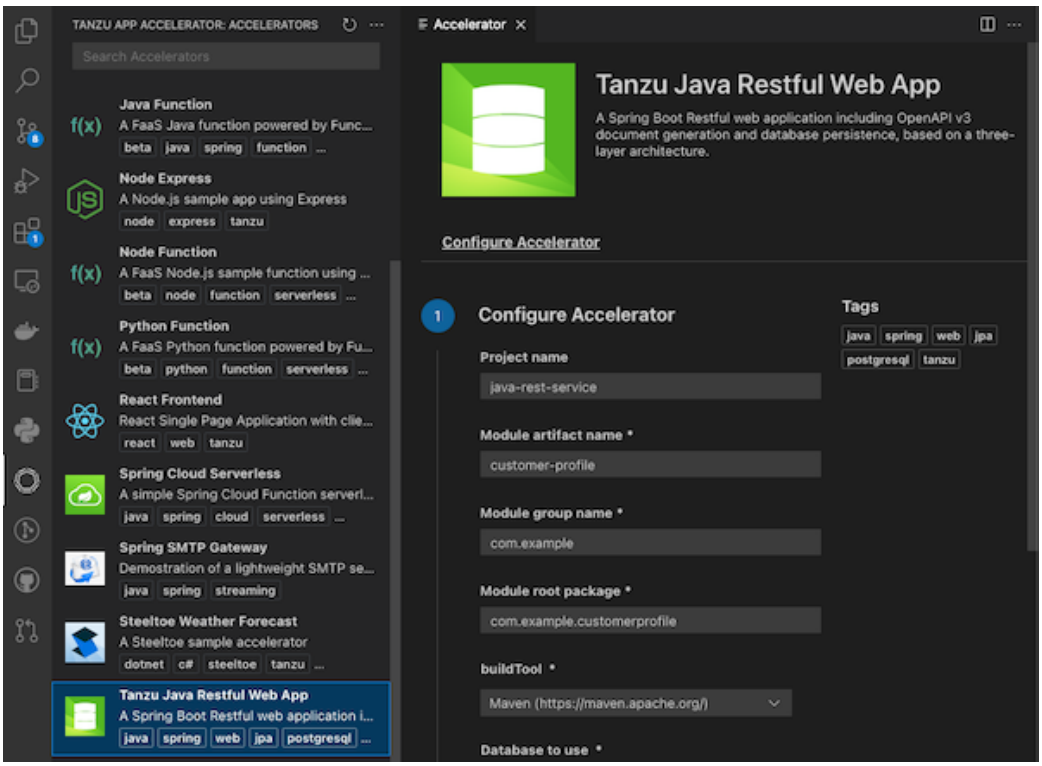
Use the extension

To use the VS Code extension:

1. Click the Tanzu Application Accelerator extension icon in the Activity Bar to explore the defined accelerators.



2. Choose any of the defined accelerators, fill in the options under **Configure Accelerator**, and click **Next**.



3. Review your settings and click **Generate Project**.

Retrieve the URL for the Tanzu Developer Portal

If you have access to the Tanzu Application Platform cluster that is running Tanzu Developer Portal, run the following command to determine the fully-qualified domain name:

```
kubectl get httpproxy tap-gui -n tap-gui
```

Example output:

```
NAME      FQDN                                    TLS SECRET     STATUS   STATUS DES
CRIPTION
```

```
tap-gui   tap-gui.tap.tapdemo.myorg.com             tap-gui-cert   valid    Valid HTTP
Proxy
```

Download and install self-signed certificates from the Tanzu Developer Portal

To enable the Application Accelerator extension for VS Code to communicate with a Tanzu Developer Portal instance that is secured using TLS, you must download and install the certificates locally.

Prerequisites

yq is required to process the YAML output.

Procedure

1. Find the name of the Tanzu Developer Portal certificate. The name of the certificate might look different to the following example.

   ```
   kubectl get secret -n cert-manager
   ```

   ```
   NAME                                          TYPE
   DATA   AGE
   canonical-registry-secret                     kubernetes.io/dockerconfigjson
   1      18d
   cert-manager-webhook-ca                       Opaque
   3      18d
   postgres-operator-ca-certificate              kubernetes.io/tls
   3      18d
   tanzu-sql-with-mysql-operator-ca-certificate  kubernetes.io/tls
   3      18d
   tap-ingress-selfsigned-root-ca                kubernetes.io/tls
   3      18d <------- This is the certificate that is needed
   ```

2. Download the certificate:

   ```
   kubectl get secret -n cert-manager tap-ingress-selfsigned-root-ca -o yaml | yq
   '.data."ca.crt"' | base64 -d > ca.crt
   ```

3. Install the certificate on your local system and fully restart any applications that uses the certificate. After restarting, the application uses the certificate to communicate with the endpoints using TLS. For more information, see Installing a root CA certificate in the trust store in the Ubuntu documentation.

   macOS
   Run:

   ```
   sudo security add-trusted-cert -d -r trustRoot -k /Library/Keychains/System.k
   eychain ca.crt
   ```

   Windows
   Complete the following steps:

   1. Use Windows Explorer to navigate to the directory where the certificate was downloaded and click on the certificate.
   2. In the Certificate window, click **Install Certificate...**.
   3. Change the **Store Location** from **Current User** to **Local Machine**. Click **Next**.

4. Select **Place all certificates in the following store**, click **Browse**, and select **Trusted Root Certification Authorities**
5. Click **Finish**.
6. A pop-up window stating **The import was successful.** is displayed.

Use the Application Accelerator IntelliJ plug-in

This topic tells you about the Application Accelerator IntelliJ plug-in. The plug-in is used to explore and generate projects from the defined accelerators in Tanzu Application Platform (commonly called TAP) using IntelliJ.

Dependencies

The plug-in must have access to the Tanzu Developer Portal URL. For information about how to retrieve the Tanzu Developer Portal URL, see Retrieving the URL for the Tanzu Developer Portal later in this topic.

Install the plug-in

The VMware Tanzu Application Accelerator plug-in for IntelliJ is available from the JetBrains Marketplace.

To install the plug-in from the JetBrains Marketplace:

1. Open IntelliJ.
2. Open the command palette, enter `Plugins`, and click **Plugins**.
3. Select the **Marketplace** tab in the **Plugins Settings** dialog box.
4. In the search box, enter `Tanzu`.
5. Click **Tanzu Application Accelerator** then click **Install**.

Update the plug-in

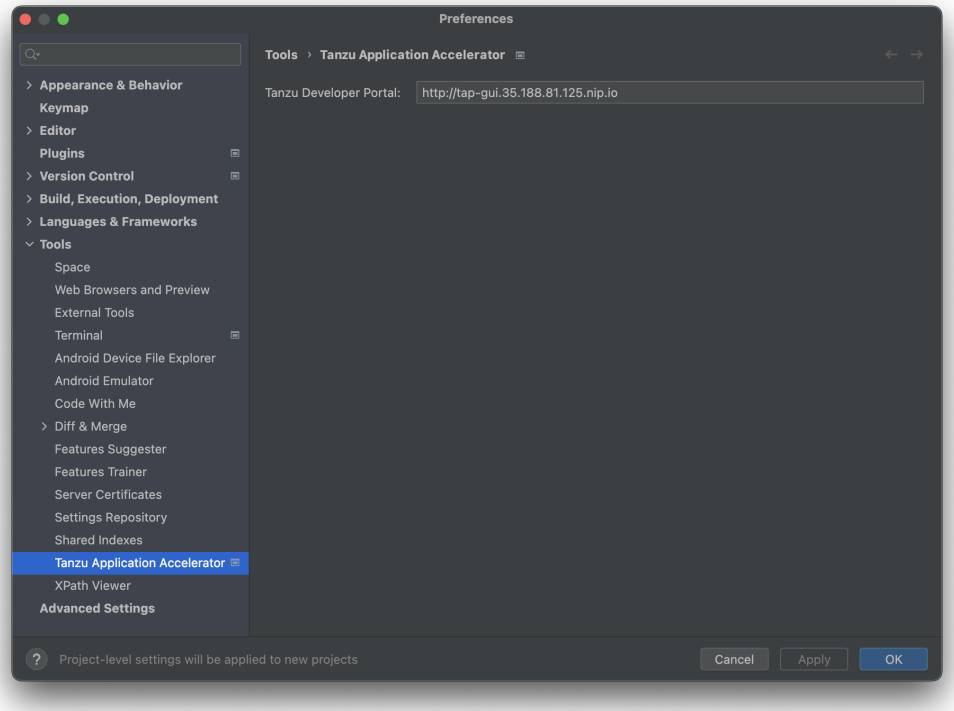
To update to a later version, repeat the steps in Install the plug-in. You do not need to uninstall your current version.

Configure the plug-in

Before using the plug-in, you must enter the Tanzu Developer Portal URL in the IntelliJ Preferences:

1. Go to the IntelliJ menu, select **IntelliJ IDEA > Preferences** > **Tools** > **Tanzu Application Accelerator**.
2. Add the Tanzu Developer Portal URL. For example, `https://tap-gui.myclusterdomain.myorg.com`. If you have access to the Tanzu Application Platform cluster that is running the Tanzu Developer Portal, run the following command to determine the fully-qualified domain name:

```
kubectl get httpproxy tap-gui -n tap-gui
```

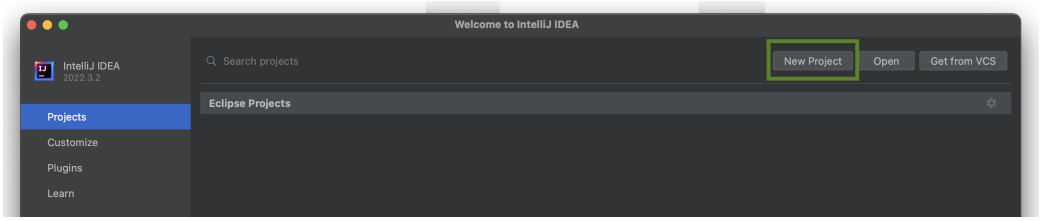


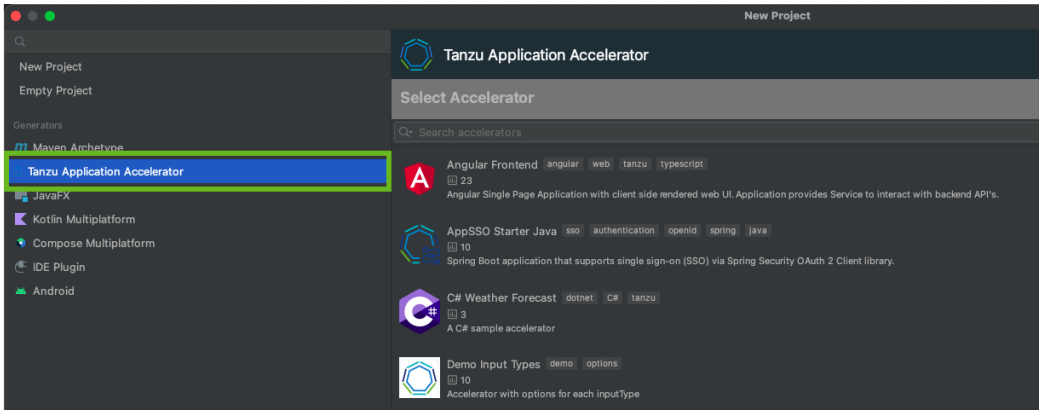
3. Click **Apply** and **OK**.

Use the plug-in

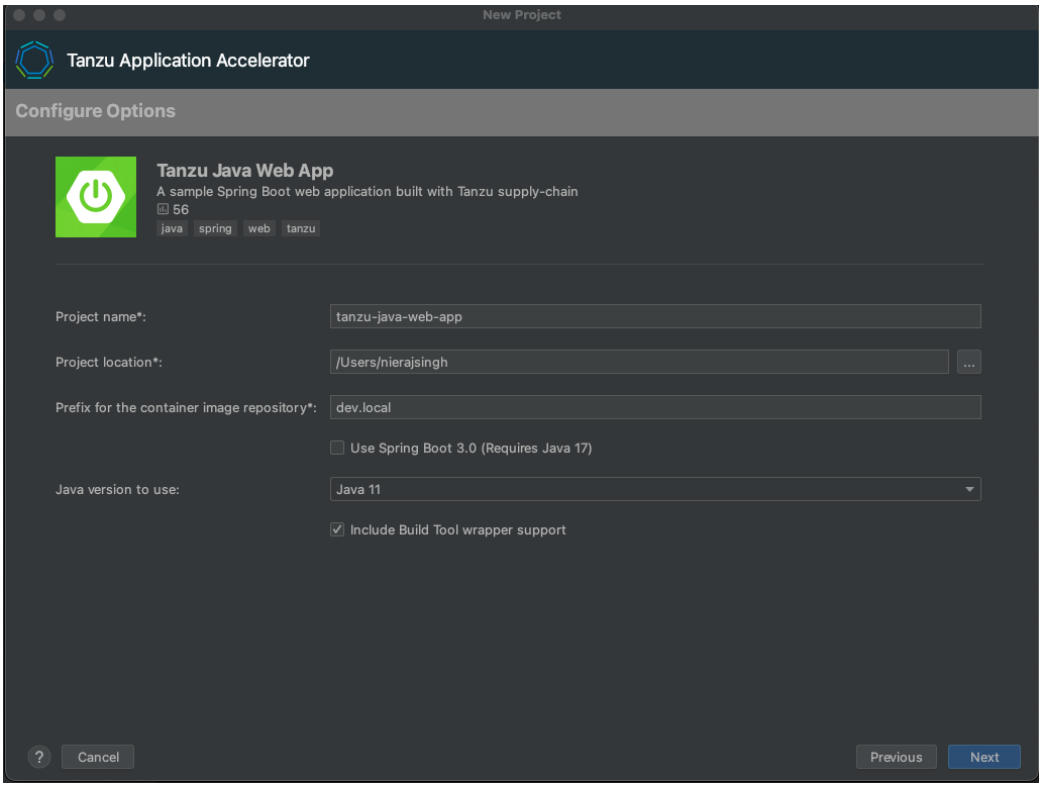
To use the IntelliJ plug-in:

1. To explore the defined accelerators, select **New Project**, then select **Tanzu Application Accelerator**.

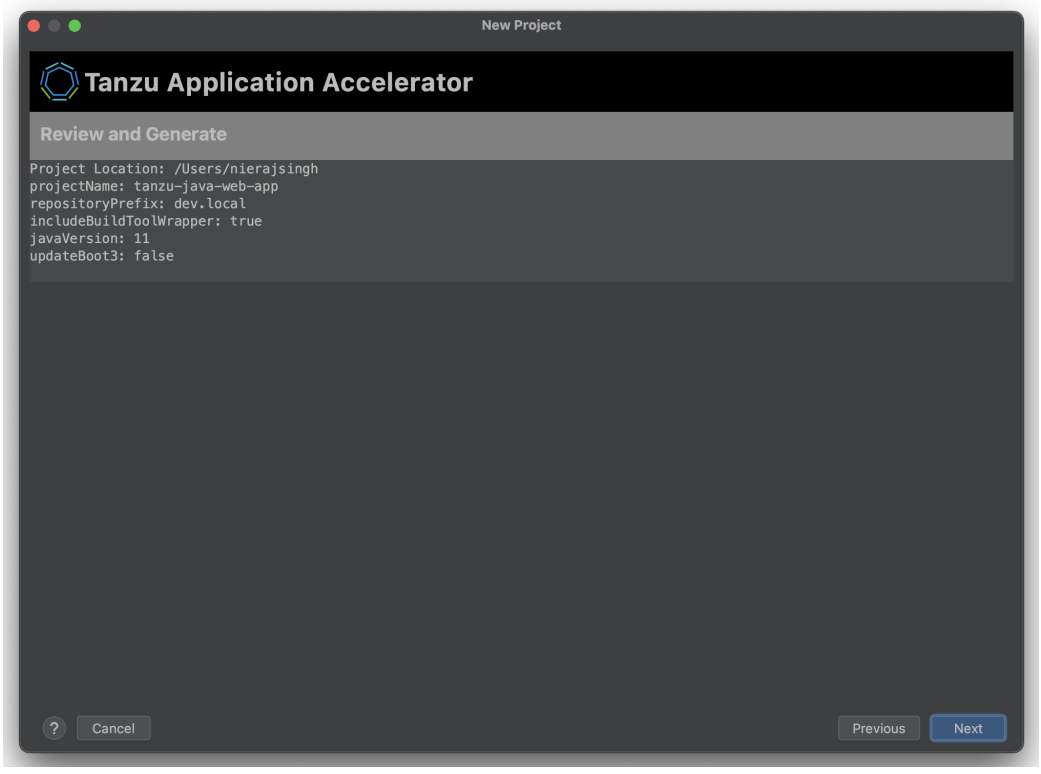




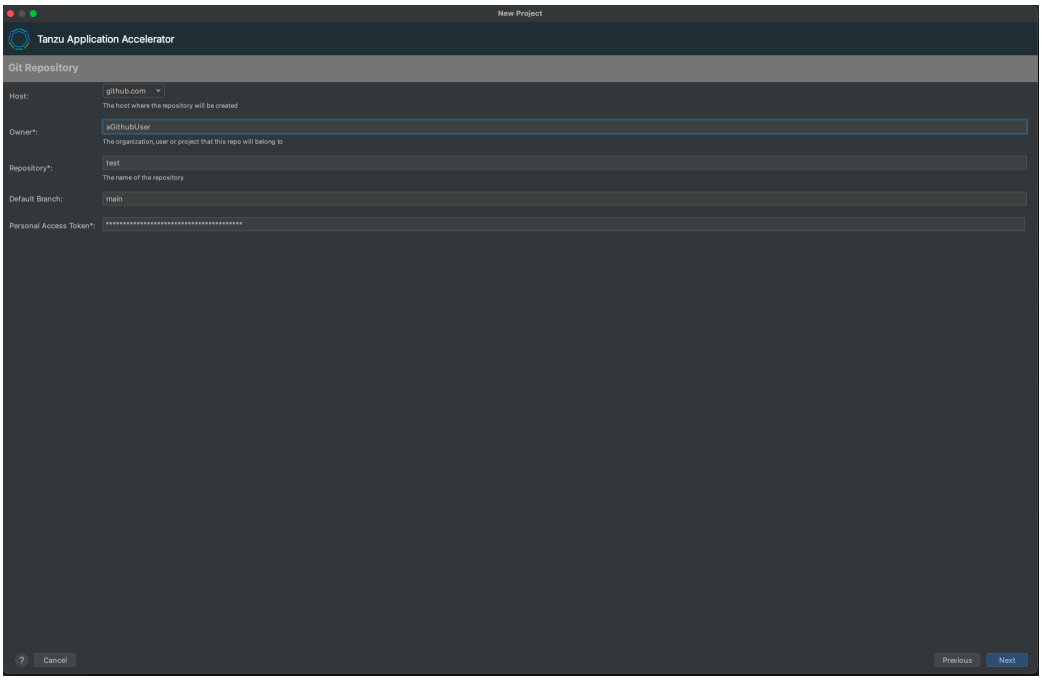
2. Choose one of the defined accelerators and configure the options.



3. Click `Next` to go to the optional step `create git repository`.



4. Fill the fields required to create the Git repository, a personal access token from the Git provider is required, this will be stored in a secured location for future use, click `Next` to go to the review step.



Note: This is an optional step, the values can be left blank if a repository isn't required.

5. Click `Next` to download the project. If the project is downloaded successfully, the `Create` button is enabled and you can now create and open the project.

Retrieving the URL for the Tanzu Developer Portal

If you have access to the Tanzu Application Platform cluster that is running the Tanzu Application Platform GUI, run the following command to determine the fully-qualified domain name:

```
kubectl get httpproxy tap-gui -n tap-gui
```

The result is similar to:

```
NAME      FQDN                                  TLS SECRET     STATUS   STATUS DES
CRIPTION
tap-gui   tap-gui.tap.tapdemo.myorg.com         tap-gui-cert   valid    Valid HTTP
Proxy
```

Download and Install Self-Signed Certificates

To enable communication between the Application Accelerator plug-in and a Tanzu Application Platform GUI instance that is secured using TLS, you must download and install the certificates locally.

Prerequisites

yq is required to process the YAML output.

Procedure

1. Find the name of the Tanzu Developer Portal certificate. The name of the certificate might look different to the following example.

   ```
   kubectl get secret -n cert-manager
   ```

```
NAME                                            TYPE
DATA   AGE
canonical-registry-secret                       kubernetes.io/dockerconfigjson
1      18d
cert-manager-webhook-ca                         Opaque
3      18d
postgres-operator-ca-certificate                kubernetes.io/tls
3      18d
tanzu-sql-with-mysql-operator-ca-certificate    kubernetes.io/tls
3      18d
tap-ingress-selfsigned-root-ca                  kubernetes.io/tls
3      18d <------- This is the certificate that is needed
```

2. Download the certificate:

```
kubectl get secret -n cert-manager tap-ingress-selfsigned-root-ca -o yaml | yq
'.data."ca.crt"' | base64 -d > ca.crt
```

3. Install the certificate on your local system and restart any applications that use the certificate. After restarting, the application uses the certificate to communicate with the endpoints using TLS.

   macOS
   Run:

   ```
   sudo security add-trusted-cert -d -r trustRoot -k /Library/Keychains/System.key
   chain ca.crt
   ```

   For more information, see Installing a root CA certificate in the trust store in the Ubuntu documentation.

   Windows
   Complete the following steps:

   1. Use Windows Explorer to navigate to the directory where the certificate was downloaded and select the certificate.
   2. In the Certificate window, click **Install Certificate...**.
   3. Change the **Store Location** from **Current User** to **Local Machine**. Click **Next**.
   4. Select **Place all certificates in the following store**, click **Browse**, and select **Trusted Root Certification Authorities**
   5. Click **Finish**.
   6. A pop-up window stating **The import was successful.** is displayed.

Uninstall the plug-in

To uninstall the VMware Tanzu Application Accelerator plug-in for IntelliJ:

1. Open the **Preferences** pane and go to **Plugins**.
2. Select the extension, click the gear icon, and click **Uninstall**.
3. Restart IntelliJ.

Application Accelerator best practices

The following topics tells you about best practices for authoring accelerators and fragments.

- **Best practices for using Accelerators**

  A collection of best practices for authoring accelerators.

- **Best practices for using Fragments**

  A collection of best practices for authoring fragments.

Best practices for using accelerators

This topic tells you about the benefits, and design considerations for accelerators.

Benefits of using an accelerator

There are several good reasons to develop accelerators:

- If you're repeatedly using the same application architecture for new applications.
- To enforce standardization of technology stacks and application setups throughout your organization.
- To share best practices around application architecture, application, and test setup.

Design considerations

Each accelerator must have only one base technology stack, combined with related tooling, and one target architecture. For example, if you use both Spring Boot and C# .NET Core applications in your target environment, you must set up two separate accelerators. Mixing multiple technology stacks and multiple target architectures makes both the directory structure and acceleratory.YAML unreadable.

The scope of your accelerator must align with your different types of deployments. For example, back-end API, front-end UI, business service, and so on.

Choose OpenRewrite-based transformation over ReplaceText-based transformation when possible. OpenRewrite-based transformations understand the semantics of the files they work on, for example, Maven pom.xml or Java source files. OpenRewrite-based transformations also provide more accurate and robust modifications. As a last resort, ReplaceText supports a regex mode. When used with capturing groups in the replacement string, ReplaceText allows most modifications.

Housekeeping rules

VMware has found that the following rules keep the set of accelerators clear and findable for end users:

- Use an intuitive name and short description that reflects the accelerators purpose. The word 'accelerator' must not be in the name.
- Use an appropriate and intuitive icon.
- Use tags that reflect language, framework, and type of service. For example, database, messaging, and so on. This helps when searching for an accelerator by tags. Tag names must use lowercase letters, consist of [a-z0-9+#] separated by [-], and not exceed 63 characters.
- Accelerators must expose options to allow configuring an accelerator for different use cases instead of creating multiple similar accelerators.

- Options must be straightforward, the description of each clearly stating the role it plays in the accelerator. Options must have default values when appropriate.
- Options must be short so that they are easy to navigate. Make options conditional on other options as appropriate.
- Free text options that have limitations on their values must ensure these limitations are met by a regular expression-based validation. This validation ensures early feedback on invalid user input.
- Generated application skeletons must have a detailed README file that describes the function and structure of a generated application. It must provide detailed information about how developers can build and deploy a generated application of the accelerator and how to use it.

Tests

Application skeleton

An accelerator that generates an application skeleton without a good test suite for the different layers of the application promotes bad behavior. It could result in code running in production without testing.

Tests you could use for the application skeleton:

- An overall application test that bootstraps the application to see if it comes online.
- A test per layer of the application. For example, presentation layer, business layer, and data layer. These tests can be unit tests that leverage stubbing or mocking frameworks.
- An integration test per layer of the application, especially the presentation and data layer. For example, you can provide an integration test with some database interaction by using test containers.

Best practices for using fragments

This topic tells you about the benefits, and design considerations for fragments.

Benefits of using Fragment

A fragment is a partial accelerator. It can do the same transformations as an accelerator, but it cannot run on its own. It’s always part of the calling (host) accelerator.

Developing a fragment is useful in the following situations:

- When you must update a version of an element of a technology stack in multiple locations. For example, when the Java Development Kit (JDK) version must be updated in the build tool configuration, the buildpack configuration, and in the deployment options.
- To add a consistent cross-cutting concern to a set of accelerators. For example, logging, monitoring, or support for a certain type of deployment or framework.
- To add integration with some technology to a generated application skeleton. For example, certain database support, support for a messaging middleware, or integration with an email provider.

Design considerations

Developing and maintaining a fragment is complex. The following is a list of design considerations:

- The fragment you develop must work with all possible syntax and format variations. For example, dependency in a `Gradle` build.gradle.kts can have the following forms:
    - `implementation('org.springframework.boot:spring-boot-starter')`
    - `implementation("org.springframework.boot:spring-boot-starter")`
    - `implementation(group = "org.springframework.boot", name= "spring-boot-starter")`
    - `implementation(group = 'org.springframework.boot', name= 'spring-boot-starter')`
    - `implementation(name= "spring-boot-starter", group = "org.springframework.boot")`
- The fragment can be used in multiple accelerator contexts and its behavior must result in a compilable and deployable application skeleton.
- Testing a fragment in isolation is more difficult than testing an accelerator. Testing takes more time because all the combinations must be tested from an accelerator perspective.
- When flexibly reusing fragments in different combinations, each fragment must cover a small, cohesive function. Fragments must follow these two UNIX principles:
    - Small is beautiful.
    - Each fragment does one thing well.
- Keep the files the fragment changes to a minimum. Only change the files that are related to the same technology stack for the same purpose.
- The design of both the accelerator and fragment is limited by the technology stack and the target deployment technology chosen for the accelerator. For example, to create a fragment for standardizing logging, you must create one fragment per base technology stack.

Housekeeping rules

Fragments are used by accelerator authors. VMware has found that the following guidelines keep fragments understandable and reusable.

- Give fragments an intuitive name and short description that reflects their purpose. Do not include “fragment” in the name.
- Fragments must expose options to allow configuring the output of execution.
- Each fragment must contain a README file explaining the additional functions the fragment adds to a generated application skeleton. List any options expected by this fragment. Also describe how this fragment can be included in a host accelerator. Be sure to state any known limitations or use cases not covered. For example, if the fragment supports Maven and Gradle as build tools but only Groovy DSL of Gradle is supported, the README file must include this information.
- If a fragment must provide additional documentation to end users, it can either be added to a README-X file of the generated application skeleton or append a section to the host’s README.

Versioning

Fragments might require the use of versioning. For example, if accelerator `acc-1` imports fragment `frag`, and accelerator `acc-2` also uses fragment `frag`, then care must be taken in the contract that

the fragment exposes. Changing its behavior for the benefit of `acc-1` might break its use in `acc-2`.

To resolve this, you can track the versions of the fragment and document with numbers when there is an incompatible change. VMware recommends that you use semantic versioning to track the contract for fragments.

To give you more flexibility with version control, Application Accelerator does not manage versioning. VMware recommends that you track the semantic version of fragments in the fragment name. For example, if fragment `frag` changes its contract in a way that is not compatible with previous accelerators that use it, it becomes `frag-v2` and is regarded as a different fragment.

You can store fragment versions where you want, but version control systems such as Git are a good choice.

Troubleshoot Application Accelerator

This topic provides troubleshooting steps for development, accelerator authorship, and operations issues in Application Accelerator.

Installation issues

Depending on the error output, you can take the following actions to troubleshoot installation problems.

Verify installed packages

The package might be already installed. Verify this by running:

```
tanzu package installed list -n tap-install
```

Look for any package called `accelerator.apps.tanzu.vmware.com`.

Look at resource events

The error might be within the custom resources such as accelerator, Git repository, fragment, and so on. Find these errors by using the Kubernetes command line interface tool (kubectl).

Here is an example using the custom resource `accelerator`:

1. Check for errors. For example, review the custom resource `accelerator` by running:

   ```
   kubectl get acc -n accelerator-system
   ```

   Note items in the output with a `READY` status `False`:

   ```
   NAME                        READY   REASON      AGE
   appsso-starter-java         True    Ready       5h2m
   where-for-dinner            True    Ready       5h2m
   java-function               True    Ready       5h2m
   java-rest-service           True    Ready       5h2m
   java-server-side-ui         True    Ready       5h2m
   node-express                True    Ready       5h2m
   node-function               False   Not-Ready   5h2m
   python-function             True    Ready       5h2m
   spring-cloud-serverless     True    Ready       5h2m
   spring-smtp-gateway         True    Ready       5h2m
   tanzu-java-web-app          True    Ready       5h2m
   tap-initialize              True    Ready       5h2m
   weatherforecast-csharp      True    Ready       5h2m
   weatherforecast-steeltoe    True    Ready       5h2m
   ```

2. To see more information about any error events you found, run:

   ```
   kubectl get acc node-function -n accelerator-system -o yaml
   ```

   Look at the event section for more information about the error.

Development issues

Failure to generate a new project

`URI is not absolute` error

The `generate` command fails with the following error:

```
% tanzu accelerator generate test --server-url https://accelerator.example.com
Error: there was an error generating the accelerator, the server response was: "URI is
not absolute"

Use:
  tanzu accelerator generate [flags]

Examples:
  tanzu accelerator generate <accelerator-name> --options '{"projectName":"test"}'

Flags:
  -h, --help                  help for generate
      --options string        options JSON string
      --options-file string   path to file containing options JSON string
      --output-dir string     directory that the zip file will be written to
      --server-url string     the URL for the Application Accelerator server

Global Flags:
      --context name      name of the kubeconfig context to use (default is current-co
ntext defined by kubeconfig)
      --kubeconfig file   kubeconfig file (default is $HOME/.kube/config)

there was an error generating the accelerator, the server response was: "URI is not ab
solute"

Error: exit status 1

✖  exit status 1
```

This indicates that the accelerator resource requested is not in a `READY` state. Review the instructions in the When Accelerator ready column is false section or contact your system admin.

Accelerator authorship issues

General tips

Speed up the reconciliation of the accelerator

Set the `git.interval` to make the accelerator reconcile sooner. The default interval is 10 minutes, which is too long when developing an accelerator.

You can set this when using the YAML manifest:

```
apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
kind: Accelerator
metadata:
```

```
  name: test-accelerator
spec:
  git:
    url: https://github.com/trisberg/test-accelerator
    ref:
      branch: main
    interval: 10s
```

You can also set this when creating the accelerator resource. To do so from the Tanzu CLI, run:

```
tanzu accelerator create test-accelerator --git-repo https://github.com/trisberg/test-accelerator --git-branch main --interval 10s
```

Use a source image with local accelerator source directory

You don't have to use a Git repository when developing an accelerator. You can create an accelerator based on content in a local directory using `--local-path` when creating the accelerator resource.

Push the local path content to an OCI image by running:

```
tanzu accelerator create test-accelerator --local-path . --source-image REPO-PREFIX/test-accelerator --interval 10s
```

Where `REPO-PREFIX` is your own repository prefix. Use a repository that the deployed Application Accelerator system can access.

The interval is 10s so that you can push changes to the source-image repository and get faster reconcile time for the accelerator resource. When you have made changes to your accelerator source, push those changes by running:

```
tanzu accelerator push --local-path . --source-image REPO-PREFIX/test-accelerator
```

Where `REPO-PREFIX` is your own repository prefix. Use a repository that is accessible to the deployed Application Accelerator system.

Expression evaluation errors

Expression evaluation errors include:

- Expression `evaluated to null`, such as:

  ```
  Could not read response from accelerator: java.lang.IllegalArgumentException: Expression '#mytestexp' evaluated to null
  ```

  In most cases, a typo in the variable name causes this error. Compare the expression with the defined options or any variables declared with `let`.

- `could not parse SpEL expression`, such as:

  ```
  Could not read response from accelerator: Error reading manifest:could not parse SpEL expression at [Source: (InputStreamReader); line: 65, column: 1] (through reference chain: com.vmware.tanzu.accelerator.engine.manifest.Manifest["engine"]->com.vmware.tanzu.accelerator.engine.transform.transforms.Combo["let"]->java.util.ArrayList[0]->com.vmware.tanzu.accelerator.engine.transform.transforms.Let$DerivedSymbol["expression"])
  ```

  In most cases, an error in a `let` expression causes this error. Review the error message and, for more information, see SpEL samples.

- `SpelEvaluationException`, such as:

```
Could not read response from accelerator: org.springframework.expression.spel.S
pelEvaluationException: EL1007E: Property or field 'test' cannot be found on nu
ll
```

In most cases, an error in a transform expression causes this error. Review the error message and, for more information, see SpEL samples.

Operations issues

Accelerator persists in Tanzu Developer Portal after deletion

If an accelerator still displays in the Tanzu Developer Portal after it is deleted using the `tanzu accelerator delete` command, complete the following steps to delete:

1. Navigate to your instance of the Tanzu Developer Portal.
2. Search for the accelerator which should be deleted and select it.
3. On the top right of the window, click the three dots, and select **Unregister Template**.

The accelerator is not longer displayed in the Tanzu Developer Portal Accelerator Catalog.

Check status of accelerator resources

Verify the status of accelerator resources by using kubectl or the Tanzu CLI:

- From kubectl, run:

  ```
  kubectl get accelerators.accelerator.apps.tanzu.vmware.com -n accelerator-syste
  m
  ```

- From the Tanzu CLI, run:

  ```
  tanzu accelerator list
  ```

Verify that the `READY` status is `true` for all accelerators.

When Accelerator ready column is blank

1. View the status of `accelerator-system` by running:

   ```
   kubectl get deployment -n accelerator-system
   ```

   Example output:

   ```
   NAME                              READY   UP-TO-DATE   AVAILABLE   AGE
   acc-engine                        1/1     1            1           3d5h
   acc-server                        1/1     1            1           2d1h
   accelerator-controller-manager    0/1     1            0           3d5h
   ```

2. View the logs for any component with no Pods available by running:

   ```
   kubectl logs deployment/COMPONENT-NAME/ -n accelerator-system -p
   ```

   Where `COMPONENT-NAME` is the component with no pods you retrieved in the previous step.

   - If the log has the following error then the Flux CD source-controller is not installed:

     ```
     2021-11-18T20:55:18.963Z ERROR setup problem running manager {"error": "f
     ailed to wait for accelerator caches to sync: no matches for kind \"GitRe
     pository\" in version \"source.toolkit.fluxcd.io/v1beta1\""}
     ```

- If the log has the following error, the Tanzu Application Platform source-controller is not installed:

  ```
  2021-11-18T20:50:10.557Z ERROR setup problem running manager {"error": "f
  ailed to wait for accelerator caches to sync: no matches for kind \"Image
  Repository\" in version \"source.apps.tanzu.vmware.com/v1alpha1\""}
  ```

When Accelerator ready column is false

View the `REASON` column for non-ready accelerators. Run:

```
kubectl get accelerators.accelerator.apps.tanzu.vmware.com -n accelerator-system
```

REASON: `GitRepositoryResolutionFailed`

For example:

```
$ kubectl get accelerators.accelerator.apps.tanzu.vmware.com -n accelerator-system
NAME        READY   REASON                          AGE
more-fun    False   GitRepositoryResolutionFailed   28s
```

1. View the resource status. Run:

   ```
   kubectl get -oyaml accelerators.accelerator.apps.tanzu.vmware.com -n accelerato
   r-system hello-fun
   ```

2. Read `status.conditions.message` near the end of the output to learn the likely cause of failure. For example:

   ```
   status:
     address:
       url: http://accelerator-engine.accelerator-system.svc.cluster.local/invocat
   ions
     artifact:
       message: 'unable to clone ''https://github.com/vmware-tanzu/application-acc
   elerator-samples'',
         error: couldn''t find remote ref "refs/heads/test"'
       ready: false
       url: ""
     conditions:
     - lastTransitionTime: "2021-11-18T21:05:47Z"
       message: |-
         failed to resolve GitRepository
         unable to clone 'https://github.com/vmware-tanzu/application-accelerator-
   samples', error: couldn't find remote ref "refs/heads/test"
       reason: GitRepositoryResolutionFailed
       status: "False"
       type: Ready
     description: Test-git
     observedGeneration: 1
   ```

   In this example, `couldn't find remote ref "refs/heads/test"` reveals that the branch or tag specified doesn't exist.

   Another common problem is that the Git repository doesn't exist. For example:

   ```
   status:
     address:
       url: http://accelerator-engine.accelerator-system.svc.cluster.local/invocat
   ions
     artifact:
   ```

```
    message: 'unable to clone ''https://github.com/vmware-tanzu/application-acc
elerator-sampl'',
      error: authentication required'
    ready: false
    url: ""
  conditions:
  - lastTransitionTime: "2021-11-18T21:09:52Z"
    message: |-
      failed to resolve GitRepository
      unable to clone 'https://github.com/vmware-tanzu/application-accelerator-
sampl', error: authentication required
    reason: GitRepositoryResolutionFailed
    status: "False"
    type: Ready
  description: Test-git
  observedGeneration: 1
```

An error message about failed authentication might display because the Git repository doesn't exist. For example:

```
unable to clone 'https://github.com/vmware-tanzu/application-accelerator-samp
l', error: authentication required
```

REASON: `GitRepositoryResolutionPending`

For example:

```
$ kubectl get accelerators.accelerator.apps.tanzu.vmware.com -n accelerator-system
NAME        READY   REASON                            AGE
more-fun    False   GitRepositoryResolutionPending    28s
```

1. See the resource status. Run:

   ```
   kubectl get -oyaml accelerators.accelerator.apps.tanzu.vmware.com -n accelerato
   r-system hello-fun
   ```

2. Locate `status.conditions` at the end of the output. For example:

   ```
   status:
     address:
       url: http://accelerator-engine.accelerator-system.svc.cluster.local/invocat
   ions
     artifact:
       message: ""
       ready: false
       url: ""
     conditions:
     - lastTransitionTime: "2021-11-18T20:17:38Z"
       message: GitRepository not yet resolved
       reason: GitRepositoryResolutionPending
       status: "False"
       type: Ready
     description: Test-git
     observedGeneration: 1
   ```

3. Verify that the Flux system is running and that the `READY` column has `1/1`. Run:

   ```
   kubectl get -n flux-system deployment/source-controller
   ```

   Example output:

```
NAME                READY   UP-TO-DATE   AVAILABLE   AGE
source-controller   1/1     0            0           5d4h
```

REASON: `ImageRepositoryResolutionPending`

For example:

```
$ kubectl get accelerators.accelerator.apps.tanzu.vmware.com -n accelerator-system
NAME        READY   REASON                            AGE
more-fun    False   ImageRepositoryResolutionPending   28s
```

1. See the resource status. Run:

   ```
   kubectl get -oyaml accelerators.accelerator.apps.tanzu.vmware.com -n accelerato
   r-system hello-fun
   ```

2. Locate `status.conditions` at the end of the output. For example:

   ```
   $ kubectl get -oyaml accelerators.accelerator.apps.tanzu.vmware.com -n accelera
   tor-system more-fun

   apiVersion: accelerator.apps.tanzu.vmware.com/v1alpha1
   kind: Accelerator
   metadata:
     annotations:
       kubectl.kubernetes.io/last-applied-configuration: |
         {"apiVersion":"accelerator.apps.tanzu.vmware.com/v1alpha1","kind":"Accele
   rator","metadata":{"annotations":{},"name":"more-fun","namespace":"accelerator-
   system"},"spec":{"description":"Test-image","source":{"image":"trisberg/more-fu
   n-source"}}}
     creationTimestamp: "2021-11-18T20:32:36Z"
     generation: 1
     name: more-fun
     namespace: accelerator-system
     resourceVersion: "605401"
     uid: 407b565d-14aa-44fe-ad8d-c9b3c3a7e5ce
   spec:
     description: Test-image
     source:
       image: trisberg/more-fun-source
   status:
     address:
       url: http://accelerator-engine.accelerator-system.svc.cluster.local/invocat
   ions
     artifact:
       message: ""
       ready: false
       url: ""
     conditions:
     - lastTransitionTime: "2021-11-18T20:32:36Z"
       message: ImageRepository not yet resolved
       reason: ImageRepositoryResolutionPending
       status: "False"
       type: Ready
     description: Test-image
     observedGeneration: 1
   ```

3. Verify that Tanzu Application Platform source-controller system is running and the `READY` column has `1/1`. Run:

   ```
   kubectl get -n source-system deployment/source-controller-manager
   ```

Expected output:

```
NAME                          READY   UP-TO-DATE   AVAILABLE   AGE
source-controller-manager     1/1     0            0           5d5h
```

Overview of Application Configuration Service for VMware Tanzu

Application Configuration Service (commonly known as App Config Service) provides a Kubernetes-native experience to enable the runtime configuration of existing Spring applications that were previously leveraged by using Spring Cloud Config Server.

Spring Cloud Config Server was an essential component in microservices architectures for providing runtime configuration to Spring Boot applications.

Spring Cloud Config Server did this by enabling configuration management to be hosted in Git repositories on different branches and in directories that could be used to generate runtime configuration properties for applications.

Application Configuration Service is compatible with the existing Git repository configuration management approach. It filters runtime configuration for any application by using slices that produce secrets.

For more information about Application Configuration Service, see the Application Configuration Service for VMware Tanzu documentation.

Overview of Application Configuration Service for VMware Tanzu

Application Configuration Service (commonly known as App Config Service) provides a Kubernetes-native experience to enable the runtime configuration of existing Spring applications that were previously leveraged by using Spring Cloud Config Server.

Spring Cloud Config Server was an essential component in microservices architectures for providing runtime configuration to Spring Boot applications.

Spring Cloud Config Server did this by enabling configuration management to be hosted in Git repositories on different branches and in directories that could be used to generate runtime configuration properties for applications.

Application Configuration Service is compatible with the existing Git repository configuration management approach. It filters runtime configuration for any application by using slices that produce secrets.

For more information about Application Configuration Service, see the Application Configuration Service for VMware Tanzu documentation.

Install Application Configuration Service for VMware Tanzu

This topic tells you how to install Application Configuration Service for VMware Tanzu (commonly known as App Config Service) from the Tanzu Application Platform (commonly known as TAP) package repository.

Prerequisites

Before installing Application Configuration Service, complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.

Install

To install Application Configuration Service on a compliant Kubernetes cluster:

1. List version information for the package by running:

   ```
   tanzu package available list application-configuration-service.tanzu.vmware.com
   --namespace tap-install
   ```

   For example:

   ```
   $ tanzu package available list application-configuration-service.tanzu.vmware.c
   om --namespace tap-install
   - Retrieving package versions for application-configuration-service.tanzu.vmwar
   e.com...
   NAME                                                VERSION  RELEASED-AT
   application-configuration-service.tanzu.vmware.com  2.0.0    2023-03-08 19:00:0
   0 -0500 EST
   ```

2. (Optional) Make changes to the default installation settings by running:

   ```
   tanzu package available get application-configuration-service.tanzu.vmware.com/
   VERSION-NUMBER \
   --values-schema --namespace tap-install
   ```

   Where `VERSION-NUMBER` is the number you discovered previously. For example, `2.0.0`.

3. Install the package by running:

   ```
   tanzu package install application-configuration-service \
   --package application-configuration-service.tanzu.vmware.com \
   --version VERSION -n tap-install \
   --values-file values.yaml
   ```

   Where `VERSION` is the version you want, such as `2.0.0`. Using a `values.yaml` file is optional.

   For example:

   ```
   $ tanzu package install application-configuration-service \
   --package application-configuration-service.tanzu.vmware.com \
   --version 2.0.0 -n tap-install

   Installing package 'application-configuration-service.tanzu.vmware.com'
   Getting package metadata for 'application-configuration-service.tanzu.vmware.co
   m'
   Creating service account 'application-configuration-service-tap-install-sa'
   Creating cluster admin role 'application-configuration-service-tap-install-clus
   ter-role'
   Creating cluster role binding 'application-configuration-service-tap-install-cl
   uster-rolebinding'
   Creating package resource
   Waiting for 'PackageInstall' reconciliation for 'application-configuration-serv
   ice'
   'PackageInstall' resource install status: Reconciling
   'PackageInstall' resource install status: ReconcileSucceeded

   Added installed package 'application-configuration-service'
   ```

4. Verify that you installed the package by running:

   ```
   tanzu package installed get application-configuration-service -n tap-install
   ```

   For example:

```
$ tanzu package installed get application-configuration-service -n tap-install

NAME:                    application-configuration-service
PACKAGE-NAME:            application-configuration-service.tanzu.vmware.com
PACKAGE-VERSION:         2.0.0
STATUS:                  Reconcile succeeded
CONDITIONS:              [{ReconcileSucceeded True  }]
USEFUL-ERROR-MESSAGE:
```

Overview of Application Live View

Application Live View is a lightweight insights and troubleshooting tool for app developers and app operators that helps you to look inside running applications. It is based on the concept of Spring Boot Actuators.

The application provides information from inside the running processes using endpoints, in this case, HTTP endpoints. Application Live View uses those endpoints to get and interact with the data from apps.

Value proposition

Application Live View is a diagnostic tool for developers to manage and analyze runtime characteristics of containerized apps. In addition, it provides a Kubernetes-native feel for developers to manage their apps in a Kubernetes environment more effectively.

Intended audience

This documentation is intended for developers and operators to visualize the actuator information of their running apps on Application Live View for VMware Tanzu. This documentation helps developers to monitor and troubleshoot apps in development, staging, and production environments. It is also intended to help app operators to deploy and administer containerized apps in a Kubernetes environment.

Supported application platforms

You can extend Application Live View to support multiple app platforms, including, but not limited to, Spring Boot, Spring Cloud Gateway, and Steeltoe.

Multicloud compatibility

Using Tanzu platform, you can integrate Application Live View to monitor apps running across on-premises, public clouds, and edge. The platform provides a centralized view to manage apps across cloud environments, which accelerates developer productivity and reduces time-to-market.

Deployment

A connector is a component responsible for discovering and registering multiple apps with Application Live View running on a Kubernetes cluster. The connector is installed as a Kubernetes Deployment by default, but you can switch to DaemonSet or Namespace-scoped mode if required.

Overview of Application Live View

Application Live View is a lightweight insights and troubleshooting tool for app developers and app operators that helps you to look inside running applications. It is based on the concept of Spring

Boot Actuators.

The application provides information from inside the running processes using endpoints, in this case, HTTP endpoints. Application Live View uses those endpoints to get and interact with the data from apps.

Value proposition

Application Live View is a diagnostic tool for developers to manage and analyze runtime characteristics of containerized apps. In addition, it provides a Kubernetes-native feel for developers to manage their apps in a Kubernetes environment more effectively.

Intended audience

This documentation is intended for developers and operators to visualize the actuator information of their running apps on Application Live View for VMware Tanzu. This documentation helps developers to monitor and troubleshoot apps in development, staging, and production environments. It is also intended to help app operators to deploy and administer containerized apps in a Kubernetes environment.

Supported application platforms

Deployment

A connector is a component responsible for discovering and registering multiple apps with Application Live View running on a Kubernetes cluster. The connector is installed as a Kubernetes Deployment by default, but you can switch to DaemonSet or Namespace-scoped mode if required.

Install Application Live View

This topic tells you how to install Application Live View from the Tanzu Application Platform (commonly known as TAP) package repository.

Overview

Application Live View includes four packages you must install. The following table lists these packages and shows the Tanzu Application Platform profiles each package is included in.

Package	Profiles	Details
Application Live View APIServer (`apiserver.appliveview.tanzu.vmware.com`)	Full, Iterate, Run	Installed in the `appliveview-tokens-system` namespace

Package	Profiles	Details
Application Live View back end (`backend.appliveview.tanzu.vmware.com`)	Full, View	Installed with Tanzu Developer Portal in the `app-live-view` namespace
Application Live View connector (`connector.appliveview.tanzu.vmware.com`)	Full, Iterate, Run	Installed as a DaemonSet in the `app-live-view-connector` namespace
Application Live View conventions (`conventions.appliveview.tanzu.vmware.com`)	Full, Iterate, Build	Installed in the `app-live-view-conventions` namespace

For more information about these packages, see Application Live View internal architecture.

Note

Follow the steps in this topic if you do not want to use a profile to install Application Live View. For more information about profiles, see About Tanzu Application Platform components and profiles.

Prerequisites

Before installing Application Live View:

- Complete all prerequisites to install Tanzu Application Platform. For more information, see Prerequisites.
- Install Cartographer Conventions, which is bundled with Supply Chain Choreographer as of v0.5.3. To install, see Installing Supply Chain Choreographer. For more information, see Cartographer Conventions.

Install Application Live View

You can install Application Live View in single cluster or multicluster environment:

- `Single cluster`: All Application Live View components are deployed in a single cluster. The user can access Application Live View plug-in information of the applications across all the namespaces in the Kubernetes cluster. This is the default mode of Application Live View.
- `Multicluster`: In a multicluster environment, the Application Live View back end component is installed only once in a single cluster and exposes a RSocket registration for the other clusters using Tanzu shared ingress. Each cluster continues to install the connector as a DaemonSet. The connectors are configured to connect to the central instance of the Application Live View back end.

The improved security and access control secures the communication between the Application Live View components. For more information, see Configure security and access control in Application Live View.

Install Application Live View back end

To install Application Live View back end:

1. List version information for the package by running:

```
tanzu package available list backend.appliveview.tanzu.vmware.com --namespace t
```

```
ap-install
```

For example:

```
$ tanzu package available list backend.appliveview.tanzu.vmware.com --namespace
tap-install

- Retrieving package versions for backend.appliveview.tanzu.vmware.com...
  NAME                                 VERSION        RELEASED-AT
  backend.appliveview.tanzu.vmware.com  1.9.0          2024-03-22T00:00:00Z
```

2. Create the file `app-live-view-backend-values.yaml` using the following information:

Single-cluster environment
For a single-cluster environment, the Application Live View back end is exposed through the Kubernetes cluster service.

By default, ingress is deactivated for Application Live View back end. You do not have to change your `app-live-view-backend-values.yaml` file in this step.

Multicluster environment
For a multicluster environment, set the flag `ingressEnabled` to `true` for the Application Live View back end to be exposed on the ingress domain.

```
appliveview:
  ingressEnabled: true
```

Profile install using shared ingress domain key
If you are using a Tanzu Application Platform profile installation and the top-level key `shared.ingress_domain` is set in the `tap-values.yaml`, the back end is automatically exposed through the shared ingress.

To override the shared ingress for Application Live View in a multicluster environment, use the following values:

```
appliveview:
  ingressEnabled: true
  ingressDomain: ${INGRESS-DOMAIN}
```

Where `INGRESS-DOMAIN` is the top-level domain you use for the `tanzu-shared-ingress` service's external IP address. The `appliveview` subdomain is prepended to the value provided.

3. Configure TLS in your `app-live-view-backend-values.yaml` file:

Activate TLS with self-signed certificate
To enable TLS for Application Live View back end using a self-signed certificate:

1. Create the `app-live-view` namespace and the TLS secret for the domain. You must do this before installing the Tanzu Application Platform packages in the cluster so that the HTTPProxy is updated with the TLS secret. To create a TLS secret, run:

   ```
   kubectl create -n app-live-view secret tls alv-cert --cert=CERT-FILE -
   -key=KEY-FILE
   ```

   Where:

- `SECRET-NAME` is the name you want for the TLS secret for the domain, for example, `alv-cert`.
- `CERT-FILE` is a .crt file that contains the PEM encoded server certificate.
- `KEY-FILE` is a .key file that contains the PEM encoded server private key.

2. Provide the following properties in your `app-live-view-backend-values.yaml`:

```
appliveview:
  ingressEnabled: true
  tls:
    namespace: "NAMESPACE"
    secretName: "SECRET-NAME"
```

Where:

- `NAMESPACE` is the targeted namespace of TLS secret for the domain.
- `SECRET-NAME` is the name of TLS secret for the domain.

You can edit the values to suit your project needs or leave the default values as is.

When `ingressEnabled` is `true`, the HTTPProxy object is created in the cluster.

3. Verify the HTTPProxy object with the TLS secret by running:

```
kubectl get httpproxy -A
```

Expected output:

```
NAMESPACE       NAME          FQDN                                TLS S
ECRET               STATUS   STATUS DESCRIPTION
app-live-view   appliveview   appliveview.192.168.42.55.nip.io   app-l
ive-view/alv-cert   valid    Valid HTTPProxy
```

Activate TLS using ClusterIssuer

To enable TLS for Application Live View back end using ClusterIssuer:

1. Set the `ingressEnabled` key to `true` for TLS to be enabled on Application Live View back end using ClusterIssuer. This key is set to `false` by default.

```
appliveview:
  ingressEnabled: true
```

TLS is then automatically enabled on Application Live View back end using the shared ClusterIssuer. The `appliveview-cert` certificate is generated by default and its issuerRef points to the `.ingress_issuer` value. The `ingress_issuer` key consumes the value `shared.ingress_issuer` from `tap-values.yaml` by default if you don't specify the `ingress_issuer` in `tap-values.yaml`.

When `ingressEnabled` is `true`, HTTPProxy object is created in the cluster and also `appliveview-cert` certificate is generated by default in the `app_live_view` namespace. Here, the secretName `appliveview-cert` stores this certificate.

2. To verify the HTTPProxy object with the secret, run:

```
kubectl get httpproxy -A
```

Expected output:

```
NAMESPACE        NAME           FQDN                                  TLS S
ECRET          STATUS   STATUS DESCRIPTION
app-live-view    appliveview    appliveview.192.168.42.55.nip.io    appli
veview-cert    valid    Valid HTTPProxy
```

3. To verify the Application Live View pages in a multicluster setup, set the appropriate connector configuration in your run cluster as listed in Install Application Live View connector later in this topic.

Deactivate TLS

By default, Tanzu Application Platform installs and uses a self-signed CA as its ingress issuer for all components. If you don't specify the `ingress_issuer` in `tap-values.yaml`, the `ingress_issuer` key consumes the value `shared.ingress_issuer` from `tap-values.yaml`. This automatically enables TLS validation on Application Live View back end.

To deactivate TLS validation on Application Live View back end do one of the following:

- While VMware discourages it, you can deactivate the ingress issuer by setting `shared.ingress_issuer:` to `""` in `tap-values.yaml`. For example:

  ```
  ...
      shared:
        ingress_issuer: ""
  ```

- Set `ingress_issuer` to `""` in `app-live-view-backend-values.yaml`. For example:

  ```
  appliveview:
    ...
    ingress_issuer: ""
  ```

4. (Optional) View additional changes you can make in your `app-live-view-backend-values.yaml` file by running:

   ```
   tanzu package available get backend.appliveview.tanzu.vmware.com/VERSION-NUMBER
   \
     --values-schema \
     --namespace tap-install
   ```

   Where `VERSION-NUMBER` is the version of the package listed earlier. For example, `1.9.0`.

   For example:

   ```
   $ tanzu package available get backend.appliveview.tanzu.vmware.com/1.9.0 \
       --values-schema \
       --namespace tap-install

     KEY                      DEFAULT          TYPE        DESCRIPTION
     tls.namespace            <nil>            string      The targeted namespace
   for secret consumption by the HTTPProxy.

     tls.secretName           <nil>            string      The name of secret for
   consumption by the HTTPProxy.

     ingressDomain            tap.example.com  string      Domain to be used by th
   e HTTPProxy ingress object. The "appliveview"
                                                          subdomain will be prepe
   nded to the value provided. For example:
                                                          "example.com" would bec
   ome "appliveview.example.com".
     ingressEnabled           false            boolean     Flag for whether or not
   ```

```
to create an HTTPProxy for ingress.

  ingress_issuer                              string      Cluster issuer to be us
ed in App Live View Backend.
  kubernetes_distribution                     string      Kubernetes distribution
that this package is being installed on. Accepted
                                                          values: ['''',''openshi
ft'']
  kubernetes_version                          string      Optional: The Kubernete
s Version. Valid values are '1.24.*', or ''

  server.tls.crt                              string      TLS cert file
  server.tls.enabled       false              boolean     Flag to enable tls on b
ackend
  server.tls.key                              string      TLS key file
```

5. Install the Application Live View back end package by running:

```
tanzu package install appliveview \
  --package backend.appliveview.tanzu.vmware.com \
  --version VERSION-NUMBER \
  --namespace tap-install \
  --values-file app-live-view-backend-values.yaml
```

Where `VERSION-NUMBER` is the version of the package listed earlier. For example, `1.9.0`.

For example:

```
$ tanzu package install appliveview \
    --package backend.appliveview.tanzu.vmware.com \
    --version 1.9.0 \
    --namespace tap-install \
    --values-file app-live-view-backend-values.yaml

- Installing package 'backend.appliveview.tanzu.vmware.com'
| Getting namespace 'tap-install'
| Getting package metadata for 'backend.appliveview.tanzu.vmware.com'
| Creating service account 'appliveview-tap-install-sa'
| Creating cluster admin role 'appliveview-tap-install-cluster-role'
| Creating cluster role binding 'appliveview-tap-install-cluster-rolebinding'
| Creating package resource
| Package install status: Reconciling

Added installed package 'appliveview' in namespace 'tap-install'
```

The Application Live View back end component is deployed in `app-live-view` namespace by default.

6. Verify the Application Live View back end package installation by running:

```
tanzu package installed get appliveview -n tap-install
```

For example:

```
$ tanzu package installed get appliveview -n tap-install

\ Retrieving installation details for appliveview...
NAME:                    appliveview
PACKAGE-NAME:            backend.appliveview.tanzu.vmware.com
PACKAGE-VERSION:         1.9.0
STATUS:                  Reconcile succeeded
CONDITIONS:              [{ReconcileSucceeded True  }]
USEFUL-ERROR-MESSAGE:
```

Verify that `STATUS` is `Reconcile succeeded`.

Install Application Live View connector

To install Application Live View connector:

1. List version information for the package by running:

```
tanzu package available list connector.appliveview.tanzu.vmware.com --namespace
tap-install
```

For example:

```
$ tanzu package available list connector.appliveview.tanzu.vmware.com --namespa
ce tap-install

- Retrieving package versions for connector.appliveview.tanzu.vmware.com...
  NAME                                    VERSION        RELEASED-AT
  connector.appliveview.tanzu.vmware.com  1.9.0          2024-03-22T00:00:00Z
```

2. Create the file `app-live-view-connector-values.yaml` using the following details:

Single-cluster environment
For a single-cluster environment, the Application Live View connector connects to the `cluster-local` Application Live View back end to register the applications.

By default, ingress is deactivated for connector. You do not have to change your `app-live-view-connector-values.yaml` file in this step.

Multicluster environment
For a multicluster environment, set the flag `ingressEnabled` to `true` for the Application Live View connector to connect to the Application Live View back end by using the ingress domain. For example:

```
appliveview_connector:
  backend:
    ingressEnabled: true
```

Profile install using shared ingress domain key
If you are using a Tanzu Application Platform profile installation and the top-level key `shared.ingress_domain` is set in the `tap-values.yaml`, the Application Live View connector and Application Live View back end are configured to communicate through ingress. The Application Live View connector then uses the `shared.ingress_domain` to reach the back end.

To override the shared ingress for Application Live View in a multicluster environment, use the following values:

```
appliveview_connector:
  backend:
    host: appliveview.INGRESS-DOMAIN
```

Where `INGRESS-DOMAIN` is the top-level domain the Application Live View back end exposes by using `tanzu-shared-ingress` for the connectors in other clusters to reach the Application Live View back end. Prepend the `appliveview` subdomain to the provided value.

3. Configure TLS in your `app-live-view-connector-values.yaml`. Choose a tab depending on how you configured TLS in Install Application Live View back end earlier.

Configure TLS with self-signed certificate

The `backend.sslDeactivated` is set to `false` by default. Set the CA certificate for the ingress domain in the `backend.caCertData` key for SSL validation as follows:

```
appliveview_connector:
  backend:
    ...
    caCertData: |-
      -----BEGIN CERTIFICATE-----
      MIIGMzCCBBugAwIBAgIJALHHzQjxM6wMMA0GCSqGSIb3DQEBDQUAMGcxCzAJBgNV
      BAgMAk1OMRQwEgYDVQQHDAtNaW5uZWFwb2xpczEPMA0GA1UECgwGVk13YXJlMRMw
      -----END CERTIFICATE-----
```

Configure TLS using ClusterIssuer

To enable TLS using ClusterIssuer:

1. Retrieve the certificate from the HTTPProxy secret by running the following command in the view cluster:

   ```
   kubectl get secret appliveview-cert -n app-live-view -o yaml |  yq '.d
   ata."ca.crt"' | base64 -d
   ```

2. Set the following connector configuration in the run cluster:

   ```
   appliveview_connector:
     backend:
       ingressEnabled: true
       sslDeactivated: false
       host: appliveview.INGRESS-DOMAIN
       caCertData: |-
         -----BEGIN CERTIFICATE-----
         MIIGMzCCBBugAwIBAgIJALHHzQjxM6wMMA0GCSqGSIb3DQEBDQUAMGcxCzAJBgNV
         BAgMAk1OMRQwEgYDVQQHDAtNaW5uZWFwb2xpczEPMA0GA1UECgwGVk13YXJlMRMw
         -----END CERTIFICATE-----
   ```

   Where:

   - `caCertData` is the certificate you retrieved from the HTTPProxy secret exposed by the Application Live View back end in the view cluster.
   - `host` is the backend host in the view cluster.

Deactivate TLS

If TLS is not enabled for the `INGRESS-DOMAIN` in the Application Live View back end, set `backend.sslDeactivated` to `true`. For example:

```
appliveview_connector:
  backend:
    ...
    sslDeactivated: true
```

Note

The `sslDisabled` key is deprecated and has been renamed to `sslDeactivated`.

You can edit the values to suit your project needs or leave the default values as is.

Using the HTTP proxy either on 80 or 443 based on SSL config exposes the back end service running on port 7000. The connector connects to the back end on port 80/443 by default. Therefore, you are not required to explicitly configure the `port` field.

4. (Optional) View additional changes you can make in your `app-live-view-connector-values.yaml` file by running:

```
tanzu package available get connector.appliveview.tanzu.vmware.com/VERSION-NUMB
ER \
  --values-schema \
  --namespace tap-install
```

Where `VERSION-NUMBER` is the version of the package listed earlier. For example, `1.9.0`.

For example:

```
$ tanzu package available get connector.appliveview.tanzu.vmware.com/1.9.0 \
    --values-schema \
    --namespace tap-install

  KEY                                  DEFAULT             TYPE        DESCRIP
TION
  backend.caCertData                     cert-in-pem-format  string    CA Cert
Data for ingress domain
  backend.host                           <nil>               string    Domain
to be used to reach the application live view backend. Prepend
                                                                       "appliv
eview" subdomain to the value if you are using shared ingress. For
                                                                       exampl
e: "example.com" would become "appliveview.example.com".

  activateAppLiveViewSecureAccessControl                     boolean   Optiona
l: Configuration required to enable Secure Access Connection between App
                                                                       Live Vi
ew components
  activateSensitiveOperations                                boolean   Optiona
l: Configuration to allow connector to execute sensitive operations on a
```

```
                                                                    running
application
```

5. By default, the connector is deployed as a Kubernetes Deployment. You can override the default settings to run the connector in DaemonSet mode or a Namespace-scope mode. For more information, see Connector deployment modes in Application Live View.

6. Install the Application Live View connector package by running:

   ```
   tanzu package install appliveview-connector \
     --package connector.appliveview.tanzu.vmware.com \
     --version VERSION-NUMBER \
     --namespace tap-install \
     --values-file app-live-view-connector-values.yaml
   ```

   Where `VERSION-NUMBER` is the version of the package listed earlier. For example, `1.9.0`.

   For example:

   ```
   $ tanzu package install appliveview-connector \
       --package connector.appliveview.tanzu.vmware.com \
       --version 1.9.0 \
       --namespace tap-install \
       --values-file app-live-view-connector-values.yaml

   | Installing package 'connector.appliveview.tanzu.vmware.com'
   | Getting namespace 'tap-install'
   | Getting package metadata for 'connector.appliveview.tanzu.vmware.com'
   | Creating service account 'appliveview-connector-tap-install-sa'
   | Creating cluster admin role 'appliveview-connector-tap-install-cluster-role'
   | Creating cluster role binding 'appliveview-connector-tap-install-cluster-role
   binding'
   - Creating package resource
   / Package install status: Reconciling

   Added installed package 'appliveview-connector' in namespace 'tap-install'
   ```

   The connector is configured to connect to the central instance of the back end. The Application Live View connector component is deployed in `app-live-view-connector` namespace by default.

7. Verify the `Application Live View connector` package installation by running:

   ```
   tanzu package installed get appliveview-connector -n tap-install
   ```

   For example:

   ```
   $ tanzu package installed get appliveview-connector -n tap-install

   | Retrieving installation details for appliveview-connector...
   NAME:                    appliveview-connector
   PACKAGE-NAME:            connector.appliveview.tanzu.vmware.com
   PACKAGE-VERSION:         1.9.0
   STATUS:                  Reconcile succeeded
   CONDITIONS:              [{ReconcileSucceeded True  }]
   USEFUL-ERROR-MESSAGE:
   ```

   Verify that `STATUS` is `Reconcile succeeded`.

Install Application Live View conventions

To install Application Live View conventions:

1. List version information for the package by running:

```
tanzu package available list conventions.appliveview.tanzu.vmware.com --namespa
ce tap-install
```

For example:

```
$ tanzu package available list conventions.appliveview.tanzu.vmware.com --names
pace tap-install

- Retrieving package versions for conventions.appliveview.tanzu.vmware.com...
  NAME                                       VERSION        RELEASED-AT
  conventions.appliveview.tanzu.vmware.com   1.9.0          2024-03-22T00:00:00Z
```

2. (Optional) View the changes you can make to the default installation settings by running:

```
tanzu package available get conventions.appliveview.tanzu.vmware.com/VERSION-NU
MBER \
  --values-schema \
  --namespace tap-install
```

Where `VERSION-NUMBER` is the version of the package listed earlier. For example, `1.9.0`.

For example:

```
$ tanzu package available get conventions.appliveview.tanzu.vmware.com/1.9.0 \
    --values-schema \
    --namespace tap-install

  KEY                                DEFAULT             TYPE     DESCRIPTION
  kubernetes_distribution                                string   Kubernetes dist
ribution that this package is installed on. Accepted values: ['''',''openshif
t''].
  kubernetes_version                                     string   Optional: The K
ubernetes Version. Valid values are '1.24.*', or ''.
```

3. (Optional) Create a file named `app-live-view-conventions-values.yaml` to override the default installation settings using the information output in the previous step.

4. Install the Application Live View conventions package.

Default values

To install Application Live View conventions with the default settings, run:

```
tanzu package install appliveview-conventions \
  --package conventions.appliveview.tanzu.vmware.com \
  --version VERSION-NUMBER \
  --namespace tap-install
```

Where `VERSION-NUMBER` is the version of the package listed earlier. For example, `1.9.0`.

For example:

```
$ tanzu package install appliveview-conventions \
    --package conventions.appliveview.tanzu.vmware.com \
    --version 1.9.0 \
    --namespace tap-install

- Installing package 'conventions.appliveview.tanzu.vmware.com'
| Getting namespace 'tap-install'
| Getting package metadata for 'conventions.appliveview.tanzu.vmware.com'
| Creating service account 'appliveview-conventions-tap-install-sa'
| Creating cluster admin role 'appliveview-conventions-tap-install-cluster-ro
```

```
le'
| Creating cluster role binding 'appliveview-conventions-tap-install-cluster-
rolebinding'
- Creating package resource
\ Package install status: Reconciling

Added installed package 'appliveview-conventions' in namespace 'tap-install'
```

Overriding values

To install Application Live View conventions while overriding the default settings, run:

```
tanzu package install appliveview-conventions \
  --package conventions.appliveview.tanzu.vmware.com \
  --version VERSION-NUMBER \
  --namespace tap-install \
  --values-file app-live-view-conventions-values.yaml
```

Where `VERSION-NUMBER` is the version of the package listed earlier. For example, `1.9.0`.

5. Verify the package install for Application Live View conventions package by running:

   ```
   tanzu package installed get appliveview-conventions -n tap-install
   ```

   For example:

   ```
   $ tanzu package installed get appliveview-conventions -n tap-install

   | Retrieving installation details for appliveview-conventions...
   NAME:                    appliveview-conventions
   PACKAGE-NAME:            conventions.appliveview.tanzu.vmware.com
   PACKAGE-VERSION:         1.9.0
   STATUS:                  Reconcile succeeded
   CONDITIONS:              [{ReconcileSucceeded True  }]
   USEFUL-ERROR-MESSAGE:
   ```

   Verify that `STATUS` is `Reconcile succeeded`.

Install Application Live View APIServer

To install Application Live View APIServer:

1. List version information for the package by running:

   ```
   tanzu package available list apiserver.appliveview.tanzu.vmware.com --namespace
   tap-install
   ```

   For example:

   ```
   $ tanzu package available list apiserver.appliveview.tanzu.vmware.com --namespa
   ce tap-install

   - Retrieving package versions for apiserver.appliveview.tanzu.vmware.com...
     NAME                                    VERSION       RELEASED-AT
     apiserver.appliveview.tanzu.vmware.com  1.9.0         2024-03-22T00:00:00Z
   ```

2. (Optional) View the changes you can make to the default installation settings by running:

   ```
   tanzu package available get apiserver.appliveview.tanzu.vmware.com/VERSION-NUMB
   ER \
   ```

```
  --values-schema \
  --namespace tap-install
```

Where `VERSION-NUMBER` is the version of the package listed earlier. For example, `1.9.0`.

For example:

```
$ tanzu package available get apiserver.appliveview.tanzu.vmware.com/1.9.0 \
    --values-schema \
    --namespace tap-install \

  KEY                               DEFAULT             TYPE     DESCRIPTION
  kubernetes_distribution                               string  Kubernetes dist
ribution that this package is installed on. Accepted values: ['''',''openshif
t''].
  kubernetes_version                                    string  Optional: The K
ubernetes Version. Valid values are '1.24.*', or ''.
```

3. (Optional) Create a file named `app-live-view-apiserver-values.yaml` to override the default installation settings using the information output in the previous step.
4. Install the Application Live View APIServer package.

Default values

To install Application Live View APIServer with the default settings, run:

```
tanzu package install appliveview-apiserver \
  --package apiserver.appliveview.tanzu.vmware.com \
  --version VERSION-NUMBER \
  --namespace tap-install
```

Where `VERSION-NUMBER` is the version of the package listed earlier. For example, `1.9.0`.

For example:

```
$ tanzu package install appliveview-apiserver \
    --package apiserver.appliveview.tanzu.vmware.com \
    --version 1.9.0 \
    --namespace tap-install

- Installing package 'apiserver.appliveview.tanzu.vmware.com'
| Getting namespace 'tap-install'
| Getting package metadata for 'apiserver.appliveview.tanzu.vmware.com'
- Creating package resource
\ Package install status: Reconciling

Added installed package 'appliveview-apiserver' in namespace 'tap-install'
```

Overriding values

To install Application Live View APIServer while overriding the default settings, run:

```
tanzu package install appliveview-apiserver \
  --package apiserver.appliveview.tanzu.vmware.com \
  --version VERSION-NUMBER \
  --namespace tap-install \
  --values-file app-live-view-apiserver-values.yaml
```

Where `VERSION-NUMBER` is the version of the package listed earlier. For example, `1.9.0`.

5. Verify the package install for Application Live View APIServer package by running:

```
tanzu package installed get appliveview-apiserver -n tap-install
```

For example:

```
$ tanzu package installed get appliveview-apiserver -n tap-install

| Retrieving installation details for appliveview-apiserver...
NAME:                    appliveview-apiserver
PACKAGE-NAME:            apiserver.appliveview.tanzu.vmware.com
PACKAGE-VERSION:         1.9.0
STATUS:                  Reconcile succeeded
CONDITIONS:              [{ReconcileSucceeded True  }]
USEFUL-ERROR-MESSAGE:
```

Verify that `STATUS` is `Reconcile succeeded`.

The Application Live View UI plug-in is part of Tanzu Developer Portal. To access the Application Live View UI, see Application Live View in Tanzu Application Platform GUI.

Deprecation notice for the sslDisabled key

The `appliveview_connector.backend.sslDisabled` key has been replaced by `appliveview_connector.backend.sslDeactivated`.

Connector deployment modes in Application Live View

This topic tells you about the different ways in which you can deploy the connector in Tanzu Application Platform (commonly known as TAP).

Deploy the connector as a regular deployment

This is the default mode of Application Live View connector in Tanzu Application Platform. When the connector is running as a regular deployment, it observes all the applications across all the namespaces in the cluster and registers with the back end.

Deploy the connector as a Kubernetes DaemonSet

When deployed as a Kubernetes DaemonSet the connector discovers applications across all the namespaces running in a worker node of a Kubernetes cluster.

To run the connector as a DaemonSet:

1. Change the default installation settings for Application Live View connector by running:

   ```
   tanzu package available get connector.appliveview.tanzu.vmware.com/VERSION-NUMB
   ER --values-schema --namespace tap-install
   ```

   Where `VERSION-NUMBER` is the version of the package listed. For example, `1.9.0`.

   For example:

   ```
   $ tanzu package available get connector.appliveview.tanzu.vmware.com/1.9.0 --va
   lues-schema --namespace tap-install
    KEY                                  DEFAULT             TYPE        DESCRIPT
   ION
    kubernetes_version                                       string      Optiona
   l: The Kubernetes Version. Valid values are '1.24.*', or ''.

    backend.sslDeactivated               false               boolean     Flag for
   ```

```
whether to disable SSL.
 backend.caCertData                    cert-in-pem-format  string      CA Cert
Data for ingress domain.
 backend.host                          <nil>               string      Domain u
sed to reach the Application Live View back end. Prepend
                                                                       "applive
view" subdomain to the value if you use shared ingress. For
                                                                       example:
"example.com" becomes "appliveview.example.com".
 backend.ingressEnabled                false               boolean     Flag for
the connector to connect to ingress on back end.

 backend.port                          <nil>               number      Port to
reach the Application Live View back end.
 connector.deployment.enabled          true                boolean      Flag fo
r the connector to run in deployment mode
 connector.deployment.replicas           1                 number      Number o
f replicas of connector pods at any given time
 connector.namespace_scoped.enabled    false               boolean     Flag for
the connector to run in namespace scope.
 connector.namespace_scoped.namespace  default             string      Namespac
e to deploy connector.
 kubernetes_distribution                                   string      Kubernet
es distribution that this package is being installed on. Accepted
                                                                       values:
[''''],''openshift''].
 activateAppLiveViewSecureAccessControl                    boolean     Optiona
l: Configuration required to enable Secure Access Connection between App Live V
iew components.
 activateSensitiveOperations                               boolean     Optiona
l: Configuration to allow connector to execute sensitive operations on a runnin
g application.
```

For more information about values schema options, see the properties listed earlier.

2. Override the deployment mode for the connector by using the following configuration values for the `app-live-view-connector-values.yaml`:

```
appliveview_connector:
  connector:
    deployment:
      enabled: false
      replicas: 1
```

By default, `connector.deployment.enabled` is set to `true`.

The `connector.deployment.replicas` key specifies the number of replicas of connector pods running at any given time.

Deploy the connector in namespace-scoped mode

When the connector is deployed in namespace-scoped mode, it discovers applications within the namespace of a Kubernetes cluster.

To deploy the connector in namespace-scoped mode, use the following configuration values for the connector in `app-live-view-connector-values.yaml`:

```
appliveview_connector:
  connector:
    namespace_scoped:
      enabled: true
      namespace: "NAMESPACE"
```

Where `NAMESPACE` specifies the namespace for deploying the connector

Configure security and access control in Application Live View

This topic tells you how to enable improved security and access control in Application Live View in Tanzu Application Platform (commonly known as TAP). Improved security and access control in Application Live View secures the REST API exposed by the Application Live View back end.

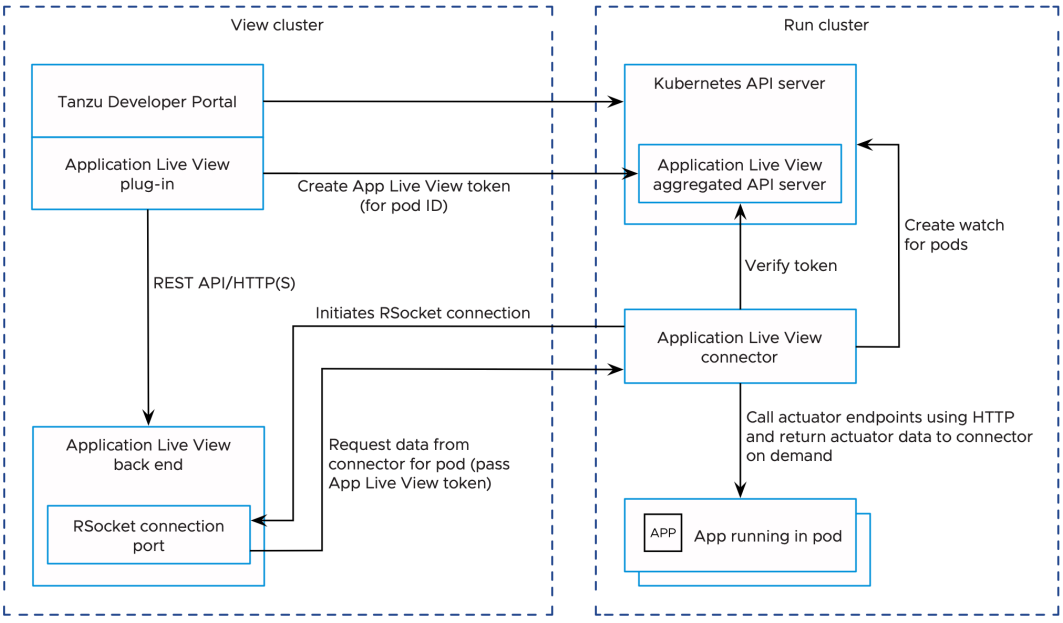
For more information about Application Live View packages, see Install Application Live View.

Security and access control overview

There is one instance of Application Live View back end installed per View profile. Multiple users access this back-end API to fetch actuator data for different applications. All the REST API calls to the back end are secured. A token must be passed to the Application Live View back end on each call to the REST API to fetch actuator data. This token is obtained from Application Live View APIServer.

The Application Live View APIServer generates a unique token upon access validation of a user to a pod. The Application Live View back end passes this token to the Application Live View connector when requesting the actuator data. The Application Live View connector verifies this token by calling the Application Live View APIServer and proxies the actuator data only if the token is valid.

The Application Live View UI plug-in part of Tanzu Developer Portal uses the preceding approach to securely query for the actuator data for a pod. It requests a token from Application Live View APIServer and passes it in the subsequent calls to the back end. This ensures that actuator data from the running application is fetched only if the user is authorized to see the live information for the pod.



The Application Live View UI plug-in relies on Tanzu Developer Portal authentication and authorization to access the Application Live View APIServer and fetch the Application Live View tokens.

The Tanzu Developer Portal controls the access to Kubernetes resources based on user roles and permissions for each of the remote clusters. For more information, see View runtime resources on authorization-enabled clusters.

For more information about how to set up unrestricted remote cluster visibility, see Viewing resources on multiple clusters in Tanzu Developer Portal.

Prerequisites

1. You install the Application Live View APIServer package (`apiserver.appliveview.tanzu.vmware.com`) in Tanzu Application Platform. For more information, see Install Application Live View APIServer.
2. Assign users necessary roles and permissions for the Kubernetes clusters. For more information about managing role-based access control, see Assign roles and permissions on Kubernetes clusters

For example: If you are using Service Account to view resources on a cluster in Tanzu Developer Portal, verify that the `ClusterRole` has rules to access and request tokens from the Application Live View APIServer.

```
- apiGroups: ['appliveview.apps.tanzu.vmware.com']
  resources:
  - resourceinspectiongrants
  verbs: ['get', 'watch', 'list', 'create']
```

For more information, see Set up a Service Account to view resources on a cluster.

Note

With the Service Account approach to view resources on a cluster, every user with the Service Account Token with access to view the pods is able to see the live information in Application Live View.

Configure improved security

The improved security feature is enabled by default for Application Live View.

In a Tanzu Application Platform profile install, the Application Live View connector (`connector.appliveview.tanzu.vmware.com`) and the Tanzu Application Platform GUI (`tap-gui.tanzu.vmware.com`) are automatically configured to enable the secure communication between Application Live View components.

You can control this feature by setting the top-level key `shared.activateAppLiveViewSecureAccessControl` in the `tap-values.yaml`.

For example:

```
shared:
    activateAppLiveViewSecureAccessControl: true
```

To override the security feature at the individual component level, take the following steps.

Application Live View connector

1. (Optional) Change the default installation settings for Application Live View connector by running:

```
tanzu package available get connector.appliveview.tanzu.vmware.com/VERSION-NUMB
ER --values-schema --namespace tap-install
```

Where `VERSION-NUMBER` is the version of the package listed. For example, `1.9.0`.

For example:

```
$ tanzu package available get connector.appliveview.tanzu.vmware.com/1.9.0 --va
lues-schema --namespace tap-install
  KEY                                  DEFAULT             TYPE        DESCRIP
TION
  kubernetes_version                                       string      Optiona
l: The Kubernetes Version. Valid values are '1.24.*', or ''.

  backend.sslDeactivated               false               boolean     Flag fo
r whether to disable SSL.
  backend.caCertData                   cert-in-pem-format  string      CA Cert
Data for ingress domain.
  backend.host                         <nil>               string      Domain
used to reach the Application Live View back end. Prepend
                                                                       "appliv
eview" subdomain to the value if you use shared ingress. For
                                                                       exampl
e: "example.com" becomes "appliveview.example.com".
  backend.ingressEnabled               false               boolean     Flag fo
r the connector to connect to ingress on back end.

  backend.port                         <nil>               number      Port to
reach the Application Live View back end.
  connector.deployment.enabled           true              boolean     Flag for
the connector to run in deployment mode
  connector.deployment.replicas            1               number      Number
of replicas of connector pods at any given time
  connector.namespace_scoped.enabled   false               boolean     Flag fo
r the connector to run in namespace scope.
  connector.namespace_scoped.namespace  default            string      Namespa
ce to deploy connector.
  kubernetes_distribution                                  string      Kuberne
tes distribution that this package is being installed on. Accepted
                                                                       values:
[''''],''openshift''].
  activateAppLiveViewSecureAccessControl                   boolean     Optiona
l: Configuration required to enable Secure Access Connection between App Live V
iew components.
  activateSensitiveOperations                              boolean     Optiona
l: Configuration to allow connector to execute sensitive operations on a runnin
g application.
```

For more information about values schema options, see the properties listed earlier.

2. Create `app-live-view-connector-values.yaml` with the following details:

   To override the default security settings for connector, use the following values:

   ```
   activateAppLiveViewSecureAccessControl: false
   ```

   By default, activateAppLiveViewSecureAccessControl is set to `true`.

   The `activateSensitiveOperations` key activates/deactivates the execution of sensitive operations, such as editing environment variables, downloading heap dump data, and changing log levels for the applications in the cluster. It is set to `false` by default.

   To enable the sensitive operations, set `activateSensitiveOperations` to `true`.

```
activateSensitiveOperations: true
```

To control permissions to execute sensitive operations at a user level, see Authorize a user to execute sensitive operations.

3. Install the Application Live View connector package by running:

```
tanzu package install appliveview-connector \
  --package connector.appliveview.tanzu.vmware.com \
  --version VERSION-NUMBER \
  --namespace tap-install \
  --values-file app-live-view-connector-values.yaml
```

Where `VERSION-NUMBER` is the version of the package listed. For example, `1.9.0`.

For example:

```
$ tanzu package install appliveview-connector \
    --package connector.appliveview.tanzu.vmware.com \
    --version 1.9.0 \
    --namespace tap-install \
    --values-file app-live-view-connector-values.yaml
| Installing package 'connector.appliveview.tanzu.vmware.com'
| Getting namespace 'tap-install'
| Getting package metadata for 'connector.appliveview.tanzu.vmware.com'
| Creating service account 'appliveview-connector-tap-install-sa'
| Creating cluster admin role 'appliveview-connector-tap-install-cluster-role'
| Creating cluster role binding 'appliveview-connector-tap-install-cluster-role
binding'
- Creating package resource
/ Package install status: Reconciling

Added installed package 'appliveview-connector' in namespace 'tap-install'
```

4. Verify the `Application Live View connector` package installation by running:

```
tanzu package installed get appliveview-connector -n tap-install
```

For example:

```
tanzu package installed get appliveview-connector -n tap-install
5s
| Retrieving installation details for appliveview-connector...
NAME:                    appliveview-connector
PACKAGE-NAME:            connector.appliveview.tanzu.vmware.com
PACKAGE-VERSION:         1.9.0
STATUS:                  Reconcile succeeded
CONDITIONS:              [{ReconcileSucceeded True  }]
USEFUL-ERROR-MESSAGE:
```

Verify that `STATUS` is `Reconcile succeeded`.

Application Live View UI plug-in

The Application Live View UI plug-in is part of Tanzu Developer Portal. To override the default security settings for the Application Live View UI plug-in, take the following steps.

1. (Optional) Make changes to the default installation settings by running:

```
tanzu package available get tap-gui.tanzu.vmware.com/VERSION-NUMBER --values-sc
hema --namespace tap-install
```

Where `VERSION-NUMBER` is the number you discovered previously. For example, `1.4.6`.

For more information about values schema options, see the individual product documentation.

2. Create `tap-gui-values.yaml` and paste in the following code:

```
ingressEnabled: true
ingressDomain: "INGRESS-DOMAIN"
app_config:
  catalog:
    locations:
      - type: url
        target: https://GIT-CATALOG-URL/catalog-info.yaml
  appLiveView:
    activateAppLiveViewSecureAccessControl: false
```

Where:

- `INGRESS-DOMAIN` is the subdomain for the host name that you point at the `tanzu-shared-ingress` service's External IP address.
- `GIT-CATALOG-URL` is the path to the `catalog-info.yaml` catalog definition file from either the included Blank catalog (provided as an additional download named "Blank Tanzu Developer Portal Catalog") or a Backstage-compliant catalog that you've already built and posted on the Git infrastructure specified in Add Tanzu Developer Portal integrations.

3. Install the package by running:

```
tanzu package install tap-gui \
  --package tap-gui.tanzu.vmware.com \
  --version VERSION \
  --namespace tap-install \
  --values-file tap-gui-values.yaml
```

Where `VERSION` is the version that you want. For example, `1.4.6`.

For example:

```
$ tanzu package install tap-gui \
    --package tap-gui.tanzu.vmware.com \
    --version 1.4.6 \
    --namespace tap-install \
    --values-file tap-gui-values.yaml
- Installing package 'tap-gui.tanzu.vmware.com'
| Getting package metadata for 'tap-gui.tanzu.vmware.com'
| Creating service account 'tap-gui-default-sa'
| Creating cluster admin role 'tap-gui-default-cluster-role'
| Creating cluster role binding 'tap-gui-default-cluster-rolebinding'
| Creating secret 'tap-gui-default-values'
- Creating package resource
- Package install status: Reconciling

 Added installed package 'tap-gui' in namespace 'tap-install'
```

4. Verify that the package installed by running:

```
tanzu package installed get tap-gui -n tap-install
```

For example:

```
$ tanzu package installed get tap-gui -n tap-install
| Retrieving installation details for cc...
NAME:                    tap-gui
PACKAGE-NAME:            tap-gui.tanzu.vmware.com
PACKAGE-VERSION:         1.4.6
STATUS:                  Reconcile succeeded
CONDITIONS:              [{ReconcileSucceeded True  }]
USEFUL-ERROR-MESSAGE:
```

Verify that `STATUS` is `Reconcile succeeded`.

5. To access Tanzu Developer Portal, use the service you exposed in the `service_type` field in the values file.

Authorize a user to execute sensitive operations

You can limit the access to execute sensitive operations to specific users. This secures operations such as editing environment variables, downloading heap dump data, and changing log levels for applications.

To authorize a user to execute these sensitive operations:

1. Create a `ClusterRole` with a rule that specifies the `execute` verb for the `SensitiveOperationsAccess` resource and a corresponding `RoleBinding` to bind it to a user:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: alv-execute-sensitive-op-role
rules:
- apiGroups: ['appliveview.apps.tanzu.vmware.com']
  resources:
  - sensitiveoperationsaccesses
  verbs: ['execute']
---
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: alice-alv-execute-sensitive-op-role-binding
  namespace: dev-team-1
roleRef:
  apiGroup: rbac.authorization.k8s.io
  kind: ClusterRole
  name: alv-execute-sensitive-op-role
subjects:
- kind: User
  name: "alice@example.com"
  apiGroup: rbac.authorization.k8s.io
```

2. If you are using service account to view resources on a cluster in Tanzu Developer Portal, create a `ClusterRole` with a rule that specifies the `execute` verb for the `SensitiveOperationsAccess` resource and a corresponding `RoleBinding` to bind it to the `tap-gui` service account:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  name: alv-execute-sensitive-op-role
rules:
- apiGroups: ['appliveview.apps.tanzu.vmware.com']
  resources:
  - sensitiveoperationsaccesses
```

```
  verbs: ['execute']
---
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
  name: alv-execute-sensitive-op-role-binding
  namespace: dev-team-1
subjects:
- kind: ServiceAccount
  namespace: tap-gui
  name: tap-gui-viewer
roleRef:
  kind: ClusterRole
  name: alv-execute-sensitive-op-role
  apiGroup: rbac.authorization.k8s.io
```

3. (Optional) Edit the tap-gui cluster role `k8s-reader` to add a rule that specifies the `execute` verb for the `SensitiveOperationsAccess` resource in a single cluster setup:

```
kubectl edit clusterrole k8s-reader -n tap-gui
```

4. Add the following rule to the cluster role:

```
- apiGroups: ['appliveview.apps.tanzu.vmware.com']
  resources:
  - sensitiveoperationsaccesses
  verbs: ['execute']
```

Note

Executing sensitive operations is deactivated by default. You can enable it at the cluster level by setting the `activateSensitiveOperations: true` key in the appliveview_connector config or at the individual user level by assigning the roles and permissions mentioned earlier.

Enabling Spring Boot apps for Application Live View

This topic for developers tells you how to configure a Spring Boot app for observation by Application Live View within Tanzu Application Platform (commonly known as TAP).

Enable Spring Boot apps

For Application Live View to interact with a Spring Boot app within Tanzu Application Platform, add the `spring-boot-starter-actuator` module dependency.

Add the maven dependency in `pom.xml` as follows:

```
<dependency>
  <groupId>org.springframework.boot</groupId>
  <artifactId>spring-boot-starter-actuator</artifactId>
</dependency>
```

Add the following plugin configuration in `pom.xml`:

```
<plugin>
  <groupId>org.springframework.boot</groupId>
  <artifactId>spring-boot-maven-plugin</artifactId>
  <executions>
```

```
    <execution>
      <goals>
        <goal>build-info</goal>
      </goals>
      <configuration>
        <additionalProperties>
          <spring.boot.version>${project.parent.version}</spring.boot.version>
        </additionalProperties>
      </configuration>
    </execution>
  </executions>
</plugin>
```

Add the preceding configuration to generate `build-info.properties` into your Spring Boot application. This information is then used to display the Spring Boot version that the app uses in Application Live View.

To enable Application Live View for Spring Boot apps, Spring Boot conventions automatically sets the Application Live View labels onto the PodSpec. For more information about the labels automatically set by Spring Boot conventions, see Enable Application Live View for Spring Boot applications.

Enable Spring Boot 3 apps

For Application Live View to interact with a Spring Boot 3 app within Tanzu Application Platform, add the `spring-boot-starter-actuator` module dependency.

Add the maven dependency in `pom.xml` as follows:

```
<dependency>
  <groupId>org.springframework.boot</groupId>
  <artifactId>spring-boot-starter-actuator</artifactId>
</dependency>
```

Add the following plugin configuration in `pom.xml`:

```
<plugin>
  <groupId>org.springframework.boot</groupId>
  <artifactId>spring-boot-maven-plugin</artifactId>
  <executions>
    <execution>
      <goals>
        <goal>build-info</goal>
      </goals>
      <configuration>
        <additionalProperties>
          <spring.boot.version>${project.parent.version}</spring.boot.version>
        </additionalProperties>
      </configuration>
    </execution>
  </executions>
</plugin>
```

Add the preceding configuration to generate `build-info.properties` into your Spring Boot application. This information is then used to display the Spring Boot version that the app uses in Application Live View.

To enable Application Live View for Spring Boot 3 apps, Spring Boot conventions automatically sets the Application Live View labels onto the PodSpec. For more information about the labels automatically set by Spring Boot conventions, see Enable Application Live View for Spring Boot applications.

Here is an example of creating a workload for a Spring Boot 3 Application:

```
tanzu apps workload create spring-boot-3 --git-repo https://github.com/martinlippert/sb3-demo.git --git-branch main --annotation autoscaling.knative.dev/min-scale=1 --yes --label app.kubernetes.io/part-of=tanzu-java-web-app --type web --build-env "BP_JVM_VERSION=17" --label apps.tanzu.vmware.com/auto-configure-actuators="true"
```

Enable Spring Cloud Gateway apps

For Application Live View to interact with a Spring Cloud Gateway app within Tanzu Application Platform, add the `spring-boot-starter-actuator` and `spring-cloud-starter-gateway` module dependency.

Add the maven dependencies in `pom.xml` as follows:

```
<dependency>
  <groupId>org.springframework.boot</groupId>
  <artifactId>spring-boot-starter-actuator</artifactId>
</dependency>
<dependency>
  <groupId>org.springframework.cloud</groupId>
  <artifactId>spring-cloud-starter-gateway</artifactId>
</dependency>
```

To enable Application Live View on the Spring Cloud Gateway Tanzu Application Platform workload, Spring Boot conventions automatically applies labels on the workload, such as `tanzu.app.live.view.application.flavours: spring-boot_spring-cloud-gateway` and `tanzu.app.live.view: true`, based on the Spring Cloud Gateway image metadata.

Here is an example of creating a workload for a Spring Cloud Gateway Application:

```
tanzu apps workload create tanzu-scg-web-app --git-repo https://github.com/ksankaranara-vmw/gs-gateway.git --git-branch main --type web --label app.kubernetes.io/part-of=tanzu-scg-web-app --yes --annotation autoscaling.knative.dev/min-scale=1
```

Workload image NOT built with Tanzu Build Service

If your application image is NOT built with Tanzu Build Service, to enable Application Live View on `Spring Boot` Tanzu Application Platform workload, use the following command. For example:

```
tanzu apps workload create boot-app --type web --app boot-app --image <IMAGE NAME> --annotation autoscaling.knative.dev/min-scale=1 --yes --label tanzu.app.live.view=true --label tanzu.app.live.view.application.name=boot-app --label tanzu.app.live.view.application.flavours=spring-boot
```

If your application image is NOT built with Tanzu Build Service, to enable Application Live View on `Spring Cloud Gateway` Tanzu Application Platform workload, use the following command. For example:

```
tanzu apps workload create scg-app --type web --app scg-app --image <IMAGE NAME> --annotation autoscaling.knative.dev/min-scale=1 --yes --label tanzu.app.live.view=true --label tanzu.app.live.view.application.name=scg-app --label tanzu.app.live.view.application.flavours=spring-boot_spring-cloud-gateway
```

If your application image is NOT built with Tanzu Build Service, to enable Application Live View on `Steeltoe` Tanzu Application Platform workload, use the following command. For example:

```
tanzu apps workload create steeltoe-app --type web --app steeltoe-app --image <IMAGE NAME> --annotation autoscaling.knative.dev/min-scale=1 --yes --label tanzu.app.live.vie
```

```
w=true --label tanzu.app.live.view.application.name=steeltoe-app --label tanzu.app.liv
e.view.application.flavours=steeltoe
```

Enabling Spring Boot apps for Application Live View

This topic for developers tells you how to configure a Spring Boot app for observation by Application Live View within Tanzu Application Platform (commonly known as TAP).

Enable Spring Boot apps

For Application Live View to interact with a Spring Boot app within Tanzu Application Platform, add the `spring-boot-starter-actuator` module dependency.

Add the maven dependency in `pom.xml` as follows:

```
<dependency>
  <groupId>org.springframework.boot</groupId>
  <artifactId>spring-boot-starter-actuator</artifactId>
</dependency>
```

Add the following plugin configuration in `pom.xml`:

```
<plugin>
  <groupId>org.springframework.boot</groupId>
  <artifactId>spring-boot-maven-plugin</artifactId>
  <executions>
    <execution>
      <goals>
        <goal>build-info</goal>
      </goals>
      <configuration>
        <additionalProperties>
          <spring.boot.version>${project.parent.version}</spring.boot.version>
        </additionalProperties>
      </configuration>
    </execution>
  </executions>
</plugin>
```

Add the preceding configuration to generate `build-info.properties` into your Spring Boot application. This information is then used to display the Spring Boot version that the app uses in Application Live View.

To enable Application Live View for Spring Boot apps, Spring Boot conventions automatically sets the Application Live View labels onto the PodSpec. For more information about the labels automatically set by Spring Boot conventions, see Enable Application Live View for Spring Boot applications.

Enable Spring Boot 3 apps

For Application Live View to interact with a Spring Boot 3 app within Tanzu Application Platform, add the `spring-boot-starter-actuator` module dependency.

Add the maven dependency in `pom.xml` as follows:

```
<dependency>
  <groupId>org.springframework.boot</groupId>
  <artifactId>spring-boot-starter-actuator</artifactId>
</dependency>
```

Add the following plugin configuration in `pom.xml`:

```
<plugin>
  <groupId>org.springframework.boot</groupId>
  <artifactId>spring-boot-maven-plugin</artifactId>
  <executions>
    <execution>
      <goals>
        <goal>build-info</goal>
      </goals>
      <configuration>
        <additionalProperties>
          <spring.boot.version>${project.parent.version}</spring.boot.version>
        </additionalProperties>
      </configuration>
    </execution>
  </executions>
</plugin>
```

Add the preceding configuration to generate `build-info.properties` into your Spring Boot application. This information is then used to display the Spring Boot version that the app uses in Application Live View.

To enable Application Live View for Spring Boot 3 apps, Spring Boot conventions automatically sets the Application Live View labels onto the PodSpec. For more information about the labels automatically set by Spring Boot conventions, see Enable Application Live View for Spring Boot applications.

Here is an example of creating a workload for a Spring Boot 3 Application:

```
tanzu apps workload create spring-boot-3 --git-repo https://github.com/martinlippert/s
b3-demo.git --git-branch main --annotation autoscaling.knative.dev/min-scale=1 --yes -
-label app.kubernetes.io/part-of=tanzu-java-web-app --type web --build-env "BP_JVM_VER
SION=17" --label apps.tanzu.vmware.com/auto-configure-actuators="true"
```

Enable Spring Cloud Gateway apps

For Application Live View to interact with a Spring Cloud Gateway app within Tanzu Application Platform, add the `spring-boot-starter-actuator` and `spring-cloud-starter-gateway` module dependency.

Add the maven dependencies in `pom.xml` as follows:

```
<dependency>
  <groupId>org.springframework.boot</groupId>
  <artifactId>spring-boot-starter-actuator</artifactId>
</dependency>
<dependency>
  <groupId>org.springframework.cloud</groupId>
  <artifactId>spring-cloud-starter-gateway</artifactId>
</dependency>
```

To enable Application Live View on the Spring Cloud Gateway Tanzu Application Platform workload, Spring Boot conventions automatically applies labels on the workload, such as `tanzu.app.live.view.application.flavours: spring-boot_spring-cloud-gateway` and `tanzu.app.live.view: true`, based on the Spring Cloud Gateway image metadata.

Here is an example of creating a workload for a Spring Cloud Gateway Application:

```
tanzu apps workload create tanzu-scg-web-app --git-repo https://github.com/ksankaranar
a-vmw/gs-gateway.git --git-branch main --type web --label app.kubernetes.io/part-of=ta
```

```
nzu-scg-web-app --yes --annotation autoscaling.knative.dev/min-scale=1
```

Workload image NOT built with Tanzu Build Service

If your application image is NOT built with Tanzu Build Service, to enable Application Live View on `Spring Boot` Tanzu Application Platform workload, use the following command. For example:

```
tanzu apps workload create boot-app --type web --app boot-app --image <IMAGE NAME> --a
nnotation autoscaling.knative.dev/min-scale=1 --yes --label tanzu.app.live.view=true -
-label tanzu.app.live.view.application.name=boot-app --label tanzu.app.live.view.appli
cation.flavours=spring-boot
```

If your application image is NOT built with Tanzu Build Service, to enable Application Live View on `Spring Cloud Gateway` Tanzu Application Platform workload, use the following command. For example:

```
tanzu apps workload create scg-app --type web --app scg-app --image <IMAGE NAME> --ann
otation autoscaling.knative.dev/min-scale=1 --yes --label tanzu.app.live.view=true --l
abel tanzu.app.live.view.application.name=scg-app --label tanzu.app.live.view.applicat
ion.flavours=spring-boot_spring-cloud-gateway
```

If your application image is NOT built with Tanzu Build Service, to enable Application Live View on `Steeltoe` Tanzu Application Platform workload, use the following command. For example:

```
tanzu apps workload create steeltoe-app --type web --app steeltoe-app --image <IMAGE N
AME> --annotation autoscaling.knative.dev/min-scale=1 --yes --label tanzu.app.live.vie
w=true --label tanzu.app.live.view.application.name=steeltoe-app --label tanzu.app.liv
e.view.application.flavours=steeltoe
```

Enable Spring Native apps for Application Live View

This topic for developers tells you how to configure a Spring Native app to be observed by Application Live View within Tanzu Application Platform (commonly known as TAP).

Configure a Spring Native application

To make Application Live View interact with a Spring Native app within Tanzu Application Platform:

1. Add the `spring-boot-starter-actuator` module dependency for Maven in `pom.xml` as follows:

   ```
   <dependency>
    <groupId>org.springframework.boot</groupId>
    <artifactId>spring-boot-starter-actuator</artifactId>
   </dependency>
   ```

2. Add a native profile that includes the `native-maven-plugin` for the build phase in `pom.xml`, as follows:

   ```
   <profiles>
    <profile>
        <id>native</id>
        <build>
          <plugins>
              <plugin>
                <groupId>org.graalvm.buildtools</groupId>
                  <artifactId>native-maven-plugin</artifactId>
                </plugin>
   ```

```
        </plugins>
    </build>
 </profile>
</profiles>
```

Important

For Maven-based projects, you must add the `org.graalvm.buildtools` build plug-in and configure it to run when the native profile is active.

3. Add the following configuration in `pom.xml` to generate `build-info.properties` in your Spring Boot application. Application Live View uses this information to display the Spring Boot version that the app uses.

```
<plugin>
<groupId>org.springframework.boot</groupId>
<artifactId>spring-boot-maven-plugin</artifactId>
<executions>
 <execution>
   <goals>
     <goal>build-info</goal>
   </goals>
   <configuration>
     <additionalProperties>
       <spring.boot.version>${project.parent.version}</spring.boot.version>
     </additionalProperties>
   </configuration>
 </execution>
</executions>
</plugin>
```

Create a native workload

Create a workload for the Spring Native application similar to the following example:

```
$ tanzu apps workload create spring-cloud-serverless \
--git-repo https://github.com/vudayani-vmw/spring-cloud-serverless --git-branch main \
--type web --label apps.tanzu.vmware.com/auto-configure-actuators=true \
--label app.kubernetes.io/part-of=spring-cloud-serverless --yes \
--annotation autoscaling.knative.dev/min-scale=1 \
--build-env "BP_JVM_VERSION=17" --build-env "BP_NATIVE_IMAGE=true" \
--build-env "BP_MAVEN_BUILD_ARGUMENTS= -Pnative -Dmaven.test.skip=true \
--no-transfer-progress package \
-Dspring-boot.aot.jvmArguments='-Dmanagement.endpoint.health.probes.add-additional-pat
hs='true' \
-Dmanagement.endpoint.health.show-details='always' \
-Dmanagement.endpoints.web.base-path='/actuator' \
-Dmanagement.endpoints.web.exposure.include='*' \
-Dmanagement.health.probes.enabled='true' \
-Dmanagement.server.port=8081 -Dserver.port=8080' "
```

Where:

- The required build arguments, such as `BP_JVM_VERSION`, `BP_NATIVE_IMAGE`, and `BP_MAVEN_BUILD_ARGUMENTS`, are configured to build a native executable file as shown in the example. The build environment variables are required to enable a native build profile and native image-building.
- The override configuration options at runtime provide AOT (Ahead-Of-Time) configuration to the build process by using the `spring-boot.aot.jvmArguments` option. For Gradle builds,

the `spring-boot.aot.jvmArguments` is set as part of the `BP_GRADLE_ADDITIONAL_BUILD_ARGUMENTS` build environment variable.

These build environment parameters do not directly set the runtime values. The build environment parameters, provided as part of `spring-boot.aot.jvmArguments`, are only used as build-time signals. These signals indicate to generate code that allows configuration options to be set at runtime.

Configure at runtime

There are two methods to override the configuration at runtime. You can, by default, let Spring Boot conventions configure automatically, or you can use environment variables to configure manually.

Configure automatically (default)

Automatic configuration by Spring Boot conventions is the default method. Spring Boot conventions add the necessary environment variables and labels to the workload `PodSpec` based on the `apps.tanzu.vmware.com/auto-configure-actuators` flag. When the `apps.tanzu.vmware.com/auto-configure-actuators` is set to `true`, Spring Boot conventions adds the following environment variables to the native workload `PodSpec`:

```
Spec:
  Containers:
    Env:
      Name:   MANAGEMENT_SERVER_PORT
      Value:  8081
      Name:   MANAGEMENT_ENDPOINT_HEALTH_PROBES_ADD_ADDITIONAL_PATHS
      Value:  true
      Name:   MANAGEMENT_ENDPOINT_HEALTH_SHOW_DETAILS
      Value:  always
      Name:   MANAGEMENT_ENDPOINTS_WEB_BASE_PATH
      Value:  /actuator
      Name:   MANAGEMENT_ENDPOINTS_WEB_EXPOSURE_INCLUDE
      Value:  *
      Name:   MANAGEMENT_HEALTH_PROBES_ENABLED
      Value:  true
      Name:   SERVER_PORT
      Value:  8080
      Name:   SERVER_SHUTDOWN_GRACE_PERIOD
      Value:  24s
```

Configure manually

You can manually override runtime configuration settings by providing environment variables. To customize the configuration, set the relevant environment variables in accordance with your requirements. The following example overrides `MANAGEMENT_SERVER_PORT` as `8088`, and it overrides `SERVER_PORT` as `8082`.

```
tanzu apps workload create spring-cloud-serverless \
--git-repo https://github.com/vudayani-vmw/spring-cloud-serverless --git-branch main
--type web \
--label tanzu.app.live.view.application.flavours=spring-boot_spring-native \
--label apps.tanzu.vmware.com/auto-configure-actuators=true --label \
app.kubernetes.io/part-of=spring-cloud-serverless --label apps.tanzu.vmware.com/has-
tests=true \
--yes --annotation autoscaling.knative.dev/min-scale=1 --build-env "BP_JVM_VERSION=1
7" \
--build-env "BP_NATIVE_IMAGE=true" --build-env "BP_MAVEN_BUILD_ARGUMENTS= -Pnative \
-Dmaven.test.skip=true --no-transfer-progress package \
-Dspring-boot.aot.jvmArguments='-Dmanagement.endpoint.health.probes.add-additional-p
aths='true' \
-Dmanagement.endpoint.health.show-details='always' -Dmanagement.endpoints.web.base-p
```

```
ath='/actuator' \
-Dmanagement.endpoints.web.exposure.include='*' -Dmanagement.health.probes.enabled
='true' \
-Dmanagement.server.port=8081 -Dserver.port=8080' " --env MANAGEMENT_SERVER_PORT=808
8 \
--env SERVER_PORT=8082
```

The resulting `PodSpec` is:

```
Spec:
  Containers:
    Env:
      Name:   MANAGEMENT_SERVER_PORT
      Value:  8088
      Name:   SERVER_PORT
      Value:  8082
      Name:   MANAGEMENT_ENDPOINT_HEALTH_PROBES_ADD_ADDITIONAL_PATHS
      Value:  true
      Name:   MANAGEMENT_ENDPOINT_HEALTH_SHOW_DETAILS
      Value:  always
      Name:   MANAGEMENT_ENDPOINTS_WEB_BASE_PATH
      Value:  /actuator
      Name:   MANAGEMENT_ENDPOINTS_WEB_EXPOSURE_INCLUDE
      Value:  *
      Name:   MANAGEMENT_HEALTH_PROBES_ENABLED
      Value:  true
      Name:   SERVER_SHUTDOWN_GRACE_PERIOD
      Value:  24s
```

Spring Boot conventions also set the Application Live View labels on the `PodSpec` to enable Application Live View.

Verify the applied labels and annotations

Verify the applied labels and annotations by running:

```
kubectl get podintents.conventions.carto.run WORKLOAD-NAME -o yaml
```

Where `WORKLOAD-NAME` is the name of the deployed workload. For example, `spring-cloud-serverless`.

Expected output of the Spring Boot workload:

```
...
Labels:       app.kubernetes.io/component=intent
              app.kubernetes.io/part-of=spring-cloud-serverless
              apps.tanzu.vmware.com/auto-configure-actuators=true
              apps.tanzu.vmware.com/has-tests=true
              apps.tanzu.vmware.com/workload-type=web
              carto.run/cluster-template-name=convention-template
              carto.run/resource-name=config-provider
              carto.run/supply-chain-name=source-to-url
              carto.run/template-kind=ClusterConfigTemplate
              carto.run/template-lifecycle=mutable
              carto.run/workload-name=spring-cloud-serverless
              carto.run/workload-namespace=default
              tanzu.app.live.view.application.flavours=spring-boot_spring-native
...
```

Enable Steeltoe apps for Application Live View

This topic for developers tells you how to extend .NET Core Apps to Steeltoe apps and enable Application Live View on Steeltoe workloads within Tanzu Application Platform (commonly known as TAP).

Application Live View supports Steeltoe .NET apps with .NET core runtime version `v6.0.8`.

Extend .NET Core Apps to Steeltoe Apps

A .NET Core application can be extended to a Steeltoe application by adding independent NuGet packages.

To enable the Actuators on a .NET Core App:

1. Add a PackageReference to your `.csproj` file:

   ```
   <PackageReference Include="Steeltoe.Management.EndpointCore" Version="$(Steelto
   eVersion)" />
   ```

   Note

   The PackageReference is expected to change to `Steeltoe.Management.Endpoint` from version Steeltoe 4.0 onwards.

2. Call the extension `AddAllActuators` in your `Program.cs` file:

   ```
   builder.WebHost.AddAllActuators();
   ```

3. (Optional) You can add app-specific configurations, such as the following.

   To expose all management actuator endpoints except `env` endpoint, add the following configuration to your `appsettings.json` file:

   ```
   {
     "Management": {
       "Endpoints": {
         "Actuator":{
           "Exposure": {
             "Include": [ "*" ],
             "Exclude": [ "env" ]
           }
         }
       }
     }
   }
   ```

   To enable logging, add the following configuration to your `appsettings.json` file:

   ```
   {
     "Logging": {
       "LogLevel": {
         "Default": "Information",
         "Microsoft": "Warning",
         "Steeltoe": "Warning",
         "Sample": "Information"
       }
     }
   }
   ```

   To enable heapdump, add the following configuration to your `appsettings.json` file:

```
{
  "Management": {
    "Endpoints": {
      "HeapDump": {
        "HeapDumpType": "Normal"
      }
    }
  }
}
```

Enable Application Live View on Steeltoe Tanzu Application Platform workload

You can enable Application Live View to interact with a Steeltoe app within Tanzu Application Platform.

To enable Application Live View on the Steeltoe Tanzu Application Platform workload, the Application Live View convention service automatically applies labels on the workload, such as `tanzu.app.live.view.application.flavours: steeltoe` and `tanzu.app.live.view: true`, based on the Steeltoe image metadata.

Here's an example of creating a workload for a Steeltoe Application:

```
tanzu apps workload create steeltoe-app --type web --git-repo https://github.com/vmware-tanzu/application-accelerator-samples --sub-path weatherforecast-steeltoe --git-branch main --annotation autoscaling.knative.dev/min-scale=1 --yes --label app.kubernetes.io/part-of=sample-app
```

If your application image is NOT built with Tanzu Build Service, to enable Application Live View on Steeltoe Tanzu Application Platform workload, use the following command. For example:

```
tanzu apps workload create steeltoe-app --type web --app steeltoe-app --image IMAGE-NAME --annotation autoscaling.knative.dev/min-scale=1 --yes --label tanzu.app.live.view=true --label tanzu.app.live.view.application.name=steeltoe-app --label tanzu.app.live.view.application.flavours=steeltoe
```

Where `IMAGE-NAME` is the name of your application image.

Note

Thread metrics is available in SteeltoeVersion `3.2.*`. To enable the Threads page in the Application Live View UI, add the following configuration to your `.csproj` file:

```
<PropertyGroup>
    <SteeltoeVersion>3.2.*</SteeltoeVersion>
</PropertyGroup>
```

Application Live View convention server

This topic gives you information about Application Live View convention, which provides a Webhook handler for Cartographer Conventions.

Role of Application Live View convention

Application Live View conventions works in conjunction with core Cartographer Conventions. It enhances Tanzu PodIntents with metadata such as labels, annotations, or app properties. This

metadata allows Application Live View, specifically the connector, to discover app instances so that Application Live View can access the actuator data from those workloads.

Note

Application Live View conventions now supports only Steeltoe applications. Spring Boot conventions supports both Spring Boot and Spring Cloud Gateway applications. For more information about Spring Boot conventions, see Enable Application Live View with Spring Boot apps

To run Application Live View with Steeltoe apps, the Application Live View convention recognizes PodIntents and adds the following metadata labels:

- `tanzu.app.live.view: "true"`: Enables the connector to observe application pod.
- `tanzu.app.live.view.application.name: APPLICATION-NAME`: Identifies the app name to be used internally by Application Live View.
- `tanzu.app.live.view.application.actuator.port: ACTUATOR-PORT`: Identifies the port on the pod at which the actuators are available for Application Live View.
- `tanzu.app.live.view.application.flavours: steeltoe`: Exposes the framework flavor of the app.

These metadata labels allow Application Live View to identify pods that are enabled for Application Live View. The metadata labels also tell the Application Live View connector what kind of app it is, and on which port the actuators are accessible for Application Live View.

Description of metadata labels

If a workload resource explicitly defines a label under `metadata.labels` in the `workload.yaml`, then the convention service detects the presence of that label and respects its value. When deploying a workload using Tanzu Application Platform, you can override the labels listed in the following table using the `Workload` YAML.

Metadata	Default	Type	Description
`tanzu.app.live.view`	`true`	Label	When deploying a workload in Tanzu Application Platform, this label is set to `true` as default across the supply chain.
`tanzu.app.live.view.application.name`	`steeltoe-app`	Label	When deploying a workload in Tanzu Application Platform, this label is set to `steeltoe-app` if the container image metadata does not contain the app name. Otherwise, the label is set to the app name from container image metadata.
`tanzu.app.live.view.application.flavours`	`steeltoe`	Label	When deploying a Spring Boot workload in Tanzu Application Platform, this label is set to `steeltoe` as default across the supply chain.

Verify the applied labels and annotations

You can verify the applied labels and annotations by running:

```
kubectl get podintents.conventions.carto.run WORKLOAD-NAME -o yaml
```

Where `WORKLOAD-NAME` is the name of the deployed workload, for example `steetoe-app`.

Expected output for Steeltoe workload:

```
apiVersion: conventions.carto.run/v1alpha1
kind: PodIntent
metadata:
  creationTimestamp: "2022-11-14T09:56:53Z"
  generation: 1
  labels:
    app.kubernetes.io/component: intent
    app.kubernetes.io/part-of: sample-app
    apps.tanzu.vmware.com/workload-type: web
    carto.run/cluster-template-name: convention-template
    carto.run/resource-name: config-provider
    carto.run/supply-chain-name: source-to-url
    carto.run/template-kind: ClusterConfigTemplate
    carto.run/workload-name: steeltoe-app
    carto.run/workload-namespace: default
  name: steeltoe-app
  namespace: default

```

```
          spring-boot-convention/app-live-view-appflavour-check
          appliveview-sample/app-live-view-connector-steeltoe
          appliveview-sample/app-live-view-appflavours-steeltoe
        developer.conventions/target-containers: workload
      labels:
        app.kubernetes.io/component: run
        app.kubernetes.io/part-of: sample-app
        apps.tanzu.vmware.com/workload-type: web
        carto.run/workload-name: steeltoe-app
        tanzu.app.live.view: "true"
        tanzu.app.live.view.application.flavours: steeltoe
        tanzu.app.live.view.application.name: steeltoe-app
    spec:
      containers:
      - image: dev.registry.tanzu.vmware.com/app-live-view/test/steeltoe-app-default@s
ha256:c8ea14d8714ec31ad978085ebff43d15679613a0c12df37812adf22cb47b5232
        name: workload
        resources: {}
        securityContext:
          runAsUser: 1000
      serviceAccountName: default
```

In your output:

- `status.template.metadata.labels` shows the list of applied labels by Application Live View convention server.
- `status.template.metadata.annotations` shows the list of applied annotations by Application Live View convention server.

Custom configuration for the connector

This topic for developers tells you how to custom configure an app or workload for Application Live View.

The connector component is responsible for discovering the app and registering it with Application Live View. Labels from the app PodSpec are used to discover the app and configure the connector to access the actuator data of the app.

Usually, Application Live View conventions applies the necessary configuration automatically. To deactivate the convention and configure the app and the workload manually, the list of labels in the following table gives you an overview of the options:

Label Name	Mandatory	Type	Default	Significance
`tanzu.app.live.view`	true	Boolean	None	Toggle to activate or deactivate pod discovery
`tanzu.app.live.view.application.name`	true	String	None	Application name
`tanzu.app.live.view.application.port`	false	Integer	`8080`	Application port
`tanzu.app.live.view.application.path`	false	String	`/`	Application context path
`tanzu.app.live.view.application.actuator.port`	false	Integer	`8080`	Application actuator port
`tanzu.app.live.view.application.actuator.path`	false	String	`/actuator`	Actuator context path
`tanzu.app.live.view.application.protocol`	false	http / https	`http`	Protocol scheme

Label Name	Mandatory	Type	Default	Significance
`tanzu.app.live.view.application.actuator.health.port`	false	Integer	`8080`	Health endpoint port
`tanzu.app.live.view.application.flavours`	false	Comma separated string	`spring-boot,spring-cloud-gateway`	Application flavors

You can add connector labels in the app `Workload` or override labels that the convention applies, such as `tanzu.app.live.view` and `tanzu.app.live.view.application.name`. If you do not want Application Live View to observe your app, you can override the existing label `tanzu.app.live.view: "false"`.

Configure the developer workload in Tanzu Application Platform

The following YAML is an example of a Spring PetClinic workload that overrides the connector label to `tanzu.app.live.view: "false"`:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: spring-petclinic
  namespace: default
  labels:
    tanzu.app.live.view: "false"
    app.kubernetes.io/part-of: tanzu-java-web-app
    apps.tanzu.vmware.com/workload-type: web
  annotations:
    autoscaling.knative.dev/minScale: "1"
spec:
  source:
    git:
      ref:
        branch: main
      url: https://github.com/kdvolder/spring-petclinic
```

Deploy the workload

To deploy the workload, run:

```
kapp -y deploy -n default -a workloads -f workloads.yaml
```

Verify the label has propagated through the Supply Chain

To verify the label:

1. Verify that the workload build is successful by ensuring that `SUCCEEDED` is set to `True`:

   ```
   kubectl get builds
   NAME                          IMAGE
   SUCCEEDED
   spring-petclinic-build-1      dev.registry.tanzu.vmware.com/app-live-view/test/s
   pring-petclinic-default@sha256:9db2a8a8e77e9215239431fd8afe3f2ecdf09cce8afac565
   dad7b5f0c5ac0cdf     True
   ```

2. Verify the PodIntent of your workload by ensuring `status.template.metadata.labels` shows the newly added label has propagated through the Supply Chain:

```
kubectl get podintents.conventions.carto.run spring-petclinic -oyaml

status:
  conditions:
  - lastTransitionTime: "2021-12-03T15:14:33Z"
    status: "True"
    type: ConventionsApplied
  - lastTransitionTime: "2021-12-03T15:14:33Z"
    status: "True"
    type: Ready
  observedGeneration: 3
  template:
    metadata:
      annotations:
        autoscaling.knative.dev/minScale: "1"
        boot.spring.io/actuator: http://:8080/actuator
        boot.spring.io/version: 2.5.6
        conventions.carto.run/applied-conventions: |-
          appliveview-sample/app-live-view-connector-boot
          appliveview-sample/app-live-view-appflavours-boot
          appliveview-sample/app-live-view-systemproperties
          spring-boot-convention/spring-boot
          spring-boot-convention/spring-boot-graceful-shutdown
          spring-boot-convention/spring-boot-web
          spring-boot-convention/spring-boot-actuator
          spring-boot-convention/service-intent-mysql
        developer.conventions/target-containers: workload
        kapp.k14s.io/identity: v1;default/carto.run/Workload/spring-petclinic;c
arto.run/v1alpha1
        kapp.k14s.io/original: '{"apiVersion":"carto.run/v1alpha1","kind":"Work
load","metadata":{"annotations":{"autoscaling.knative.dev/minScale":"2"},"label
s":{"app.kubernetes.io/part-of":"tanzu-java-web-app","apps.tanzu.vmware.com/wor
kload-type":"web","kapp.k14s.io/app":"1638455805474051000","kapp.k14s.io/associ
ation":"v1.5a9384bd7b93ca74ef494c4dec2caa4b","tanzu.app.live.view":"false"},"na
me":"spring-petclinic","namespace":"default"},"spec":{"source":{"git":{"ref":
{"branch":"main"},"url":"https://github.com/ksankaranara-vmw/spring-petclini
c"}}}}'
        kapp.k14s.io/original-diff-md5: 58e0494c51d30eb3494f7c9198986bb9
        services.conventions.carto.run/mysql: mysql-connector-java/8.0.27
      labels:
        app.kubernetes.io/component: run
        app.kubernetes.io/part-of: tanzu-java-web-app
        apps.tanzu.vmware.com/workload-type: web
        carto.run/workload-name: spring-petclinic
        conventions.carto.run/framework: spring-boot
        kapp.k14s.io/app: "1638455805474051000"
        kapp.k14s.io/association: v1.5a9384bd7b93ca74ef494c4dec2caa4b
        services.conventions.carto.run/mysql: workload
        tanzu.app.live.view: "false"
        tanzu.app.live.view.application.flavours: spring-boot
        tanzu.app.live.view.application.name: petclinic
```

3. Verify the ConfigMap was created for the app by ensuring `metadata.labels` shows the newly added label has propagated through the Supply Chain:

```
kubectl describe configmap spring-petclinic
Name:         spring-petclinic
Namespace:    default
Labels:       carto.run/cluster-supply-chain-name=source-to-url
              carto.run/cluster-template-name=config-template
              carto.run/resource-name=app-config
              carto.run/template-kind=ClusterConfigTemplate
              carto.run/workload-name=spring-petclinic
              carto.run/workload-namespace=default
Annotations:  <none>
```

```
Data
====
delivery.yml:
----
apiVersion: serving.knative.dev/v1
kind: Service
metadata:
  name: spring-petclinic
  labels:
    app.kubernetes.io/part-of: tanzu-java-web-app
    apps.tanzu.vmware.com/workload-type: web
    kapp.k14s.io/app: "1638455805474051000"
    kapp.k14s.io/association: v1.5a9384bd7b93ca74ef494c4dec2caa4b
    tanzu.app.live.view: "false"
    app.kubernetes.io/component: run
    carto.run/workload-name: spring-petclinic
```

4. Verify the running Knative application pod by ensuring `labels` shows the newly added label on the Knative application pod:

```
kubectl get pods -o yaml spring-petclinic-00002-deployment-77dbb85c65-cf7rn | g
rep labels
    kapp.k14s.io/original: '{"apiVersion":"carto.run/v1alpha1","kind":"Workloa
d","metadata":{"annotations":{"autoscaling.knative.dev/minScale":"1"},"labels":
{"app.kubernetes.io/part-of":"tanzu-java-web-app","apps.tanzu.vmware.com/worklo
ad-type":"web","kapp.k14s.io/app":"1638455805474051000","kapp.k14s.io/associati
on":"v1.5a9384bd7b93ca74ef494c4dec2caa4b","tanzu.app.live.view":"false"},"nam
e":"spring-petclinic","namespace":"default"},"spec":{"source":{"git":{"ref":{"b
ranch":"main"},"url":"https://github.com/ksankaranara-vmw/spring-petclini
c"}}}}'
```

You can add or override the connector in the `Workload` of your Knative app.

Custom configuration for application actuator endpoints

This topic for developers tells you how to configure the Application Live View connector component to access actuator endpoints for custom settings, such as a different base path. By default, the actuator endpoint for an application is exposed on `/actuator`.

The following table describes the actuator configuration scenarios and the associated labels to use, assuming that the app runs on port `8080`:

management.server.base-path	management.server.port	management.endpoints.web.base-path	server.servlet.context.path	Comments	Connector Configuration
None	None	None	None	Actuators endpoints available at `localhost:8080/actuator`	`tanzu.app.live.view.application.actuator.path=actuator`, `tanzu.app.live.view.application.actuator.port=8080`

management.server.base-path	management.server.port	management.endpoints.web.base-path	server.servlet.context.path	Comments	Connector Configuration
`/path`	`8082`	`/`	None	Actuator endpoints available at `localhost:8082/path`	`tanzu.app.live.view.application.actuator.path=path`, `tanzu.app.live.view.application.actuator.port=8082`
`/path`	`8082`	`/manage/actuator`	None	Actuator endpoints available at `localhost:8082/path/manage/actuator`	`tanzu.app.live.view.application.actuator.path=path/manage/actuator`, `tanzu.app.live.view.application.actuator.port=8082`
None	None	`/`	None	Actuators are deactivated to avoid conflicts	None
None	None	`/manage`	None	Actuator endpoints available at `/manage`	`tanzu.app.live.view.application.actuator.path=manage`, `tanzu.app.live.view.application.actuator.port=8080`
`/path`	`8082`	None	None	Actuator endpoints available at `localhost:8082/path/actuator`	`tanzu.app.live.view.application.actuator.path=path/actuator`, `tanzu.app.live.view.application.actuator.port=8082`
`/`	`8082`	None	None	Actuator endpoints available at `localhost:8082/actuator`	`tanzu.app.live.view.application.actuator.path=actuator`, `tanzu.app.live.view.application.actuator.port=8082`

management.server.base-path	management.server.port	management.endpoints.web.base-path	server.servlet.context.path	Comments	Connector Configuration
None	None	None	`/api`	Actuator endpoints available at `localhost:8080/api/actuator`	`tanzu.app.live.view.application.actuator.path=api/actuator`, `tanzu.app.live.view.application.actuator.port=8080`
`/path`	`8082`	None	`/api`	Actuator endpoints available at `localhost:8082/path/actuator`	`tanzu.app.live.view.application.actuator.path=path/actuator`, `tanzu.app.live.view.application.actuator.port=8082`
`/path`	`8082`	`/manage`	`/api`	Actuator endpoints available at `localhost:8082/path/manage`	`tanzu.app.live.view.application.actuator.path=path/manage`, `tanzu.app.live.view.application.actuator.port=8082`
`/path`	None	`/manage`	`/api`	Actuator endpoints available at `localhost:8080/api/manage`	`tanzu.app.live.view.application.actuator.path=api/manage`, `tanzu.app.live.view.application.actuator.port=8080`
`/path`	None	`/`	`/api`	Actuators are deactivated to avoid conflicts	None
`/path`	`8082`	`/`	`/api`	Actuator endpoints available at `localhost:8082/path`	`tanzu.app.live.view.application.actuator.path=path`, `tanzu.app.live.view.application.actuator.port=8082`

management.server.base-path	management.server.port	management.endpoints.web.base-path	server.servlet.context.path	Comments	Connector Configuration
None	None	`/manage`	`/api`	Actuator endpoints available at `localhost:8080/api/manage`	`tanzu.app.live.view.application.actuator.path=api/manage`, `tanzu.app.live.view.application.actuator.port=8080`

Scaling Knative apps in Tanzu Application Platform

This topic tells you how to use Application Live View when scaling Knative apps or developer workloads in Tanzu Application Platform (commonly known as TAP).

Application Live View is focused on monitoring apps for a `live` window and does not apply to any of the apps that are scaled down to zero. The intended behavior for Knative apps is to keep track of revisions to allow you to rollback easily, but also scale all of the unused revision instances down to zero to keep resource consumption low.

You can configure Knative apps to set `autoscaling.knative.dev/minScale` to `1` so that Application Live View can still observe app instance. This ensures that there is at least one instance of the latest revision, while still scaling down the older instances.

You can configure any app in Tanzu Application Platform using the `Workload` resource. To scale a Knative app, add the annotation `autoscaling.knative.dev/minScale` in the `Workload` and set it to the value you want. For Application Live View to observe an app and have at least one instance of the latest revision, set `autoscaling.knative.dev/minScale = "1"`.

The annotations or labels in the `Workload` get propagated through the Tanzu Application Platform supply chain as follows:

Workload > PodIntent > ConfigMap > Push Config > to repository/registry > git-repository/imagerepository picks the Config from repository/registry > kapp-ctrl deploys and knative runs the config > final pod running on the Kubernetes cluster.

Configure the developer workload in Tanzu Application Platform

The following YAML is an example `Workload` that adds the annotation `autoscaling.knative.dev/minScale = "1"` to set the minimum scale for the `spring-petclinic` app:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  name: spring-petclinic
  namespace: default
  labels:
    app.kubernetes.io/part-of: tanzu-java-web-app
    apps.tanzu.vmware.com/workload-type: web
  annotations:
    autoscaling.knative.dev/minScale: "1"
spec:
  source:
    git:
      ref:
```

```
    branch: main
  url: https://github.com/kdvolder/spring-petclinic
```

Deploy the workload

To deploy the workload, run:

```
kapp -y deploy -n default -a workloads -f workloads.yaml
```

Verify the annotation has propagated through the Supply Chain

To verify the annotation:

1. Verify that the workload build is successful by ensuring that `SUCCEEDED` is set to `True`:

   ```
   kubectl get builds
   NAME                          IMAGE
   SUCCEEDED
   spring-petclinic-build-1      dev.registry.tanzu.vmware.com/app-live-view/test/s
   pring-petclinic-default@sha256:9db2a8a8e77e9215239431fd8afe3f2ecdf09cce8afac565
   dad7b5f0c5ac0cdf     True
   ```

2. Verify the PodIntent of your workload by ensuring `status.template.metadata.annotations` shows the newly added annotation has propagated through the Supply Chain:

   ```
   kubectl get podintents.conventions.carto.run spring-petclinic -oyaml

   status:
     conditions:
     - lastTransitionTime: "2021-12-03T15:14:33Z"
       status: "True"
       type: ConventionsApplied
     - lastTransitionTime: "2021-12-03T15:14:33Z"
       status: "True"
       type: Ready
     observedGeneration: 3
     template:
       metadata:
         annotations:
           autoscaling.knative.dev/minScale: "1"
   ```

3. Verify the ConfigMap was created for the app by ensuring `spec.template.metadata.annotations` shows the newly added annotation has propagated through the Supply Chain:

   ```
   kubectl describe configmap spring-petclinic
   Name:         spring-petclinic
   Namespace:    default
   Labels:       carto.run/cluster-supply-chain-name=source-to-url
                 carto.run/cluster-template-name=config-template
                 carto.run/resource-name=app-config
                 carto.run/template-kind=ClusterConfigTemplate
                 carto.run/workload-name=spring-petclinic
                 carto.run/workload-namespace=default
   Annotations:  <none>

   Data
   ====
   delivery.yml:
   ```

```
---
apiVersion: serving.knative.dev/v1
kind: Service
metadata:
  name: spring-petclinic
  labels:
    app.kubernetes.io/part-of: tanzu-java-web-app
    apps.tanzu.vmware.com/workload-type: web
    kapp.k14s.io/app: "1638455805474051000"
    kapp.k14s.io/association: v1.5a9384bd7b93ca74ef494c4dec2caa4b
    tanzu.app.live.view: "false"
    app.kubernetes.io/component: run
    carto.run/workload-name: spring-petclinic
spec:
  template:
    metadata:
      annotations:
        autoscaling.knative.dev/minScale: "1"
```

4. Verify the running Knative application pod by ensuring `annotations` shows the newly added annotation on the Knative application pod:

```
kubectl get pods -o yaml spring-petclinic-00002-deployment-77dbb85c65-cf7rn | g
rep annotations
  annotations:
    kapp.k14s.io/original: '{"apiVersion":"carto.run/v1alpha1","kind":"Workloa
d","metadata":{"annotations":{"autoscaling.knative.dev/minScale":"1"},"labels":
{"app.kubernetes.io/part-of":"tanzu-java-web-app","apps.tanzu.vmware.com/worklo
ad-type":"web","kapp.k14s.io/app":"1638455805474051000","kapp.k14s.io/associati
on":"v1.5a9384bd7b93ca74ef494c4dec2caa4b","tanzu.app.live.view":"false"},"nam
e":"spring-petclinic","namespace":"default"},"spec":{"source":{"git":{"ref":{"b
ranch":"main"},"url":"https://github.com/ksankaranara-vmw/spring-petclini
c"}}}}'
```

Your Knative app is now set to a minimum scale of one so that Application Live View can observe the instance of the app.

Application Live View on OpenShift

Application Live View must run with a custom SecurityContextConstraint (SCC) to enable compliance with restricted Kubernetes Pod Security Standards on OpenShift. Tanzu Application Platform configures the following SCC for Application Live View back end, Application Live View connector, and Application Live View convention service when you configure the `kubernetes_distribution: openshift` key in the `tap-values.yaml` file.

The following is a `SecurityContextConstraints` specification for Application Live View connector:

```
---
apiVersion: security.openshift.io/v1
kind: SecurityContextConstraints
metadata:
  name: appliveview-connector-restricted-with-seccomp
allowHostDirVolumePlugin: false
allowHostIPC: false
allowHostNetwork: false
allowHostPID: false
allowHostPorts: false
allowPrivilegeEscalation: false
allowPrivilegedContainer: false
allowedCapabilities: null
defaultAddCapabilities: null
fsGroup:
  type: MustRunAs
```

```
priority: null
readOnlyRootFilesystem: false
requiredDropCapabilities:
  - ALL
runAsUser:
  type: MustRunAsNonRoot
seLinuxContext:
  type: MustRunAs
supplementalGroups:
  type: RunAsAny
volumes:
  - configMap
  - downwardAPI
  - emptyDir
  - persistentVolumeClaim
  - projected
  - secret
seccompProfiles:
  - runtime/default
```

The preceding `SecurityContextConstraints` specification is applicable to Application Live View back end and Application Live View convention service as well.

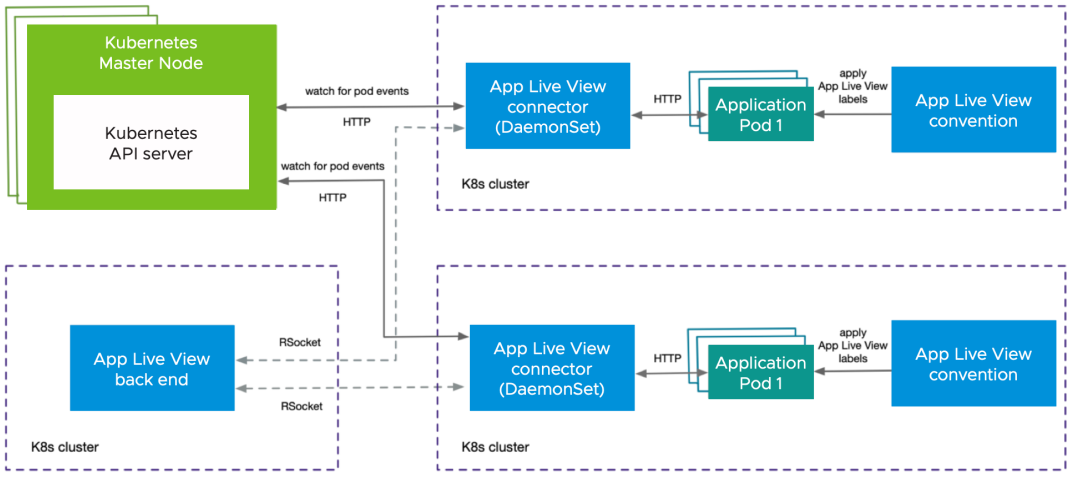
Support for polyglot apps with Application Live View

Application Live View currently supports Spring Boot, Spring Cloud Gateway, and Steeltoe apps.

- To enable Application Live View on Spring Boot and Spring Cloud Gateway apps, see Enable Application Live View for Spring Boot apps.
- To enable Application Live View on Steeltoe apps, see Enable Application Live View for Steeltoe apps.

Application Live View internal architecture

This topic describes the architecture of Application Live View and its components. You can deploy this system on a Kubernetes stack and use it to monitor containerized apps on hosted cloud platforms or on-premises.



Component overview

Application Live View includes the following components as shown in the architecture diagram:

- **Application Live View back end**

  Application Live View back end is the central server component that contains a list of registered apps. It provides a REST API that fetches the actuator data for the applications. The Application Live View UI plug-in, as part of Tanzu Developer Portal, queries this back-end REST API to get live actuator information for the pod.

- **Application Live View connector**

  Application Live View connector is the component responsible for discovering the app pods running on the Kubernetes cluster and registering the instances to the Application Live View back end for it to be observed. The Application Live View connector is also responsible for proxying the actuator queries to the app pods running in the Kubernetes cluster. The actuator data is then displayed in the Application Live View UI plug-in as part of Tanzu Developer Portal.

  You can deploy Application Live View connector in three modes:

  - `Deployment`: Deploy as a Kubernetes Deployment to discover apps running across all namespaces of a Kubernetes cluster. This is the default mode of Application Live View connector.
  - `Cluster access`: Deploy as a Kubernetes DaemonSet to discover apps across all namespaces running in a worker node of a Kubernetes cluster.
  - `Namespace scoped`: Deploy as a Kubernetes Deployment to discover apps running within a namespace across worker nodes of Kubernetes cluster.

- **Application Live View convention server**

  This component provides a webhook handler for the Tanzu convention controller. The webhook handler is registered with Tanzu convention controller. The webhook handler detects supply-chain workloads running a Spring Boot. Such workloads are annotated automatically to enable Application Live View to monitor them. Download and install the Application Live View conventions Webhook component with Tanzu Application Platform.

- **Application Live View APIServer**

  Application Live View APIServer generates a unique token when a user receives access validation to a pod. The Application Live View connector component verifies the token against the Application Live View APIServer before proxying the actuator data from the application. This ensures that the actuator data is secured and only the user who has valid access to view the live information for the pod can retrieve the data.

Design flow

As illustrated in the diagram, the applications run by the user are registered with Application Live View back end by using Application Live View connector. After the application is registered, the Application Live View back end offers the ability to serve actuator data from that registered application through its REST API. Application Live View back end proxies the call to the connector for querying actuator endpoint information.

Application Live View connector, which is a lean model, uses specific labels to discover apps across cluster or namespace. Application Live View connector serves as the connection between running applications and Application Live View back end. Application Live View connector communicates with the Kubernetes API server requesting events for pod creation and termination, and then filters out the events to find the pod of interest by using labels. Then Application Live View connector registers the filtered app instances with Application Live View back end.

Application Live View back end and Application Live View connector communicate through a bidirectional RSocket channel. Application Live View connector is implemented as a Java/Spring

Boot application and runs as a native executable file (Spring Native using GraalVM). Application Live View connector runs as a Deployment by default in the cluster.

Application Live View conventions identifies PodIntents for pods that can serve actuator data and annotates the PodSpec with application-specific labels. Those labels are used by the Application Live View connector to identify running pods that can serve actuator data. Application Live View conventions reads the image metadata to determine the application-specific labels applied on the PodSpec.

Troubleshoot Application Live View

This topic provides information to help you troubleshoot Application Live View.

App is not visible in Application Live View UI

Symptom:

Your app is not visible in the Application Live View UI.

Solution:

The connector component is responsible for discovering the app and registering it with Application Live View.

To troubleshoot, confirm the following:

1. The app must be a Spring Boot Application.
2. Confirm that an instance of a connector is located in the same namespace as your app.

   ```
   kubectl get pods -n NAMESPACE | grep connector
   ```

   Where `NAMESPACE` is the name of the namespace that your app is located in.
3. Confirm that the actuator endpoints are enabled for your app as follows:

   ```
   management.endpoints.web.exposure.include: "*"
   ```
4. Confirm that you have included the following labels within your app deployment YAML file:

   ```
   tanzu.app.live.view="true"
   tanzu.app.live.view.application.name="APP-NAME"
   ```

   Where `APP-NAME` is the name of your app.
5. Confirm that the Convention Service workload YAML file does not contain property `management.endpoints.web.exposure.include` overrides.

See also:

- App is not visible in Application Live View UI with actuator endpoints enabled
- The UI does not show any information for an app with actuator endpoints exposed at root

---

App is not visible in Application Live View UI with actuator endpoints enabled

Symptom:

Your app is not visible in Application Live View UI, but the actuator endpoints are enabled.

Solution:

To troubleshoot:

1. Check the port on which actuator endpoints are configured. By default, they are enabled on the application port. If they are configured on a port different from the application port, set the labels in your app deployment YAML file as follows:

   ```
   tanzu.app.live.view.application.port: "APPLICATION-PORT"
   tanzu.app.live.view.application.actuator.port: "ACTUATOR-PORT"
   ```

   Where:

   - `APPLICATION-PORT` is the application port.
   - `ACTUATOR-PORT` is the actuator port.

2. Check the path on which the app and actuator endpoints are configured. If they are configured on a different paths, set the labels in your app deployment YAML file as follows:

   ```
   tanzu.app.live.view.application.path: "APPLICATION-PATH"
   tanzu.app.live.view.application.actuator.path: "ACTUATOR-PATH"
   ```

   Where:

   - `APPLICATION-PATH` is the application port.
   - `ACTUATOR-PATH` is the actuator port.

The UI does not show any information for an app with actuator endpoints exposed at root

Symptom:

Your app has actuator endpoints exposed at root and the UI does not show any information.

Cause:

Application Live View cannot display the app details when the app is exposing the actuator endpoint on root (`/`) . This is due to conflict in the actuator context path and app default context path.

No information shown on the Health page

Symptom:

The app shows up in Application Live View UI, but the **Health** page does not show details of health.

Solution:

The information exposed by the health endpoint depends on the `management.endpoint.health.show-details` property. This must be set to `always` as as follows:

```
management.endpoint.health.show-details: "always"
```

Stale information in Application Live View

Symptom:

You can find your app in the UI, but it is an old instance that no longer exists while the new instance doesn't show up yet.

Solution:

To troubleshoot:

1. View the Application Live View connector pod logs to see if the connector is sending updates to the back end.
2. Delete the connector pod to recreate it by running:

   ```
   kubectl -n app-live-view-connector delete pods -l=name=application-live-view-connector
   ```

Unable to find CertificateRequests in Application Live View convention

Symptom:

The certificate request is missing for certificate `app-live-view-conventions/appliveview-webhook-cert`.

Solution:

To troubleshoot:

1. Run `kubectl get certificaterequest -A` to see if the certificate request is missing for Application Live View convention.
2. Delete the secret `appliveview-webhook-cert` that corresponds to the certificate in the `app-live-view-conventions` namespace by running:

   ```
   kubectl delete secret appliveview-webhook-cert -n app-live-view-conventions
   ```

   This recreates the certificate request and updates the corresponding certificate.

No live information for pod with ID

Symptom:

In Tanzu Developer Portal, you receive the error `No live information for pod with id`.

Cause:

This might happen because of stale information in Application Live View because it is an old instance that no longer exists while the new instance doesn't show up yet.

Solution:

The workaround is to delete the connector pod so it is re-created by running:

```
kubectl -n app-live-view-connector delete pods -l=name=application-live-view-connector
```

Cannot override the actuator path in the labels

Symptom:

You are unable to override the actuator path in the labels as part of the workload deployment.

Cause:

The changes to add or override the labels or annotations in the `Workload` are in progress. The changes from the `Workload` must be propagated up through the supply chain for the PodIntent to

see the new changes.

Cannot configure SSL in appliveview-connector

Symptom:

This might be because `sslDeactivated` flag in the values YAML file does not accept values without quotes.

Cause:

The `sslDeactivated` Boolean flag is treated as a string in the Kubernetes YAML file.

Solution:

You must specify the value within double quotation marks for the configuration to be picked up.

Verify the labels in your workload YAML file

To verify that the labels in your workload YAML file are working:

1. Verify the app live view convention webhook is running properly by running:

   ```
   kubectl get pods -n app-live-view | grep webhook
   ```

2. Verify the conventions controller is running properly by running:

   ```
   kubectl get pods -n conventions-system
   ```

3. Verify that the conventions are applied properly to the PodSpec by running:

   ```
   kubectl get podintents.conventions.carto.run WORKLOAD-NAME -oyaml
   ```

   Where `WORKLOAD-NAME` is the name of your workload.

   If everything works correctly, the status will contain a transformed template that includes the labels added as part of your workload YAML file. For example:

   ```
   status:
   conditions:
   - lastTransitionTime: "2021-10-26T11:26:35Z"
     status: "True"
     type: ConventionsApplied
   - lastTransitionTime: "2021-10-26T11:26:35Z"
     status: "True"
     type: Ready
   observedGeneration: 1
   template:
     metadata:
       annotations:
         conventions.carto.run/applied-conventions: |-
           appliveview-sample/app-live-view-connector
           appliveview-sample/app-live-view-appflavours
           appliveview-sample/app-live-view-systemproperties
       labels:
         tanzu.app.live.view: "true"
         tanzu.app.live.view.application.flavours: spring-boot
         tanzu.app.live.view.application.name: petclinic
     spec:
       containers:
       - env:
         - name: JAVA_TOOL_OPTIONS
   ```

```
        value: -Dmanagement.endpoint.health.show-details=always -Dmanagement.en
dpoints.web.exposure.include=*
    image: index.docker.io/kdvolder/alv-spring-petclinic:latest@sha256:1aa7bd22
8137471ea38ce36cbf5ffcd629eabeb8ce047f5533b7b9176ff51f98
    name: workload
    resources: {}
```

Override labels set by the Application Live View convention service

It is not possible to override the labels set by the Application Live View convention service for the workload deployment in Tanzu Application Platform. The labels `tanzu.app.live.view`, `tanzu.app.live.view.application.flavours` and `tanzu.app.live.view.application.name` cannot be overridden. The default values set by the Application Live View convention server are used.

However, if you want to override `management.endpoints.web.exposure.include` or `management.endpoint.health.show-details`, you can override these environment properties in `application.properties` or `application.yml` in the Spring Boot Application before deploying the workload in Tanzu Application Platform. Environment properties updated in your app take precedence over the default values set by Application Live View convention server.

Configure labels when management.endpoints.web.base-path and management.server.port are set

If the custom actuator context path is configured as follows:

```
management.endpoints.web.base-path=/manage
management.server.port=8085
```

Configure the connector as follows:

```
tanzu.app.live.view.application.actuator.path=/manage   (manage is the custom actuator
path set on the application)
tanzu.app.live.view.application.actuator.port=8085   (8085 is the custom management se
rver port set on the application)
```

Uninstall Application Live View

This topic tells you how to uninstall Application Live View from Tanzu Application Platform (commonly known as TAP).

To uninstall the Application Live View back end, Application Live View connector, and Application Live View convention server, run:

```
tanzu package installed delete appliveview -n tap-install
tanzu package installed delete appliveview-connector -n tap-install
tanzu package installed delete appliveview-conventions -n tap-install
```

Overview of Application Single Sign-On for VMware Tanzu® 5.0

Application Single Sign-On for VMware Tanzu® (AppSSO) provides APIs for curating and consuming a “Single Sign-On as a service” offering on Tanzu Application Platform.

To get started with Application Single Sign-On, see Get started with Application Single Sign-On.

With AppSSO, Service Operators can configure and deploy authorization servers. Application Operators can then secure their Workloads with these authorization servers to provide Single Sign-On to their end-users.

AppSSO allows integrating authentication and authorization decisions early in the software development and release life cycle. It provides a seamless transition for workloads from development to production when including Single Sign-On solutions in your software.

It's easy to get started with AppSSO, deploy an authorization server with static test users, and eventually progress to multiple authorization servers of production-grade scale with token key rotation, multiple upstream identity providers, configured secure storage, and client restrictions.

AppSSO's authorization server is based on the Spring Authorization Server project. For more information, see Spring documentation.

Document organization

The Application Single Sign-On component documentation consists of the following subsections that relate to what you want to achieve:

- Get started: To understand the basics of getting started with Application Single Sign-On.
- How-to guides: To find a set of steps to solve a specific problem acting as a certain user persona.
- Concepts: To gain a deeper understanding of Application Single Sign-On.
- Reference: To find specific information such as Application Single Sign-On's APIs.

Tutorials and concepts are of most relevance when studying, while how-to guides and reference material are of most use while working.

The following is a selection of useful topics on offer:

For application developers:

- Application Single Sign-On for App Operators

For service operators:

- Application Single Sign-On for Service Operators

For platform operators:

- Application Single Sign-On for Platform Operators

For everyone:

- Levels of consumption for Application Single Sign-On

Overview of Application Single Sign-On for VMware Tanzu® 5.0

Application Single Sign-On for VMware Tanzu® (AppSSO) provides APIs for curating and consuming a "Single Sign-On as a service" offering on Tanzu Application Platform.

To get started with Application Single Sign-On, see Get started with Application Single Sign-On.

With AppSSO, Service Operators can configure and deploy authorization servers. Application Operators can then secure their Workloads with these authorization servers to provide Single Sign-On to their end-users.

AppSSO allows integrating authentication and authorization decisions early in the software development and release life cycle. It provides a seamless transition for workloads from development to production when including Single Sign-On solutions in your software.

It's easy to get started with AppSSO, deploy an authorization server with static test users, and eventually progress to multiple authorization servers of production-grade scale with token key rotation, multiple upstream identity providers, configured secure storage, and client restrictions.

AppSSO's authorization server is based on the Spring Authorization Server project. For more information, see Spring documentation.

Application Single Sign-On concepts

This topic tells you about the following concepts about Application Single Sign-On (commonly called AppSSO):

- The three levels of AppSSO consumption
- Grant types
- Token signatures

Levels of consumption for Application Single Sign-On

This topic tells you about the three levels of consuming Application Single Sign-On (commonly called AppSSO) services and explains the when and why for selecting a specific level over another.

VMware recommends using `ClassClaim` to consume an Application Single Sign-On service. However, there might be situations where the lower level `WorkloadRegistration` or `ClientRegistration` are a better fit.

At its core, the process of consuming Application Single Sign-On involves obtaining client credentials for an authorization server and loading them into a running workload. This process consists of the following steps:

1. Define your environment-independent OAuth2 client configurations, for example, client authentication method, scopes, and so on.
2. Define your OAuth2 client's redirect URIs.
3. Specify the authorization server that you want credentials for.
4. Create a resource that expresses your configuration.
5. Mount the client credentials into a workload.

Each of the following levels gradually takes away some of these steps by distributing them across APIs. As a result, each persona becomes responsible only for the tasks within their domain:

- **Platform operators** manage the installations of Tanzu Application Platform and Application Single Sign-On.
- **Service operators** curate and manage Application Single Sign-On services.
- **Application operators** consume Application Single Sign-On services from their workloads.

Level 1: ClientRegistration

The lowest-level and most general client API Application Single Sign-On offers is `ClientRegistration`. It holds all relevant OAuth2 client configurations. However, it requires fully qualified redirect URIs and targets its host `AuthServer` by using a label selector.

A hypothetical, fully-configured `ClientRegistration` is provided as follows:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: ClientRegistration
metadata:
  name: my-clientregistration
  namespace: my-namespace
spec:
  authServerSelector:
    matchLabels:
      sso.apps.tanzu.vmware.com/env: staging
      sso.apps.tanzu.vmware.com/ldap: ""
  redirectURIs:
    - https://profile.shop.staging.example.com/login
    - https://profile.shop.example.com/login
    - http://profile.shop.dev.example.com/login
  scopes:
    - name: openid
    - name: email
    - name: profile
    - name: roles
    - name: coffee.make
      description: bestows the ultimate power
  authorizationGrantTypes:
    - client_credentials
    - authorization_code
    - refresh_token
  clientAuthenticationMethod: client_secret_basic
  requireUserConsent: true
```

To specify redirect URIs for an application running on Tanzu Application Platform, you must know its scheme and FQDN in advance. For example, your redirect URI must be `https://profile.shop.example.com/login`. However, the various components of a redirect URI are controlled by multiple personas such as platform operators and application operators.

In most cases, platform operators control how FQDNs are templated and whether TLS is used. For the redirect URI, platform operators have full control over all the elements in

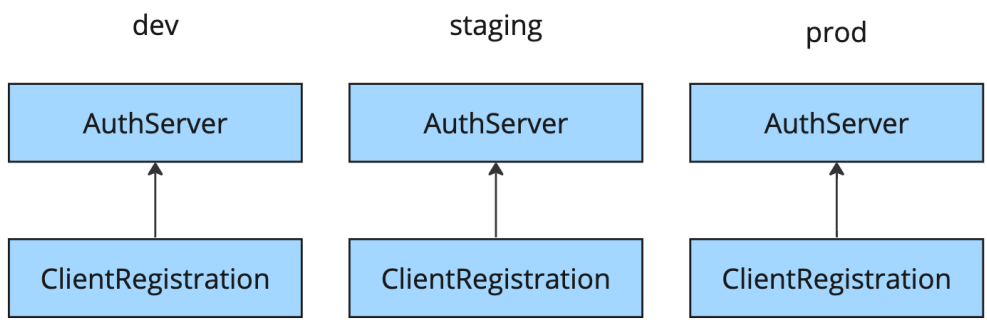
`https://profile.shop.example.com`, which include TLS, the domain name template, and the top-level ingress domain. These configurations can vary across different environments. Therefore, in an alternative environment, setting `https://profile.shop.staging.example.com` can be the appropriate choice.

Application operators control the application's code and its paths. Specifically, they are responsible for managing the `/login` path within the redirect URI. This path is unlikely to change and remains the same regardless of the target environment.

As a result, in a given environment, application operators might not know the FQDN and scheme. In such cases, they must seek assistance from platform operators to obtain this information. On the other hand, platform operators aim to change settings without being coupled to the application operator's configuration.

A `ClientRegistration` must uniquely identify an `AuthServer` by using a label selector. Service operators are in charge of managing `AuthServer`. The labels for a resource are not required to be consistent across environments. However, this can create complications for application operators. Label selectors are considered an advanced concept, and application operators might not be familiar with the specific labels associated with their desired `AuthServers`. It might be worth considering restricting the visibility of `AuthServers` to application operators because it falls within the domain of service operators.

All these factors make it challenging for application operators to use the same `ClientRegistration` across different environments.



In conclusion, although `ClientRegistration` offers flexibility, it is also complex and not easily transferable between different environments. It combines the responsibilities of multiple personas, making it a less straightforward solution.

Level 2: WorkloadRegistration

A higher-level abstraction over `ClientRegistration` is `WorkloadRegistration`. It is similar to `ClientRegistration` except for one major difference: it templates redirect URIs.

Instead of providing full redirect URIs, a `WorkloadRegistration` receives absolute redirect paths. Platform operators configure the template for redirect URIs while installing Tanzu Application Platform, which includes Application Single Sign-On. They configure this template to match the template for workload domains.

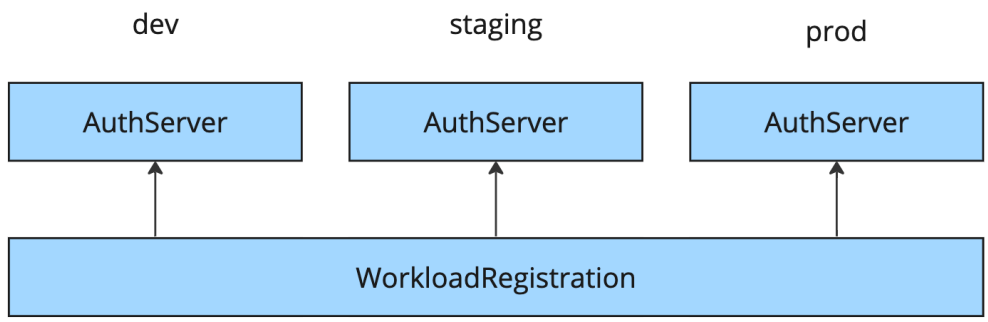
The following is a hypothetical `WorkloadRegistration` example. It is similar to the earlier `ClientRegistration` example, except that it specifies the redirect paths. In its truncated `status`, you can observe the templated redirect URIs.

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: WorkloadRegistration
metadata:
  name: my-workloadregistration
  namespace: my-namespace
spec:
  authServerSelector:
    matchLabels:
      sso.apps.tanzu.vmware.com/env: staging
      sso.apps.tanzu.vmware.com/ldap: ""
  redirectPaths:
    - /login
  workloadRef:
    name: my-workload
    namespace: my-namespace
  scopes:
    - name: openid
    - name: email
    - name: profile
    - name: roles
    - name: coffee.make
      description: bestows the ultimate power
  authorizationGrantTypes:
    - client_credentials
    - authorization_code
    - refresh_token
  clientAuthenticationMethod: client_secret_basic
  requireUserConsent: true
status:
  workloadDomainTemplate: "{{.Name}}.{{.Namespace}}.{{.Domain}}"
  redirectURIs:
    - https://my-workload.my-namespace.example.com/login
```

The additional `spec.workloadRef` provides templates for the redirect URIs.

Templating redirect URIs template decouples the application operators from the platform operators. Now the application operator only needs to provide the absolute redirect paths, which are consistent across environments. The platform operators can configure domain templates, ingress domains, and TLS as they see fit, and rest assured that settings are updated without interruption.

However, `WorkloadRegistration` still requires matching an `AuthServer` by the label selector. That means application operators and service operators are still coupled.



In summary, `WorkloadRegistration` is less flexible, but it is portable across environments when redirect URIs can be templated. However, it still mixes the concerns of personas.

Level 3: ClassClaim (recommended)

The final level is to obtain client credentials by claiming them from an Application Single Sign-On service. Unlike the previous levels that directly interacted with `AuthServer` resources, this level abstracts this part away with Services Toolkit's APIs. This eliminates the last remaining coupling between application operators and service operators.

You can pair Application Single Sign-On's `ClusterWorkloadRegistrationClass` with an `AuthServer` as a claimable service. These two APIs allow the service operators to manage the entire life cycle of an Application Single Sign-On service offering.

A `ClusterWorkloadRegistrationClass` exposes an `AuthServer` as a claimable service by creating a Services Toolkit `ClusterInstanceClass` and defining a blueprint `WorkloadRegistration`. This blueprint allows service operators to record the correct label selector for the `AuthServer`, which eliminates application operators' concerns.

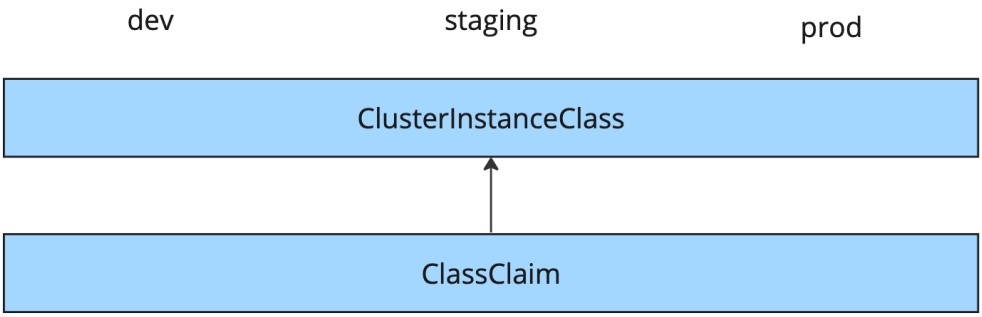
Credentials for a service are requested by using Services Toolkit's general-purpose `ClassClaim` API. A `ClassClaim` identifies a `ClusterInstanceClass` and it carries parameters that further describe the request. For Application Single Sign-On services, the parameters are essentially the trimmed `spec` of a `WorkloadRegistration`.

With the Tanzu Service CLI, application operators can discover and consume services in a self-service style. Commonly, this is how service operators provide all the services required for application teams to run their applications. This includes databases, queues, in-memory stores, and single sign-on by Application Single Sign-On.

The following is a hypothetical `ClassClaim` for an Application Single Sign-On service called `sso`:

```
---
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ClassClaim
metadata:
  name: my-client-credentials
  namespace: my-namespace
spec:
  classRef:
    name: sso
  parameters:
    workloadRef:
      name: sample-workload
    redirectPaths:
      - /login
    scopes:
      - name: openid
      - name: email
      - name: profile
      - name: roles
      - name: coffee.make
        description: bestows the ultimate power
    authorizationGrantTypes:
      - client_credentials
      - authorization_code
      - refresh_token
    clientAuthenticationMethod: client_secret_basic
    requireUserConsent: true
```

This level completely decouples all three personas by providing them with APIs to fulfill their jobs.



In summary, `ClassClaim` is less flexible but it is portable across environments when the redirect URIs can be templated. It completely decouples the concerns of personas. Additionally, offering a single resource for application operators to manage.

Summary

As an application operator, if your workload and its associated resources must be deployed across multiple environments, `ClassClaim` offers you the highest degree of portability, as long as the redirect URIs of your workload can be templated. In this case, consuming an Application Single Sign-On service only requires a single resource, a `ClassClaim`.

If you require control over the template for your workload's redirect URIs, `WorkloadRegistration` offers the desired flexibility. However, this flexibility comes with the cost of matching an `AuthServer` with a label selector. In situations where you want to consume the Application Single Sign-On service with such a setup, it requires multiple resources: a `WorkloadRegistration` and a `ResourceClaim`.

If your workload's redirect URIs cannot be templated and portability is not a concern, `ClientRegistration` offers the necessary flexibility. However, this flexibility comes at the cost of having to match an `AuthServer` with a label selector. Depending on your setup, consuming AppSSO requires multiple resources: a `ClientRegistration` and a `ResourceClaim`.

In conclusion, VMware recommend to use `ClassClaim` whenever possible.

Configure grant types

This topic tells you how to configure grant types for Application Single Sign-On (commonly called AppSSO).

Apps use grant types or flows to get an access token on behalf of a user. If not included, the default grant type is `['client_credentials']`. You must include these grant types in the `authorizationGrantTypes` property list in the Client Registration.

To register a client/application, apply the `yaml` with your specifications to your cluster `kubectl apply -f <path-to-your-yaml>`.

Topics

- Client Credentials Grant
- Authorization Code Grant

Client Credentials Grant Type

This grant type allows an application to get an access token for resources about the client itself, rather than a user.

Dynamic Client Registration (via `ClientRegistration` custom resource):

```
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: ClientRegistration
metadata:
  name: <your client name>
spec:
  authorizationGrantTypes:
    - client_credentials
  # ...
```

Note

Ensure that you are able to retrieve a token through your setup

1. Apply your ClientRegistration

   ```
   kubectl apply -f <path-to-the-clientregistration-yaml>
   ```

2. Verify your `ClientRegistration` was created

   ```
   kubectl get clientregistrations
   ```

   –> you should see a `ClientRegistration` with the name you provided

3. Verify your Secret was created

   ```
   kubectl get secrets
   ```

   –> you should see a Secret with that same name you provided for the `ClientRegistration`

4. Get the client secret and decode it

   ```
   kubectl get secret <your-client-registration-name> -o jsonpath="{.data.client-secret}" | base64 -d
   ```

5. Get the client id (or get it from your configuration)

   ```
   kubectl get secret <your-client-registration-name> -o jsonpath="{.data.client-id}" | base64 -d
   ```

6. Request token

   ```
   curl -X POST <AUTH-DOMAIN>/oauth2/token \
    -d "grant_type=client_credentials" \
    -u "YOUR_CLIENT_ID:DECODED_CLIENT_SECRET"
   ```

Authorization Code Grant Type

This grant type allows clients to exchange this code for access tokens.

Dynamic Client Registration (via `ClientRegistration` custom resource):

```
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: ClientRegistration
metadata:
  name: <your client name>
```

```
spec:
  authorizationGrantTypes:
    - authorization_code
  scopes:
     - openid
  # ...
```

Note

Ensure that you are able to retrieve a token through your setup

Ensure there is an Identity Provider configured

1. Get your authserver's label name

   ```
   kubectl get authserver sso4k8s -o jsonpath="{.metadata.labels.name}"
   ```

2. Apply this sample ClientRegistration (read more about ClientRegistrations

   The following is an example ClientRegistration that will work in this setup. The required scopes are `openid, email, profile, roles`. The redirect URI here has been set to match that of `oauth2-proxy`.

   ```
   apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
   kind: ClientRegistration
   metadata:
    name: oauth2-proxy-client
    namespace: <your-namespace>
   spec:
    authServerSelector:
    matchLabels:
      name: <your-authserver-label-name>
    authorizationGrantTypes:
      - client_credentials
      - authorization_code
    requireUserConsent: false
    redirectURIs:
      - http://127.0.0.1:4180/oauth2/callback
    scopes:
      - name: openid
      - name: email
      - name: profile
      - name: roles
   ```

   ```
   kubectl apply -f <path-to-the-clientregistration-yaml>
   ```

3. Verify your `ClientRegistration` was created

   ```
   kubectl get clientregistrations
   ```

   –> you should see a `ClientRegistration` with the name you provided

4. Verify your Secret was created

   ```
   kubectl get secrets
   ```

   –> you should see a Secret with that same name you provided for the `ClientRegistration`

5. Get the client secret and decode it

```
CLIENT_SECRET=$(kubectl get secret <your-client-registration-name> -o jsonpath
="{.data.client-secret}" | base64 -d)
```

6. Get the client id (or get it from your configuration)

```
CLIENT_ID=$(kubectl get secret <your-client-registration-name> -o jsonpath="{.d
ata.client-id}" | base64 -d)
```

7. Get the issuer uri

```
ISSUER_URI=$(kubectl get secret <your-client-registration-name> -o jsonpath="{.
data.issuer-uri}" | base64 -d)
```

8. Use the oauth2-proxy to spin up a quick trial run of the configured Authserver and run it with docker.

```
docker run -p 4180:4180 --name oauth2-proxy bitnami/oauth2-proxy:latest \
--oidc-issuer-url "$ISSUER_URI" \
--client-id "$CLIENT_ID" \
--insecure-oidc-skip-issuer-verification true \
--client-secret "$CLIENT_SECRET" \
--cookie-secret "0000000000000000" \
--http-address "http://:4180" \
--provider oidc \
--scope "openid email profile roles" \
--email-domain='*' \
--insecure-oidc-allow-unverified-email true \
--upstream "static://202" \
--oidc-groups-claim "roles" \
--oidc-email-claim "sub" \
--redirect-url "http://127.0.0.1:4180/oauth2/callback"
```

> **Note**
>
> Ensure that your issuer URL does not resolve to `127.0.0.1`.

9. Check your browser at `127.0.0.1:4180` to see if your configuration allows you to sign in.

   You should see a message that says “Authenticated”.

About token signatures

This topic tells you about the concept of token signatures.

Token signature 101

Token signature keys are used by an `AuthServer` to sign JSON Web Tokens (JWTs), produce a JWS Signature and attach it to the JOSE Header of a JWT. The client application can then verify the JWT signature.

A private key signs a JWT. A public key verifies the signature of a signed JWT.

The sign-and-verify mechanism serves multiple security purposes:

- **Authenticity**: signature verification ensures that the issuer of the JWT is from a source that is advertised.
- **Integrity**: signature verification ensures that the JWT has not been altered in transit or during its issued lifetime. Integrity is a foundational pillar of the CIA triad concept in

Information Security.

- **Non-repudiation**: signature verification ensures that the authorization server that signed the JWT cannot deny that they have signed it after its issuance (granted that the signing key that signed the JWT is available).

AppSSO only supports the `RS256` algorithm for signing tokens. For more information, see JSON Web Algorithms (JWA) documentation.

Token signature of an `AuthServer`

You must configure token signatures for `AuthServer`. An `AuthServer` receives its keys under `spec.tokenSignature`. For example:

```
spec:
  tokenSignature:
    signAndVerifyKeyRef:
      name: sample-token-signing-key
    extraVerifyKeyRefs:
      - name: sample-token-verification-key-1
      - name: sample-token-verification-key-2
```

There can only be **one** token signing key `spec.tokenSignature.signAngVerifyKeyRef` at any given time, and arbitrarily many token verification keys `spec.tokenSignature.extraVerifyKeyRefs`. The token signing key is used to sign and verify actively issued JWTs in circulation, whereas token verification keys are used to verify issued JWTs signatures. Token verification keys are thought to be previous token signing keys but have been rotated into verify only mode as a rotation mechanism measure, and can potentially be slated for eviction at a predetermined time.

The `AuthServer` serves its public keys at `{spec.issuerURI}/oauth2/jwks`. For example:

```
$ curl -s authserver-sample.default/oauth2/jwks | jq
{
  "keys": [
    {
      "kty": "RSA",
      "e": "AQAB",
      "kid": "sample-token-signing-key",
      "n": "0iCinir7sWKZE_3QXq4eTub_GU-lvdAKFI9dzDlwX7XZwwSERuzzQQ_Fs7i9djMl5bpv2ma_3Z

> Changes to `spec.tokenSignature.signAngVerifyKeyRef` have immediate effects.

As a service operator, you have control over which keys are used for certain purposes. For more information, see Manage token signature keys for Application Single Sign-On.

Get Started with Application Single Sign-On

This topic tells you about concepts important to getting started with Application Single Sign-On (commonly called AppSSO).

Use this topic to learn how to:

1. Curate an AppSSO service offering.
2. Claim credentials.
3. Deploy your workload.

After completing these steps, you can proceed with securing a workload. For more information, see Secure a workload with Application Single Sign-On.

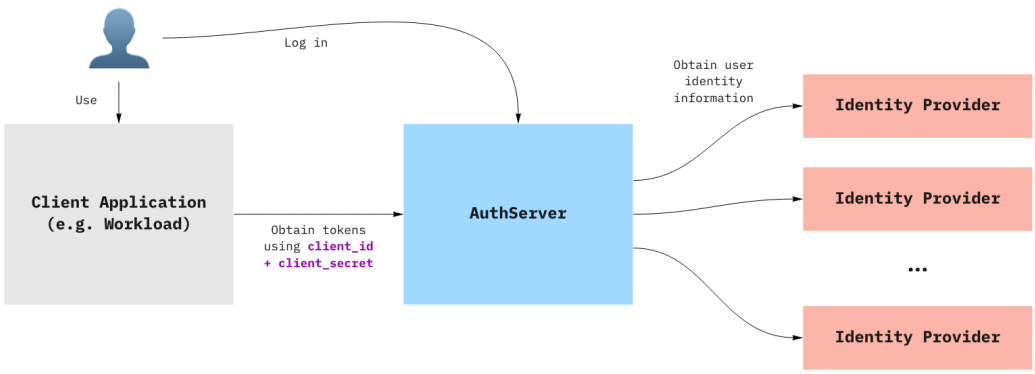
Prerequisites

To get start with Application Single Sign-On, you must:

- Install Application Single Sign-On on your Tanzu Application Platform cluster. For more information, see Install Application Single Sign-On.
- Install the Tanzu CLI on your machine and connect to a Tanzu cluster.

Key concepts

At the core of Application Single Sign-On is the concept of the Authorization Server, outlined by the AuthServer custom resource. Service Operators create those resources to provision running Authorization Servers, which are OpenID Connect Providers. They issue ID Tokens to the client applications, which contain identity information about the end user, such as email, first name, last name and so on.



The following steps outline how a client application uses an `AuthServer` to authenticate an end-user:

1. The end-user visits the client application.
2. The client application redirects the end-user to the `AuthServer`, with an OAuth2 request.
3. The end-user logs in with the `AuthServer` by using an external identity provider, for example, Google or Azure AD.
    1. The identity providers are set up by Service Operators.
    2. `AuthServer`s use various protocols to obtain identity information about the user, such as OpenID Connect, SAML, or LDAP, which might require additional redirects.
4. The `AuthServer` redirects the end-user to the client application with an authorization code.
5. The client application communicates with the `AuthServer` to receive an `id_token`.
    1. The client application does not know how the `AuthServer` collected identity information. It only receives the identity information as an `id_token`.

ID Tokens are JSON Web Tokens containing standard claims about the identity of the user, for example, name or email, and standard claims about the token itself, for example, “expires at” or “audience”. Here is an example of an `id_token` issued by an Authorization Server:

```
{
        "iss": "https://appsso.example.com",
        "sub": "213435498y",
        "aud": "my-client",
        "nonce": "fkg0-90_mg",
        "exp": 1656929172,
        "iat": 1656928872,
        "name": "Jane Doe",
        "given_name": "Jane",
        "family_name": "Doe",
        "email": "jane.doe@example.com",
        "roles": [
                "developer",
                "org-user"
        ]
}
```

`roles` claim is included in an `id_token` only if user roles are mapped and the `roles` scope is requested. For more information about mapping for OpenID Connect, LDAP and SAML, see:

- OpenID external groups mapping
- LDAP external groups mapping
- SAML (experimental) external groups mapping

ID Tokens are signed by the `AuthServer` by using Token signature keys. Client applications can verify their validity by using the `AuthServer`’s public keys.

Curate an AppSSO service offering

This section tells you how to provision an `AuthServer` for Application Single Sign-On. Use this topic to learn how to:

1. Discover the existing Application Single Sign-On service offerings in your cluster.
2. Set up your first `ClusterUnsafeTestLogin`.
3. Ensure the `AuthServer` is running and users can log in.

Prerequisites

You must install and correctly configure Application Single Sign-On on your Tanzu Application Platform cluster.

Application Single Sign-On is installed with the `run`, `iterate`, and `full` profiles. No extra steps are required.

To verify Application Single Sign-On is installed on your cluster, run:

```
tanzu package installed list -A | grep "sso.apps.tanzu.vmware.com"
```

For more information about the Application Single Sign-On installation, see Install Application Single Sign-On.

Discover the existing Application Single Sign-On service offerings

The Application Single Sign-On login servers are a consumable service offering in Tanzu Application Platform. The `ClusterWorkloadRegistrationClass` represents these service offerings.

In your Kubernetes cluster, run the following command:

```
tanzu service class list
```

If there is not a login offering you want to connect to, you must create your own.

Caution

The `AuthServer` example uses an unsafe testing-only identity provider. Never use it in production environments. For more information about the identity providers, see Identity providers.

Set up your first `ClusterUnsafeTestLogin`

In a non-poduction environment, `ClusterUnsafeTestLogin` is the recommended way to get started with Application Single Sign-On.

```
cat <<EOF | kubectl apply -f -
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: ClusterUnsafeTestLogin
metadata:
  name: my-login
EOF
```

Verify that your `AuthServer` is running

To see the service offering, run:

```
tanzu service class list
```

Expect to see the following output:

```
NAME                          DESCRIPTION
my-login  Login by AppSSO - user:password - UNSAFE FOR PRODUCTION!
```

Caution

> This login offering is not safe for production because it hard codes the user and password.

You can wait for the `ClusterUnsafeTestLogin` to be ready by running:

```
kubectl wait --for=condition=Ready clusterUnsafeTestLogin my-login
```

Alternatively, you can inspect your `ClusterUnsafeTestLogin` like any other resource:

```
kubectl get clusterunsafetestlogin.sso.apps.tanzu.vmware.com --all-namespaces
```

Expect to see the following output:

```
NAME       ISSUER URI                           STATUS
my-login   http://unsafe-my-login.appsso.<...>  Ready
```

You can visit the login page by using the `ISSUER URI`.

Claim credentials

Now that you have an Application Single Sign-On service offering. The next step is to create a `ClassClaim`, which creates consumable credentials for your workload, and allows your workload to connect to the login service offering by using the credentials.

Select your preferred login offering from the available options:

```
tanzu service class list
```

If there are none available, you can create one yourself:

```
tanzu service class-claim create my-workload \
  --class my-login \
  --parameter workloadRef.name=appsso-starter-java \
  --parameter redirectPaths='["/login/oauth2/code/appsso-starter-java"]'
```

The `redirectPaths` is the login redirect within your application. This example deploys a minimal Spring application, so you can use the Spring Security path.

Verify the status of your `ClassClaim` by running:

```
tanzu service class-claim list
```

Deploy an application with AppSSO

This section tells you how to deploy a minimal Kubernetes application that is protected by Application Single Sign-On (commonly called AppSSO) by using the credentials that tanzu service class-claim creates.

For more information about how a Client application uses an AuthServer to authenticate an end user, see the Overview of Application Single Sign-On.

Deploy a minimal application

Follow these steps to deploy a minimal Spring Boot application:

1. List the available accelerators by running:

```
tanzu accelerator list
```

Expect to see an accelerator named `appsso-starter-java`. This is the accelerator to use.

2. Create a project by running:

```
tanzu accelerator generate appsso-starter-java --server-url YOUR-TAP-SERVER-URI
--options '{"appssoOfferingName": "my-login"}'
```

This command creates a zip file.

3. Unzip the file by running:

```
unzip appsso-starter-java.zip
```

4. Make the following changes in `config/workload.yaml`:

    1. The reference to the `serviceClaims` is the `ServiceClaim` you generated in the previous step. Replace `appsso-starter-java` in the `serviceClaims` section with `my-workload`.
    2. There is a reference to a remote version of your repository. You can push this repository to your preferred Git repository and provide the reference here.

    The following code sample claimes the `ServiceClaim` from your appliction:

```
---
spec:
  serviceClaims:
    - name: YOUR-SERVICE-CLAIM
      ref:
        apiVersion: services.apps.tanzu.vmware.com/v1alpha1
        kind: ClassClaim
        name: YOUR-SERVICE-CLAIM
```

5. Deploy the workload by running:

```
kubectl apply -f config/workload.yaml
```

The `ServiceClaim` connects your application to the `AppSSO AuthServer`.

See the workload section of the Tanzu Application Platform Portal where you can find the URL for your workload at `https://tap-gui.YOUR-TAP-CLUSTER-DOMAIN`.

Application Single Sign-On how-to guides

This subsection describes the how-to guides for specific persona working with Application Single Sign-On (commonly called AppSSO):

- Platform operators
- Service operators
- Application operators
- Troubleshoot Application Single Sign-on

Application Single Sign-On for Platform Operators

The topics in this section tell you how to manage the Application Single Sign-On (commonly called AppSSO) package installation and what it installs. Use this section to learn:

- Install AppSSO
- Upgrades
- Uninstall AppSSO

Application Single Sign-On for Platform Operators

The topics in this section tell you how to manage the Application Single Sign-On (commonly called AppSSO) package installation and what it installs. Use this section to learn:

- Install AppSSO
- Upgrades
- Uninstall AppSSO

Install Application Single Sign-On

This topic tells you how to install Application Single Sign-On for VMware Tanzu (commonly called AppSSO) from the Tanzu Application Platform (commonly called TAP) package repository.

Note

Follow the steps in this topic if you do not want to use a profile to install Application Single Sign-On. For more information about profiles, see Components and installation profiles.

What's inside

The AppSSO package installs the following resources:

- The `appsso` namespace with a deployment of the AppSSO controller and services for webhooks.
- RBAC
- APIs

Prerequisites

Before installing Application Single Sign-On, ensure that you have Tanzu Application Platform installed on your Kubernetes cluster.

The `sso.apps.tanzu.vmware.com` package has these dependencies:

- `cert-manager.tanzu.vmware.com`: Required at installation time and runtime. For more information see, Install cert-manager.
- `crossplane.tanzu.vmware.com`: Required at installation time and runtime. For more information see, Install Crossplane.
- `service-bindings.tanzu.vmware.com`: Required at runtime. For more information see, Install Service Bindings.

Important

Installation time dependencies must be present on the cluster at the time the Application Single Sign-On package is being applied.

Runtime dependencies don't have to be present when the Application Single Sign-On package is being applied, but they are required eventually for it to function fully.

Install Application Single Sign-On for VMware Tanzu

1. Learn more about the AppSSO package by running:

```
tanzu package available get sso.apps.tanzu.vmware.com --namespace tap-install
```

2. Install the AppSSO package by running:

```
tanzu package install appsso \
 --namespace tap-install \
 --package sso.apps.tanzu.vmware.com \
 --version 5.0
```

3. Confirm the package has reconciled by running:

```
tanzu package installed get appsso --namespace tap-install
```

See also

- To configure the Application Single Sign-On package to meet your needs, see Package configuration for Application Single Sign-On.
- To upgrade to a later version of the package, see Upgrade Application Single Sign-On.
- When deployed on an OpenShift cluster, additional OpenShift-specific resources are installed. For more information, see Application Single Sign-On for OpenShift clusters.

Upgrade Application Single Sign-On

This topic tells you how to upgrade Application Single Sign-On (commonly called AppSSO).

The `AppSSO` package is upgraded as part of your `TAP` package installation.

For migrating your resources in between versions, see the Migration guides.

If you installed the `AppSSO` package on its own, and not as part of `TAP`, you can upgrade it individually by running:

```
tanzu package installed update PACKAGE-INSTALLATION-NAME -p sso.apps.tanzu.vmware.com
-v 5.0 --values-file PATH-TO-YOUR-VALUES-YAML -n YOUR-INSTALL-NAMESPACE
```

Note

You can also upgrade Application Single Sign-On as part of upgrading Tanzu Application Platform as a whole. See Upgrade Tanzu Application Platform for more information.

Migration guides

`v3.0.0` to `v3.1.0`

VMware recommends that you recreate your `AuthServers` after upgrading your Application Single Sign-On to `v3.1.0` with the following changes:

- Migrate field `.spec.identityProviders[*].openid.claimMappings["roles"]` to `.spec.identityProviders[*].openid.roles.fromUpstream.claim`.
- Migrate field `.spec.identityProviders[*].ldap.group.roleAttribute` to `.spec.identityProviders[*].ldap.roles.fromUpstream.attribute`.
- Migrate field `.spec.identityProviders[*].ldap.group.search` to `.spec.identityProviders[*].ldap.roles.fromUpstream.search`.
- Migrate field `.spec.identityProviders[*].saml.claimMappings["roles"]` to `.spec.identityProviders[*].saml.roles.fromUpstream.attribute`.

(Optional) If you plan to run Spring Boot 3 based `Workload`s, you must perform the following migration tasks in your existing `ClientRegistration` resources:

- Migrate `.spec.clientAuthenticationMethod` values.
- Migrate the existing value `post` to `client_secret_post` or migrate the existing value `basic` to `client_secret_basic`.

`v2.0.0` to `v3.0.0`

VMware recommends that you recreate your `AuthServers` after upgrading your Application Single Sign-On to `v3.0.0` with the following changes:

- Migrate the field `.spec.tls.disabled` to `.spec.tls.deactivated`.

`v1.0.0` to `v2.0.0`

VMware recommends that you recreate your `AuthServers` after upgrading your Application Single Sign-On to `v2.0.0` with the following changes:

- Migrate from `.spec.issuerURI` to `.spec.tls`:

    1. Configure one of `.spec.tls.{issuerRef, certificateRef, secretRef}`. See Issuer URI & TLS for more information.
    2. (Optional) Disable TLS with `.spec.tls.disabled`.
    3. Remove `.spec.issuerURI`.
    4. Delete your `AuthServer`-specific `Service` and ingress resources.
    5. Apply your `AuthServer`. You can find its issuer URI in `.status.issuerURI`.
    6. Update the redirect URIs in your upstream identity providers.

    Application Single Sign-On templates your issuer URI and enables TLS. When using the newer `.spec.tls`, a custom `Service` and an ingress resource are no longer required.

    It is not recommended to continue using `.spec.issuerURI` in Application Single Sign-On `v2.0.0`. To use `.spec.issuerURI` in `v2.0.0`, you must provide a `Service` and an ingress resource as in `v1.0.0`.

- If you use the `internalUnsafe` identity provider to migrate the existing users by replacing the bcrypt hash through the plaintext equivalent, you can still use the existing bcrypt passwords by prefixing them with `{bcrypt}`:

    ```
    ---
    apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
    kind: AuthServer
    metadata:
    ```

```
 # ...
spec:
 identityProviders:
   - name: internal
     internalUnsafe:
       users:
         # v1.0
         - username: test-user-1
           password: $2a$10$201z9o/tHlocFsHFTo0plukh03ApBYe4dRiXcqeyRQH6CNNtS8j
WK # bcrypt-encoded "password"
           # ...
         # v2.0
         - username: "test-user-1"
           password: "{bcrypt}$2a$10$201z9o/tHlocFsHFTo0plukh03ApBYe4dRiXcqeyRQ
H6CNNtS8jWK" # same bcrypt hash, with {bcrypt} prefix
         - username: "test-user-2"
           password: "password" # plaintext
 # ...
```

Uninstall Application Single Sign-On

This topic tells you how to uninstall Application Single Sign-On (commonly called AppSSO).

Delete the AppSSO package by running:

```
tanzu package installed delete appsso --namespace tap-install
```

To permanently delete and exclude AppSSO package from your Tanzu Application Platform install, edit your Tanzu Application Platform values file by including the following configuration:

```
excluded_packages:
  - sso.apps.tanzu.vmware.com
```

For more information, navigate to Exclude packages from a Tanzu Application Platform profile.

Application Single Sign-On for Service Operators

The following topics tell you how to configure a fully operational authorization server for Application Single Sign-On (commonly called AppSSO).

`AuthServer` represents the request for an OIDC authorization server. It results in the deployment of an authorization server backed by Redis. A Redis with mTLS is either automatically deployed for `AuthServer` or credentials to external storage can be provided. You can configure the labels with which clients can select an `AuthServer`, the namespaces it allows clients from, its issuer URI, its token signature keys, identity providers, and further details for its deployment.

`ClusterWorkloadRegistrationClass` exposes an `AuthServer` as a ready-to-claim service offering. Application operators can discover this offering and claim credentials. The mechanisms for this are provided by Services Toolkit. This is the recommended way for offering and consuming AppSSO.

If you just want to get started in a non-production environment, `ClusterUnsafeTestLogin` is a zero-config API that produces an unsafe, ready-to-claim AppSSO service offering. It is a higher-level alternative to the combination of `AuthServer` and `ClusterWorkloadRegistrationClass`.

For a full explanation of the available APIs, refer to the API reference.

The following sections outline the essential steps to configure a fully operational, ready-to-claim AppSSO service offering:

- Configure an unsafe test login
- Annotations and labels

- Issuer URI and TLS
- TLS scenario guides
- CA certificates
- Configure workloads to trust a custom CA
- Identity providers
- Configure authorization
- Public clients and CORS
- Token settings
- Token signatures
- Session settings
- Storage
- AuthServer readiness
- Scale AuthServer
- Curate an AppSSO service offering

Application Single Sign-On for Service Operators

The following topics tell you how to configure a fully operational authorization server for Application Single Sign-On (commonly called AppSSO).

`AuthServer` represents the request for an OIDC authorization server. It results in the deployment of an authorization server backed by Redis. A Redis with mTLS is either automatically deployed for `AuthServer` or credentials to external storage can be provided. You can configure the labels with which clients can select an `AuthServer`, the namespaces it allows clients from, its issuer URI, its token signature keys, identity providers, and further details for its deployment.

`ClusterWorkloadRegistrationClass` exposes an `AuthServer` as a ready-to-claim service offering. Application operators can discover this offering and claim credentials. The mechanisms for this are provided by Services Toolkit. This is the recommended way for offering and consuming AppSSO.

- Storage
- AuthServer readiness
- Scale AuthServer
- Curate an AppSSO service offering

Configure an unsafe test login

This topic for service operators describes how you can get started with Application Single Sign-On for VMware Tanzu (commonly called AppSSO) in a non-production environment by using `ClusterUnsafeTestLogin`.

`ClusterUnsafeTestLogin` is a zero-config API that produces an unsafe, ready-to-claim AppSSO service offering. When you create a `ClusterUnsafeTestLogin`, you get a simple `AuthServer` and a `ClusterWorkloadRegistrationClass` for it. The `AuthServer` has a single login `user:password` and is configured to work without extra configuration.

Caution

`ClusterUnsafeTestLogin` is not safe for production. For production, use `AuthServer` and `ClusterWorkloadRegistrationClass`.

Configure a `ClusterUnsafeTestLogin`

The `ClusterUnsafeTestLogin` resource takes zero configuration except a `name`.

To configure a `ClusterUnsafeTestLogin` create a YAML file as follows:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: ClusterUnsafeTestLogin
metadata:
  name: demo
```

Use the unsafe test login

After applying the `ClusterUnsafeTestLogin` resource, application operators can discover credentials for it by running:

```
tanzu service class list
```

Example output:

```
NAME  DESCRIPTION
demo  Login by AppSSO - user:password - UNSAFE FOR PRODUCTION!
```

For how to application operators can claim credentials, see Claim credentials for an Application Single Sign-On service offering.

Annotations and labels for AppSSO

This topic tells you how to configure annotations and labels for Application Single Sign-On (commonly called AppSSO).

An `AuthServer` is selectable by `ClientRegistration` through labels. The namespace an `AuthServer` allows `ClientRegistrations` from is controlled with an annotation.

Labels

`ClientRegistrations` select an `AuthServer` with `spec.authServerSelector`. Therefore, an `AuthServer` must have a set of labels that uniquely identifies it amongst all `AuthServer`. A `ClientRegistration` must match only one `AuthServer`. Registration fails if multiple or no `AuthServer` resources are matched.

For example:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  labels:
    env: dev
    ldap: True
    saml: True
# ...
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  labels:
    env: prod
    saml: True
# ...
```

Allowing client namespaces

`AuthServer` optionally controls from which namespace (one of more) it allows `ClientRegistrations` with the annotation:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  annotations:
    sso.apps.tanzu.vmware.com/allow-client-namespaces: "my-apps"
```

To allow `ClientRegistrations` only from a restricted set of namespaces, you must set this annotation. Its value is a comma-separated list of allowed `Namespaces`, for example, `"app-team-red,app-team-green"`. If the annotation is missing, the default value is `*`, denoting that all client namespaces are allowed.

VMware recommends explicitly restricting to only workload-related namespaces to narrow the scope of the `AuthServer` operation.

Unsafe configuration

`AuthServer` enforces secure and production-ready configuration. However, sometimes it is required to opt-out those constraints, for example, when deploying `AuthServer` on an iterate cluster.

Caution

Allowing **unsafe** is not recommended for production.

Unsafe identity provider

The `InternalUnsafe` identity provider cannot be used unless explicitly allowed by including the annotation `sso.apps.tanzu.vmware.com/allow-unsafe-identity-provider` as follows:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  annotations:
    sso.apps.tanzu.vmware.com/allow-unsafe-identity-provider: ""
spec:
  identityProviders:
    - name: static-users
      internalUnsafe:
      # ...
```

If the annotation is not present and an `InternalUnsafe` identity provider is configured the `AuthServer` will not apply.

Unsafe issuer URI

It's not possible to use a plain HTTP issuer URI, unless it's explicitly allowed by including the annotation `sso.apps.tanzu.vmware.com/allow-unsafe-issuer-uri` as follows:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  annotations:
    sso.apps.tanzu.vmware.com/allow-unsafe-issuer-uri: ""
spec:
  issuerURI: http://this.is.unsafe
```

If the annotation is not present and a plain HTTP issuer URI is configured, the `AuthServer` does not apply.

Issuer URI and TLS for AppSSO

This topic tells you how to configure the issuer URI and TLS for Application Single Sign-On (commonly called AppSSO).

Overview

An `AuthServer` entry point for its clients and their end-users is called *issuer URI*. AppSSO will template the issuer URI and create a TLS-enabled `Ingress` for it. For this purpose, your platform operator configures the domain name and template. Once you created and `AuthServer` you can find the actual URL in `.status.issuerURI`.

You can configure whether and how to obtain a TLS certificate for the issuer URI by using `.spec.tls`. Unless TLS is deactivated, HTTPS is enforced. For example, requests for `http://` are redirected to `https://`. You can observe the TLS configuration in `.status.tls`.

If AppSSO is installed with a default issuer, you can omit `AuthServer.spec.tls` and a TLS certificate is obtained automatically. This is the recommended approach for TLS.

For example:

```
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  name: login
  namespace: services
  # ...
spec:
# ...
status:
  issuerURI: https://login.services.example.com
  tls:
    issuerRef:
      name: my-default-issuer
      kind: ClusterIssuer
      group: cert-manager.io
  # ...
```

This `AuthServer` is reachable at its templated issuer URI `https://login.services.example.com` and serves a TLS certificate obtained from `my-default-issuer`.

Learn how to configure TLS for your `AuthServer`:

- Issuer URI and TLS for AppSSO
  - Overview
  - Configure TLS by using a (Cluster)Issuer
  - Configure TLS by using a Certificate
  - Configure TLS by using a Secret
  - Deactivate TLS (unsafe)
  - Allow `Workloads` to trust a custom CA `AuthServer`

There are many use-cases that pertain to TLS use. To find out which scenario applies to you and how to configure it, see TLS scenario guides.

If your `AuthServer` obtains a certificate from a custom CA, you can enable App Operators to trust it. See Allow Workloads to trust a custom CA AuthServer for more information.

Configure TLS by using a (Cluster)Issuer

You can obtain a TLS certificate for your `AuthServer` by referencing a `cert-manager.io/v1/Issuer` or `cert-manager.io/v1/ClusterIssuer`. This enables AppSSO to retrieve a `cert-manager.io/v1/Certificate` from the issuer and apply it to the `Ingress` configuration.

The composition of an `AuthServer` and a self-signed `Issuer` looks as follows:

```
---
apiVersion: cert-manager.io/v1
kind: Issuer
metadata:
  name: my-selfsigned-issuer
  namespace: services
spec:
  selfSigned: { }

---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  name: login
  namespace: services
  # ...
```

```
spec:
  tls:
    issuerRef:
      name: my-selfsigned-issuer
      # 'kind: Issuer' can be omitted. It is the default.
```

The composition of an `AuthServer` and a *self-signed* `ClusterIssuer` for looks as follows:

```
---
apiVersion: cert-manager.io/v1
kind: ClusterIssuer
metadata:
  name: my-selfsigned-cluster-issuer
spec:
  selfSigned: { }

---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  name: login
  namespace: services
  # ...
spec:
  tls:
    issuerRef:
      name: my-selfsigned-cluster-issuer
      kind: ClusterIssuer
```

Confirm that your `AuthServer` serves a TLS certificate from the specified issuer by visiting its `{.status.issuerURI}`.

For more information about cert-manager and its APIs. see cert-manager documentation.

Configure TLS by using a Certificate

In order to configure TLS for your `AuthServer` using a `cert-manager.io/v1/Certificate` you must know what its templated issuer URI will be. You can infer it from the AppSSO package's domain template.

The composition of an `AuthServer` and a `Certificate` looks as follows:

```
apiVersion: cert-manager.io/v1
kind: Certificate
metadata:
  name: login
  namespace: services
spec:
  dnsNames:
    - login.services.example.com
  issuerRef:
    name: my-cluster-issuer
    kind: ClusterIssuer
  secretName: login-cert

---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  name: login
  namespace: services
  # ...
spec:
  tls:
```

```
    certificateRef:
      name: login
```

Confirm that your `AuthServer` serves the specified Certificate by visiting its `{.status.issuerURI}`.

For more information about cert-manager and its APIs. see cert-manager documentation.

Configure TLS by using a Secret

If you don't want to use cert-manager.io's APIs or you have a raw TLS certificate in a TLS `Secret`, you can compose it with your `AuthServer` by referencing it. The certificate must be for the issuer URI that will be templated for the `AuthServer`. You can infer it from the AppSSO package's domain template.

The composition of an `AuthServer` and TLS `Secret` looks as follows:

```
apiVersion: v1
kind: Secret
metadata:
  name: my-tls-cert
  namespace: services
type: kubernetes.io/tls
data:
  tls.key: # ...
  tls.crt: # ...

---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  name: login
  namespace: services
  # ...
spec:
  tls:
    secretRef:
      name: my-tls-cert
```

Deactivate TLS (unsafe)

If you deactivate TLS autoconfiguration, `AuthServer` only works over plain HTTP. You must deactivate TLS with the `sso.apps.tanzu.vmware.com/allow-unsafe-issuer-uri: ""` annotation.

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  name: login
  namespace: services
  annotations:
    sso.apps.tanzu.vmware.com/allow-unsafe-issuer-uri: ""
  # ...
spec:
  tls:
    deactivated: true
```

Caution

Deactivating TLS is unsafe and not recommended for production.

Allow `Workloads` to trust a custom CA `AuthServer`

If your `AuthServer` obtains a certificate from a custom CA, its consumers do not trust it by default. You can enable App Operators' `Workloads` to trust your `AuthServer` by exporting a `ca-certificates` service binding `Secret` to their `Namespace`.

A composition of `SecretTemplate` and `SecretExport` are a way to achieve this. If your custom CA's TLS `Secret` is present in the namespace `my-certs`, then you can provide a `ca-certificates` service binding `Secret` like so:

```
---
apiVersion: secretgen.carvel.dev/v1alpha1
kind: SecretTemplate
metadata:
  name: ca-cert
  namespace: my-certs
spec:
  inputResources:
    - name: my-custom-ca
      ref:
        apiVersion: v1
        kind: Secret
        name: my-custom-ca
  template:
    data:
      ca.crt: $(.my-custom-ca.data.tls\.crt)
    stringData:
      type: ca-certificates

---
apiVersion: secretgen.carvel.dev/v1alpha1
kind: SecretExport
metadata:
  name: ca-cert
  namespace: my-certs
spec:
  toNamespace: "*"
```

This templates a `ca-certificates` service binding `Secret` which `Workload` can claim to trust the custom CA. It does not contain the CA's private key and is generally safe to share.

However, be careful, this example exports to all namespace on the cluster. If this does not comply with your policies, then adjust the target namespaces if required.

For more information about secretgen-controller and its APIs, see secretgen-controller documentation in GitHub.

TLS scenario guides for AppSSO

This topic tells you how to obtain a TLS certificate in different scenarios for Application Single Sign-On (commonly called AppSSO).

Overview

`AuthServer` is a piece of security infrastructure. It is imperative to configure TLS for it, so that its issuer URI's scheme is `https://`.

`AuthServer.spec.tls` accommodates different scenarios for obtaining a TLS certificate. Select the scenario that matches your case.

The recommended path is to install AppSSO with a default issuer. In that case, you can omit `AuthServer.spec.tls` and a TLS certificate is obtained automatically.

Prerequisites

Each of the scenarios requires that the AppSSO package is installed and configured. In particular, its `domain_name` must match the ingress domain of your cluster. The presented YAML resources assume `my-tap.example.com` as the ingress domain. Therefore, the AppSSO configuration values look as follows:

```
#! AppSSO values
domain_name: "my-tap.example.com"
```

The default `domain_template: "{{.Name}}.{{.Namespace}}.{{.Domain}}"` works for most scenarios. If a scenario requires a bespoke `domain_template`, it contains the relevant instructions.

After applying each scenario, wait for your `AuthServer` to become ready and then test it by running:

```
kubectl wait --namespace login authserver/sso --for condition=Ready=True --timeout 500
s
curl --location "$(kubectl get --namespace login authserver sso --output=jsonpath='{.s
tatus.issuerURI}')/.well-known/openid-configuration"
```

Alternatively, visit the `AuthServer` with your browser. You can obtain its issuer URI by running:

```
kubectl get --namespace login authserver sso --output=jsonpath='{.status.issuerURI}'
```

Caution

Before applying each scenario, you must configure your AppSSO correctly, and make sure that all certificates and DNS names comply with your setup.

Using a default issuer

VMware recommend using a default issuer,
because this approach separates the responsibilities of platform operators and service operators. In this case, the `Authserver.spec.tls` field is not required.

To verify whether `AppSSO` was installed with a default issuer, run:

```
kctrl package installed get --namespace tap-install --package-install tap --values-fil
e-output tap-values.yaml
```

If a `shared.ingress_issuer` appears in your `tap-values.yaml` file, you have a default issuer.

Important

Ensure kctrl is installed.

```
apiVersion: v1
kind: Namespace
metadata:
  name: login

---
```

```
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  name: sso
  namespace: login
  annotations:
    sso.apps.tanzu.vmware.com/allow-unsafe-identity-provider: ""
    sso.apps.tanzu.vmware.com/documentation: Uses the default issuer for TLS
spec:
  identityProviders:
    - name: test-users
      internalUnsafe:
        users:
          - username: user
            password: password
  tokenSignature:
    signAndVerifyKeyRef:
      name: signing-key

---
apiVersion: secretgen.k14s.io/v1alpha1
kind: RSAKey
metadata:
  name: signing-key
  namespace: login
spec:
  secretTemplate:
    type: Opaque
    stringData:
      key.pem: $(privateKey)
      pub.pem: $(publicKey)
```

Using a `ClusterIssuer`

A `ClusterIssuer` is a cluster-scoped API provided by cert-manager from which certificates can be obtained programmatically.

This scenario puts all resources into a single YAML file and uses Let's Encrypt's production API. You might get the `ClusterIssuer` from your platform operators.

For more information, see cert-manager documentation.

Caution

Let's Encrypt's production API rate limits apply.

```
---
apiVersion: cert-manager.io/v1
kind: ClusterIssuer
metadata:
  name: letsencrypt-production
spec:
  acme:
    privateKeySecretRef:
      name: letsencrypt-production
    server: https://acme-v02.api.letsencrypt.org/directory
    solvers:
      - http01:
          ingress:
            class: contour

---
```

```
apiVersion: v1
kind: Namespace
metadata:
  name: login

---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  name: sso
  namespace: login
  annotations:
    sso.apps.tanzu.vmware.com/allow-unsafe-identity-provider: ""
spec:
  #! --- TLS ---
  tls:
    issuerRef:
      name: letsencrypt-production
      kind: ClusterIssuer
  #! -----------
  identityProviders:
    - name: test-users
      internalUnsafe:
        users:
          - username: user
            password: password
  tokenSignature:
    signAndVerifyKeyRef:
      name: signing-key

---
apiVersion: secretgen.k14s.io/v1alpha1
kind: RSAKey
metadata:
  name: signing-key
  namespace: login
spec:
  secretTemplate:
    type: Opaque
    stringData:
      key.pem: $(privateKey)
      pub.pem: $(publicKey)
```

Using an `Issuer`

This scenario is identical to Using a ClusterIssuer, except that the Issuer is scoped to a namespace and must be located in the same namespace as the `AuthServer`.

```
---
apiVersion: v1
kind: Namespace
metadata:
  name: login

---
apiVersion: cert-manager.io/v1
kind: Issuer
metadata:
  name: letsencrypt-production
  namespace: login
spec:
  acme:
    privateKeySecretRef:
      name: letsencrypt-production
```

```
    server: https://acme-v02.api.letsencrypt.org/directory
    solvers:
      - http01:
          ingress:
            class: contour

---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  name: sso
  namespace: login
  annotations:
    sso.apps.tanzu.vmware.com/allow-unsafe-identity-provider: ""
spec:
  #! --- TLS ---
  tls:
    issuerRef:
      name: letsencrypt-production
  #! -----------
  identityProviders:
    - name: test-users
      internalUnsafe:
        users:
          - username: user
            password: password
  tokenSignature:
    signAndVerifyKeyRef:
      name: signing-key

---
apiVersion: secretgen.k14s.io/v1alpha1
kind: RSAKey
metadata:
  name: signing-key
  namespace: login
spec:
  secretTemplate:
    type: Opaque
    stringData:
      key.pem: $(privateKey)
      pub.pem: $(publicKey)
```

Using an existing `Certificate`

A `Certificate` is an API provided by cert-manager that is scoped to a namespace and represents a TLS certificate obtained from a `(Cluster)Issuer`. To create a `Certificate`, you must know the name and kind of your issuer.

These scenarios use Let's Encrypt's production API and require that a `ClusterIssuer` by the name `letsencrypt-production` exists. See Using a `ClusterIssuer` for how to set up the issuer.

When using `Certificate`, its `.spec.dnsNames` must contain the FQDN of the templated issuer URI. The `domain_name` and `domain_template` of your AppSSO package installation must comply with your DNS name.

If you have an existing `Certificate` in the same `Namespace` where the `AuthServer` is installed, use the following AppSSO configuration values:

```
---
apiVersion: v1
kind: Namespace
metadata:
  name: login
```

```
---
apiVersion: cert-manager.io/v1
kind: Certificate
metadata:
  name: sso
  namespace: login
spec:
  dnsNames:
    - "sso.login.my-tap.example.com"
  issuerRef:
    name: letsencrypt-production
    kind: ClusterIssuer
  secretName: sso-cert

---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  name: sso
  namespace: login
  annotations:
    sso.apps.tanzu.vmware.com/allow-unsafe-identity-provider: ""
spec:
  #! --- TLS ---
  tls:
    certificateRef:
      name: sso
  #! -----------
  identityProviders:
    - name: test-users
      internalUnsafe:
        users:
          - username: user
            password: password
  tokenSignature:
    signAndVerifyKeyRef:
      name: signing-key

---
apiVersion: secretgen.k14s.io/v1alpha1
kind: RSAKey
metadata:
  name: signing-key
  namespace: login
spec:
  secretTemplate:
    type: Opaque
    stringData:
      key.pem: $(privateKey)
      pub.pem: $(publicKey)
```

secretgen-controller allows you to export and import `Secrets` across namespaces. When your `Certificate` is located in another namespace, for example, it's controlled by another team, you can import its `Secret` to other namespaces. If you have an existing `Certificate` in another `Namespace`, use the following AppSSO configuration values:

```
---
apiVersion: v1
kind: Namespace
metadata:
  name: tls

---
apiVersion: cert-manager.io/v1
```

```
kind: Certificate
metadata:
  name: sso
  namespace: tls
spec:
  dnsNames:
    - "sso.login.my-tap.example.com"
  issuerRef:
    name: letsencrypt-production
    kind: ClusterIssuer
  secretName: sso-cert

---
apiVersion: secretgen.carvel.dev/v1alpha1
kind: SecretExport
metadata:
  name: sso-cert
  namespace: tls
spec:
  toNamespace: login

---
apiVersion: v1
kind: Namespace
metadata:
  name: login

---
apiVersion: secretgen.carvel.dev/v1alpha1
kind: SecretImport
metadata:
  name: sso-cert
  namespace: login
spec:
  fromNamespace: tls

---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  name: sso
  namespace: login
  annotations:
    sso.apps.tanzu.vmware.com/allow-unsafe-identity-provider: ""
spec:
  #! --- TLS ---
  tls:
    secretRef:
      name: sso-cert
  #! -----------
  identityProviders:
    - name: test-users
      internalUnsafe:
        users:
          - username: user
            password: password
  tokenSignature:
    signAndVerifyKeyRef:
      name: signing-key

---
apiVersion: secretgen.k14s.io/v1alpha1
kind: RSAKey
metadata:
  name: signing-key
  namespace: login
```

```
spec:
  secretTemplate:
    type: Opaque
    stringData:
      key.pem: $(privateKey)
      pub.pem: $(publicKey)
```

Caution

Be cautious when using `SecretExport` and `SecretImport` to facilitate the transfer across namespaces.

Using an existing TLS certificate

If you have an existing TLS certificate and private key, for example, if your TLS certificate was created outside the cluster, you can apply it directly.

If you don't have a TLS certificate, there are numerous ways to obtain TLS certificates. One of the simplest methods is to use a tool such as mkcert, step or openssl in GitHub.

If you have an existing TLS certificate in the same `Namespace` where the AuthServer is installed, use the following AppSSO configuration values:

```
---
apiVersion: v1
kind: Namespace
metadata:
  name: login

---
apiVersion: v1
kind: Secret
type: kubernetes.io/tls
metadata:
  name: my-cert
  namespace: login
stringData:
  #! --- ReplaceMe - certificate and private key for "sso.login.my-tap.example.com ---
  tls.crt: |
    -----BEGIN CERTIFICATE-----
    # redacted
    -----END CERTIFICATE-----
  tls.key: |
    -----BEGIN PRIVATE KEY-----
    # redacted
    -----END PRIVATE KEY-----
  #! ---------------------------------------------------------------------------

---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  name: sso
  namespace: login
  annotations:
    sso.apps.tanzu.vmware.com/allow-unsafe-identity-provider: ""
spec:
  #! --- TLS ---
  tls:
    secretRef:
      name: my-cert
  #! -----------
```

```
  identityProviders:
    - name: test-users
      internalUnsafe:
        users:
          - username: user
            password: password
  tokenSignature:
    signAndVerifyKeyRef:
      name: signing-key

---
apiVersion: secretgen.k14s.io/v1alpha1
kind: RSAKey
metadata:
  name: signing-key
  namespace: login
spec:
  secretTemplate:
    type: Opaque
    stringData:
      key.pem: $(privateKey)
      pub.pem: $(publicKey)
```

Important

The TLS certificate `tls.crt` and its corresponding private key `tls.key` must be stored in a secret with these keys.

If you have an existing TLS certificate in another `Namespace`, use the following AppSSO configuration values:

```
---
apiVersion: v1
kind: Namespace
metadata:
  name: tls

---
apiVersion: v1
kind: Secret
type: kubernetes.io/tls
metadata:
  name: my-cert
  namespace: tls
stringData:
  #! --- ReplaceMe - certificate and private key for "sso.login.my-tap.example.com ---
  tls.crt: |
    -----BEGIN CERTIFICATE-----
    # redacted
    -----END CERTIFICATE-----
  tls.key: |
    -----BEGIN PRIVATE KEY-----
    # redacted
    -----END PRIVATE KEY-----
  #! ---------------------------------------------------------------------------

---
apiVersion: secretgen.carvel.dev/v1alpha1
kind: SecretExport
metadata:
  name: my-cert
  namespace: tls
```

```
spec:
  toNamespace: login

---
apiVersion: v1
kind: Namespace
metadata:
  name: login

---
apiVersion: secretgen.carvel.dev/v1alpha1
kind: SecretImport
metadata:
  name: my-cert
  namespace: login
spec:
  fromNamespace: tls

---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  name: sso
  namespace: login
  annotations:
    sso.apps.tanzu.vmware.com/allow-unsafe-identity-provider: ""
spec:
  #! --- TLS ---
  tls:
    secretRef:
      name: my-cert
  #! -----------
  identityProviders:
    - name: test-users
      internalUnsafe:
        users:
          - username: user
            password: password
  tokenSignature:
    signAndVerifyKeyRef:
      name: signing-key

---
apiVersion: secretgen.k14s.io/v1alpha1
kind: RSAKey
metadata:
  name: signing-key
  namespace: login
spec:
  secretTemplate:
    type: Opaque
    stringData:
      key.pem: $(privateKey)
      pub.pem: $(publicKey)
```

Important

The TLS certificate `tls.crt` and its corresponding private key `tls.key` must be stored in a secret with these keys.

Be cautious when using `SecretExport` and `SecretImport` to facilitate the transfer across namespaces.

Using an existing wildcard TLS certificate

To use wildcard certificates for DNS names such as `*.my-tap.example.com`, you must edit the AppSSO's `domain_template` so that the templated issuer URIs for `AuthServer` match the wildcard. For example:

- `sso.login.my-tap.example.com` does not match the wildcard.
- `sso-login.my-tap.example.com` matches the wildcard.

The following AppSSO configuration values accommodates a wildcard certificate for `*.my-tap.example.com`:

```
#! AppSSO values
domain_name: "my-tap.example.com"
domain_template: "{{.Name}}-{{.Namespace}}.{{.Domain}}"
#!                          ^ note the dash
```

The following scenarios require TLS Secrets, but the same concept applies to `Certificate`.

Important

When using a `(Cluster)Issuer` for Let's Encrypt, you cannot request wildcard certificates when it uses the http01 challenge solver.

If you have an existing wildcard TLS certificate in the same `Namespace` where the AuthServer is installed, use the following AppSSO configuration values:

```
---
apiVersion: v1
kind: Namespace
metadata:
  name: login

---
apiVersion: v1
kind: Secret
type: kubernetes.io/tls
metadata:
  name: my-wildcard-cert
  namespace: login
stringData:
  #! --- ReplaceMe - certificate and private key for "*.my-tap.example.com ---
  tls.crt: |
    -----BEGIN CERTIFICATE-----
    # redacted
    -----END CERTIFICATE-----
  tls.key: |
    -----BEGIN PRIVATE KEY-----
    # redacted
    -----END PRIVATE KEY-----
  #! ---------------------------------------------------------------------------

---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  name: sso
  namespace: login
  annotations:
    sso.apps.tanzu.vmware.com/allow-unsafe-identity-provider: ""
spec:
```

```
  #! --- TLS ---
  tls:
    secretRef:
      name: my-wildcard-cert
  #! -----------
  identityProviders:
    - name: test-users
      internalUnsafe:
        users:
          - username: user
            password: password
  tokenSignature:
    signAndVerifyKeyRef:
      name: signing-key

---
apiVersion: secretgen.k14s.io/v1alpha1
kind: RSAKey
metadata:
  name: signing-key
  namespace: login
spec:
  secretTemplate:
    type: Opaque
    stringData:
      key.pem: $(privateKey)
      pub.pem: $(publicKey)
```

Note

This scenario is similar to using an existing TLS certificate in the same namespace, except that the certificate is a wildcard.

If you have an existing wildcard TLS certificate in another `Namespace`, use the following AppSSO configuration values:

```
---
apiVersion: v1
kind: Namespace
metadata:
  name: tls

---
apiVersion: v1
kind: Secret
type: kubernetes.io/tls
metadata:
  name: my-wildcard-cert
  namespace: login
stringData:
  #! --- Certificate and private key for "*.my-tap.example.com ---
  tls.crt: |
    -----BEGIN CERTIFICATE-----
    # redacted
    -----END CERTIFICATE-----
  tls.key: |
    -----BEGIN PRIVATE KEY-----
    # redacted
    -----END PRIVATE KEY-----
  #! ------------------------------------------------------------

---
```

```
apiVersion: secretgen.carvel.dev/v1alpha1
kind: SecretExport
metadata:
  name: my-cert
  namespace: tls
spec:
  toNamespace: login

---
apiVersion: v1
kind: Namespace
metadata:
  name: login

---
apiVersion: secretgen.carvel.dev/v1alpha1
kind: SecretImport
metadata:
  name: my-cert
  namespace: login
spec:
  fromNamespace: tls

---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  name: sso
  namespace: login
  annotations:
    sso.apps.tanzu.vmware.com/allow-unsafe-identity-provider: ""
spec:
  #! --- TLS ---
  tls:
    secretRef:
      name: my-wildcard-cert
  #! -----------
  identityProviders:
    - name: test-users
      internalUnsafe:
        users:
          - username: user
            password: password
  tokenSignature:
    signAndVerifyKeyRef:
      name: signing-key

---
apiVersion: secretgen.k14s.io/v1alpha1
kind: RSAKey
metadata:
  name: signing-key
  namespace: login
spec:
  secretTemplate:
    type: Opaque
    stringData:
      key.pem: $(privateKey)
      pub.pem: $(publicKey)
```

Note

This scenario is similar to using an existing TLS certificate in another namespace, except that the certificate is a wildcard.

CA certificates for Application Single Sign-On

This topic tells you how to configure CA certificates for `AuthServer` in Application Single Sign-On (commonly called AppSSO).

An `AuthServer` can trust custom CAs. You can establish either for all `AuthServer`s or for a single `AuthServer`. This is useful when either your identity provider or storage serves certificates from a custom CA.

In most cases, CA certificates are PEM-encoded and located in a `Secret` referred from `.spec.caCerts[].secretRef.name`. The controller considers all `Secret` entries matching `*.(crt|ca-bundle)`. That means you can include multiple CA certificates in a single `Secret` or spread them across multiple `Secret`s.

After being created, an `AuthServer` reports the trusted, total custom CA certificates in its `.status.caCerts` together with the location where it sources them from. This includes the CA certificates that are trusted by all `AuthServer`s.

For example:

```
---
apiVersion: v1
kind: Secret
metadata:
  name: my-ca
  namespace: services
stringData:
  my.ca-bundle: |
    This is My Company's custom CA. It's common name is "My CA".
    -----BEGIN CERTIFICATE-----
    ...
    -----END CERTIFICATE-----

---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  name: login
  namespace: services
  # ...
spec:
  caCerts:
    - secretRef:
        name: my-ca
  # ...
status:
  caCerts:
    - cert:
        subject: CN=My CA,O=My Company,C=Happyland
      source:
        secretEntry: service/my-ca[my.ca-bundle]
    - cert:
        subject: CN=My other CA,O=My Company,C=Happyland
      source:
        secretEntry: appsso/appsso-controller[controller.yaml]
  # ...
```

CA certificates configured for all `AuthServer`s by using the package installation's `ca_cert_data` are sourced from `secretEntry: appsso/appsso-controller[controller.yaml]`. This denotes the

AppSSO controller's configuration `Secret`.

Configure workloads to trust a custom CA

This topic tells you how to configure workloads to trust a custom Certificate Authority (commonly called CA) for Application Single Sign-On (commonly called AppSSO).

Overview

If your `ClientRegistration` selects an `AuthServer` that serves a certificate from a custom CA, your `Workload` does not trust it by default. This is because the certificate is not issued by a trusted certificate authority from the `Workload`'s perspective.

To establish trust between a `Workload` and an `AuthServer`:

Step	Task	Link
1.	Service Operator exports the custom CA certificate `Secret` resource from the namespace in which it is issued.	Exporting custom CA certificate Secret
2.	Service Operator imports the custom CA certificate `Secret` to the namespace in which the `Workload` is created.	Importing custom CA certificate Secret
3.	Append the deployed `Workload` as a service resource claim, denoting the custom CA certificate `Secret` in the workload namespace.	Appending custom CA certificate Secret reference to Workload

Important

These steps are mandatory if Tanzu Application Platform is installed with the default self-signed `ClusterIssuer` resource, in which the CA is custom.

Exporting custom CA certificate Secret

A `ca-certificates` service binding `Secret` allows to configure trust for custom CAs.

For more information about exporting CA certificate Secrets, see Allow Workloads to trust a custom CA AuthServer.

Example: Create a `ca-certificates`-type ServiceBinding Secret from template and offer Tanzu Application Platform's default self-signed CA certificate Secret to workloads namespace.

```
---
apiVersion: secretgen.carvel.dev/v1alpha1
kind: SecretTemplate
metadata:
  name: tap-ca-cert
  namespace: cert-manager                    # The namespace in which your custom CA
Secret resides.
spec:
  inputResources:
    - name: tap-ingress-selfsigned-root-ca
      ref:
        apiVersion: v1                       # The custom CA certificate Secret.
        kind: Secret                         # ^^
        name: tap-ingress-selfsigned-root-ca  # ^^
  template:
    data:
      ca.crt: $(.tap-ingress-selfsigned-root-ca.data.tls\.crt)
    stringData:
      type: ca-certificates
```

```
---
apiVersion: secretgen.carvel.dev/v1alpha1
kind: SecretExport
metadata:
  name: tap-ca-cert           # The name of the SecretTemplate that created the "ca-ce
rtificates" Secret.
  namespace: cert-manager     # The namespace in which Tanzu Application Platform's se
lf-signed ClusterIssuer stores its CA cert Secret.
spec:
  toNamespace: my-apps        # The namespace in which Workloads are deployed.
```

Importing custom CA certificate Secret

After the custom CA certificate Secret is exported from its original namespace, you can import it into the workloads' namespace.

Example: Accept Tanzu Application Platform's default self-signed CA certificate Secret offer.

```
---
apiVersion: secretgen.carvel.dev/v1alpha1
kind: SecretImport
metadata:
  name: tap-ca-cert
  namespace: my-apps            # The namespace in which Workloads are deployed.
spec:
  fromNamespace: cert-manager   # The namespace in which your custom CA certificate Se
cret resides.
```

Appending custom CA certificate Secret reference to Workload

With custom CA certificate available in the workloads' namespace, you can append it to the `Workload` as a service resource claim:

Example: Appending custom CA certificate Secret as a resource claim.

```
---
apiVersion: carto.run/v1alpha1
kind: Workload
# ...
spec:
  serviceClaims:
    - name: ca-cert
      ref:
        apiVersion: v1    # The custom CA Secret template that is imported into the wo
rkloads' namespace.
        kind: Secret      # ^^
        name: tap-ca-cert # ^^
    # ...
```

Alternatively, you can provide the workload with a `--service-ref` parameter for the same effect:

```
--service-ref "ca-cert=v1:Secret:tap-ca-cert"
```

For more information about secretgen-controller and its APIs, see secretgen-controller documentation in GitHub.

Identity providers for AppSSO

This topic tells you how to configure Application Single Sign-On (commonly called AppSSO) to use external identity providers (commonly called IdPs).

Users can log in by using external identity providers. OpenID Connect and LDAP providers are supported. SAML providers have limited experimental support. An `AuthServer` does not manage users internally. Developers can get started quickly without needing to connect to an IdP by using static hard-coded users, which is for development purposes only.

Identity providers are configured under `spec.identityProviders`, learn more from the API reference.

> **Caution**
>
> Changes to `spec.identityProviders` do not take effect immediately because the operator will roll out a new deployment of the authorization server.

End-users will be able to log in with these providers when they go to `{spec.issuerURI}` in their browser.

Use the following sections to learn how to configure identity providers for an `AuthServer`:

- OpenID Connect
- LDAP
- SAML (experimental)
- InternalUnsafe

Use the following sections for a deeper understanding of advanced identity provider configurations:

- Identity token claims mapping
- Roles claim filtering
- Roles claim mapping and filtering explained
- Configure authorization
- Restrictions

OpenID Connect providers

To set up an OpenID Connect provider, provide the following information for your `AuthServer`:

```
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
# ...
spec:
  identityProviders:
    - name: my-oidc-provider
      openID:
        displayName: "MyOIDC Provider"
        clientID: my-client-abcdef
        clientSecretRef:
          name: my-openid-client-secret
        configurationURI: https://openid.example.com/.well-known/openid-configuration
        issuerURI: https://openid.example.com # This field is deprecated, optional and
relies on `configurationURI`. It must be unset if `configurationURI` is set.
        scopes:
          - "openid"
          - "other-scope"
        authorizationUri: https://example.com/oauth2/authorize
```

```
        tokenUri: https://example.com/oauth2/token
        jwksUri: https://example.com/oauth2/jwks
        roles:
          fromUpstream:
            claim: "MY-OIDC-PROVIDER-GROUPS"
        idToken:
          claims:
            - fromUpstream: ""
              toClaim: ""
  # ...
---
apiVersion: v1
kind: Secret
metadata:
  name: my-openid-client-secret
  # ...
stringData:
  clientSecret: very-secr3t
```

Where:

- `.openID`: The issuer identifier. You can define as many OpenID providers as you like. If the provider supports OpenID Connect Discovery, the value of `openID` auto-configures the provider by using the information from `https://openid.example.com/.well-known/openid-configuration`.
- `.openID.configurationURI`: The OpenID Connect provider configuration endpoint, which must be suffixed with `/.well-known/openid-configuration`. This endpoint must have the HTTPS scheme. For more information, see OpenID Connect provider configuration discovery.
- `.openID.issuerURI` (optional): The issuer URI. This field is deprecated and it relies on `.openID.configurationURI`. The value of `issuerURI` must not contain `.well-known/openid-configuration` and must match the value of the `issuer` field. For more information, see the OpenID Connect documentation for your issuer, for example, at `https://openid.example.com/.well-known/openid-configuration`.

  Note

  You can retrieve the values of `issuerURI` (`https://openid.example.com`) and `clientID` (`my-client-abcdef`) when registering a client with the provider, which in most cases, is by using a web UI.

  You can also run the following to retrieve the correct `issuerURI` value from the upstream identity provider:

  ```
  curl -s "https://openid.example.com/.well-known/openid-configuration" | jq -r
  ".issuer"
  ```

- `.openID.displayName` (optional): A user-friendly display name for the provider that is rendered on the login page.
- `.openID.scopes`: The scopes requested to the issuer in the authorization request. Its value must contain `"openid"`. Other common `openID.scopes` values include `"profile"` and `"email"`.
- `.openID.clientSecretRef`: The issuer's client secret. The value of `clientSecretRef` must be a `Secret` with the entry `clientSecret`.

- `.openID.authorizationUri` (optional): The URI for performing an authorization request and obtaining an `authorization_code`. If the `configurationURI` and `issuerURI` fields are not set, this field must not be empty.
- `.openID.tokenUri` (optional): The URI for performing a token request and obtaining a token. If the `configurationURI` and `issuerURI` fields are not set, this field must not be empty.
- `.openID.jwksUri` (optional): The JSON Web Key Set (JWKS) endpoint for obtaining the JSON Web Keys to verify token signatures. If the `configurationURI` and `issuerURI` fields are not set, this field must not be empty.
- `.openID.userinfoUri` (optional): The URI for obtaining the additional identity claims from the upstream IdP (identity provider).
- `.openID.roles.fromUpstream.claim` (optional): Selects which claim in the `id_token` contains the `roles` of the user. `roles` is not a standard OpenID Connect claim. If `ClientRegistrations` or `ClassClaims` have a `roles` scope, it populates the `roles` claim in the `id_token` issued by the `AuthServer`. For more information, see OpenID external groups mapping.
    - `MY-OIDC-PROVIDER-GROUPS`: Claim from the ID token issued by `my-oidc-provider` is mapped into the `roles` claim in the id tokens issued by AppSSO.
- `.openID.idToken.claims`: Allows mapping a claim from an upstream identity provider to the current authorization server. See Identity token claims mapping for more details.

Verify the configuration by visiting the `AuthServer`'s issuer URI in your browser and select `my-oidc-provider`.

You can find the `authorizationUri`, `tokenUri`, `jwksUri`, and `userinfoUri` properties in `<issuerUri>/.well-known/openid-configuration`.

OpenID external groups mapping

Service operators may map the identity provider's "groups" (or equivalent) claim to the `roles` claim within an `AuthServer`'s identity token.

Note

Read more about roles claim mapping and filtering here

App Operators may configure their ClientRegistration to have the `roles` claim included in the `id_token`.

Configure `AuthServer` with OpenID Connect groups mapping:

```
spec:
  identityProviders:
    - name: "openid-idp"
      openid:
        scopes:
          - upstream-identity-providers-groups-claim # Optional based on the identity
provider.
        roles:
          fromUpstream:
            claim: "upstream-identity-providers-groups-claim"
```

Caution

> Some OpenID providers, such as Okta OpenID, might require requesting the roles or groups scope from the identity provider, as a result, you must include it in the `.openid.scopes` list.

For every ClientRegistration that has the `roles` scope listed, the identity token is populated with the `roles` claim:

```
kind: ClientRegistration
metadata:
  name: my-client-registration
spec:
  scopes:
    - name: openid
    - name: roles
  # ...
```

This rule also applies to ClassClaim:

```
kind: ClassClaim
metadata:
  name: my-class-claim
spec:
  parameters:
    scopes:
      - name: openid
      - name: roles
  # ...
```

When groups are mapped (as described above), all the groups provided by the identity provider are retrieved, and the relevant groups that the logged-in user is part of are appended to the `roles` claim of an `id_token`. To filter the available roles within an `id_token`, see Roles claim filtering section.

Note for registering a client with the identity provider

The `AuthServer` will set up redirect URIs based on the provider name in the configuration. For example, for a provider with `name: my-provider`, the redirect URI will be `{spec.issuerURI}/login/oauth2/code/my-provider`. The externally accessible user URI for the `AuthServer`, including scheme and port is `spec.issuerURI`. If the `AuthServer` is accessible on `https://appsso.company.example.com:1234/`, the redirect URI registered with the identity provider should be `https://appsso.company.example.com:1234/login/oauth2/code/my-provider`.

OpenID Connect provider configuration discovery

OpenID Connect provider configuration discovery is enabled when you set the `AuthServer.spec.identityProviders[*].openID.configurationURI` field.

This field has the following requirements:

- It must be a valid URI.
- It must have the HTTPS scheme. For more information about testing with the HTTP scheme, see Non-HTTPS configuration.
- It must be suffixed with `/.well-known/openid-configuration`.

Non-HTTPS configuration

For testing purposes, you can add an annotation of `sso.apps.tanzu.vmware.com/allow-unsafe-identity-provider: ""` to the `AuthServer` metadata for communicating with the insecure upstream OpenID Connect providers by using HTTP scheme.

Caution

Use this option only in the testing or prototyping environments.

Configure custom CA

For more information about using an upstream OpenID provider with a custom or private certificate authority (CA), see CA certificates for Application Single Sign-On.

Discovery mechanism

Application Single Sign-On attempts to resolve the configuration document located at the designated configuration URI. The Application Single Sign-On client attempts to wait for at most 10 seconds to receive a response. If there is no response or the response status is not HTTP `200 OK`, the `AuthServer` resource enters an authorization server configuration error state and provides a corresponding error message. The client re-attempts discovery at least 1 minute after the last failed discovery attempt.

The Application Single Sign-On client supports connecting to OpenID Connect providers configured with the TLS protocol v1.2 and later.

The Application Single Sign-On client attempts to discover the following OpenID Connect fields:

- `authorization_endpoint`
- `token_endpoint`
- `jwks_uri`
- `userinfo_endpoint`

Supported token signing algorithms

AppSSO only supports the `RS256` algorithm for token signature. For more information, see OpenID Connect documentation.

You can find out the signing algorithms your OpenID provider supports by referring to the `id_token_signing_alg_values_supported` response parameter in the OpenID Connect documentation at `.well-known/openid-configuration`.

For example, you can run:

```
curl -s "ISSUER-URI/.well-known/openid-configuration" | jq ".id_token_signing_alg_valu
es_supported"
```

LDAP

Important

You can not configure more than one `ldap` identity provider.

For example:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
# ...
spec:
  identityProviders:
    - name: ldap
      ldap:
        url: "ldaps://example.com:636"
        bind:
          dn: uid=binduser,ou=Users,dc=example,dc=com
          passwordRef:
            name: ldap-password
        user:
          searchBase: ou=Users,dc=example,dc=com
          searchFilter: cn={0}
        roles:
          fromUpstream:
            attribute: cn
            search:
              filter: member={0}
              base: ou=Users,dc=example,dc=com
              searchSubTree: true
              depth: 10
          filterBy:
            - exactMatch: "users"
            - regex: "^admin"
        idToken:
          claims:
            - fromUpstream: ""
              toClaim: ""
        group: # DEPRECATED, use 'roles' instead
          search:
            filter: member={0}
            base: ou=Users,dc=example,dc=com
            searchSubTree: true
            depth: 10
          roleAttribute: cn
  # ...
---
apiVersion: v1
kind: Secret
metadata:
  name: ldap-password
  namespace: default
stringData:
  password: confidential-password-value
```

Where:

- `.ldap.url`: The URL of the LDAP server. It must be `ldaps` and must contain a port.
- `.ldap.bind.dn`: The DN to perform the bind.
- `.ldap.bind.passwordRef`: Must be a secret with the entry `password`, which is the password to perform the bind.
- `.ldap.user.searchBase`: The branch of tree where the users are located at. Search is performed in the nested entries.
- `.ldap.user.seachFilter`: The filter for LDAP search. It must contain the string `{0}`, which is replaced by the `dn` of the user when performing a search. For example, when logging in with the user name `marie`, the filter for LDAP search is `cn=marie`.

- `.ldap.roles` (optional): Configures how LDAP groups are mapped to user roles in the `id_token` claims. Defaults to unset, meaning the user has no roles.
- `.ldap.roles.fromUpstream.attribute`: Selects which attribute of the group entry are mapped to a user role. If an attribute has multiple values, the first value is selected.
- `.ldap.roles.fromUpstream.search` (optional): Toggles OpenLDAP-style group search, optionally uses recursive search to find groups for a user.
- `.ldap.roles.filterBy` (optional): Applies roles claim filters. See Roles claim filtering section for more details.
- `.ldap.idToken.claims`: Allows for mapping a claim from an upstream identity provider to the current authorization server. See Identity token claims mapping for more details.

  LDAP providers have the following claims mapped by default:

LDAP attribute	Id token claim
givenname	given_name
sn	family_name
cn	name
mail	email
telephonenumber	phone_number

The following fields are deprecated:

- `.ldap.group` (optional): Configures how LDAP groups are mapped to user roles in the `id_token` claims. If not set, the user has no roles. Use `.ldap.roles` instead.
- `.ldap.group.roleAttribute`: Selects which attributes of the group entry are mapped to a user role. If an attribute has multiple values, the first value is selected.
- `.ldap.group.search` (optional): Toggles Active Directory search and uses recursive search to find groups for a given user.

Verify the configuration by visiting the `AuthServer`'s issuer URI in your browser and log in with the user name and password from LDAP.

LDAP external groups mapping

Service operators can map the identity provider's "groups" or equivalent attribute to the `roles` claim within an `AuthServer`'s identity token.

Note

Read more about roles claim mapping and filtering here

Configure `AuthServer` with LDAP groups attribute mapping:

```
spec:
  identityProviders:
    - name: "ldap-idp"
      ldap:
        roles:
          fromUpstream:
            attribute: "upstream-identity-providers-groups-attribute" # e.g. "cn" or
"dn"
```

For every ClientRegistration that has the `roles` scope listed, the identity token is populated with the `roles` claim:

```
kind: ClientRegistration
metadata:
  name: my-client-registration
spec:
  scopes:
    - name: openid
    - name: roles
  # ...
```

This rule also applies to ClassClaim:

```
kind: ClassClaim
metadata:
  name: my-class-claim
spec:
  parameters:
    scopes:
      - name: openid
      - name: roles
  # ...
```

When groups are mapped (as described above), all the groups provided by the identity provider are retrieved, and the relevant groups that the logged-in user is part of are appended to the `roles` claim of an `id_token`. To filter the available roles within an `id_token`, see Roles claim filtering section.

ActiveDirectory group search

In ActiveDirectory groups, user entries have a multi-value `memberOf` attribute, which contains the DNs pointing to the groups of a particular user. To enable this search mode, make sure `roles.fromUpstream.attribute` is set and `roles.fromUpstream.search` is not set.

For example:

```
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
# ...
spec:
  identityProviders:
    - name: ldap
      ldap:
        # ...
        user:
          searchBase: OU=Cloud,DC=ad,DC=example,DC=com
          searchFilter: cn={0}
        roles:
          fromUpstream:
            attribute: sAMAccountName
```

The LDIF definition is as follows:

```
dn: CN=appsso-user,OU=Cloud,DC=ad,DC=example,DC=com
objectClass: top
objectClass: person
objectClass: organizationalPerson
objectClass: user
cn: appsso user
sn: user
```

```
givenName: appsso
distinguishedName: CN=appsso user,OU=Cloud,DC=ad,DC=example,DC=com
displayName: appsso user
memberOf: CN=ssogroup,OU=Cloud,DC=ad,DC=example,DC=com
memberOf: CN=developers,OU=Cloud,DC=ad,DC=example,DC=com
sAMAccountName: appssouser
userPrincipalName: appssouser@ad.example.com
objectCategory: CN=Person,CN=Schema,CN=Configuration,DC=ad,DC=example,DC=com
# ...

# Groups
dn: CN=ssogroup,OU=Cloud,DC=ad,DC=example,DC=com
objectClass: top
objectClass: group
cn: ssogroup
member: CN=appsso-user,OU=Cloud,DC=ad,DC=example,DC=com
sAMAccountName: SSO Group
# ...

dn: CN=developers,OU=Cloud,DC=ad,DC=example,DC=com
objectClass: top
objectClass: group
cn: developers
sAMAccountName: Developers
# ...
```

The user `appsso-user` has two values for `memberOf`, pointing to two groups. Given the configuration earlier, `sAMAccountName` is used for the role, so the user has `SSO Group` and `Developers` as roles. The group is not required to have `member` attribute point to the user for the role to be mapped.

“Classic” group search

In non-ActiveDirectory LDAP, users generally do not have a `memberOf` attribute. Group search is performed by looking up groups in a base branch and filtering based on the groups `member` attribute.

An AuthServer can optionally perform:

- group search in sub-branches.
- nested group search, that is, find a hierarchy of groups, in which a group is a member of another group.

The complete configuration is as follows:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
# ...
spec:
  identityProviders:
    - name: ldap
      ldap:
        # ...
        roles:
          fromUpstream:
            attribute: description
            search:
              base: ou=Users,dc=example,dc=com
              filter: member={0}
              depth: 10
              searchSubTree: true
  # ...
```

Where:

- `search.base` is the base for running an LDAP search for groups.
- `search.filter` is the filter for running an LDAP search for groups. It must contain the string `{0}`, which is replaced by the `dn` of the user when performing group search. For example, `member=cn=marie,ou=Users,dc=example,dc=org`.
- `search.depth` (optional) is the depth at which to perform nested group search. It defaults to unset if left empty.
- `search.searchSubTree` (optional) controls whether to look for groups in sub-trees of the `search.base`. It defaults to unset if left empty.

Direct group search only

Given the following minimal configuration:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
# ...
spec:
  identityProviders:
    - name: ldap
      ldap:
        # ...
        user:
          searchBase: ou=Users,dc=example,dc=com
          searchFilter: uid={0}
        roles:
          fromUpstream:
            attribute: description
            search:
              base: ou=Users,dc=example,dc=com
              filter: member={0}
  # ...
```

The LDIF definition is as follows:

```
######################
## Users
######################
## User Marie Curie
## Marie Salomea Skłodowska Curie ; https://en.wikipedia.org/wiki/Marie_Curie
dn: cn=marie,ou=Users,dc=example,dc=org
cn: Marie
sn: Skłodowska Curie
objectClass: inetOrgPerson
objectClass: posixAccount
objectClass: shadowAccount
uid: marie

######################
## Groups
######################
dn: cn=nobels,ou=Users,dc=example,dc=org
objectClass: groupOfNames
description: Nobel Prizes
member: cn=marie,ou=Users,dc=example,dc=org
```

User `marie` has roles `Nobel Prizes`.

Groups in sub-trees

AppSSO can perform group search in sub-trees of the base for group search. This is enabled when `roles.fromUpstream.search.searchSubTree` is explicitly set to `true`. For example:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
# ...
spec:
  identityProviders:
    - name: ldap
      ldap:
        # ...
        roles:
          fromUpstream:
            attribute: description
            search:
              base: ou=Users,dc=example,dc=com
              filter: member={0}
              searchSubTree: true
  # ...
```

The LDIF definition is as follows:

```
######################
## Users
######################
## User Corazon
## Maria Corazon Sumulong Cojuangco Aquino; https://en.wikipedia.org/wiki/Corazon_Aqui
no
dn: cn=corazon,ou=Users,dc=example,dc=com
cn: Maria Corazon
sn: Sumulong Cojuangco Aquino
objectClass: inetOrgPerson
objectClass: posixAccount
objectClass: shadowAccount
uid: corazon

######################
## Groups
######################
dn: cn=presidents,ou=Users,dc=example,dc=com
objectClass: groupOfNames
description: Presidents
member: cn=corazon,ou=Users,dc=example,dc=com

dn: cn=chief-commanders,ou=LegionHonor,ou=Users,dc=example,dc=com
objectClass: groupOfNames
description: Chief Commanders
member: cn=corazon,ou=Users,dc=example,dc=com
```

User `corazon` has roles `Presidents` and `Chief Commanders`, which are retrieved from `ou=LegionHonor,ou=Users,dc=example,dc=com`, a subtree of the search base.

Nested group search

AppSSO can perform nested group search by going up a chain where a user is a member of a group, which is itself a member of a group, and so on. This is enabled by setting

`roles.fromUpstream.search.depth` to greater than `1`. `roles.fromUpstream.search.depth` controls the number of “levels” that AppSSO fetches to get the groups of a user.

For example:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
# ...
spec:
  identityProviders:
    - name: ldap
      ldap:
        # ...
        user:
          searchBase: ou=Users,dc=example,dc=com
          searchFilter: uid={0}
        roles:
          fromUpstream:
            attribute: description
            search:
              base: ou=Users,dc=example,dc=com
              filter: member={0}
              depth: 2
  # ...
```

The LDIF definition is as follows:

```
######################
## Users
######################
## User Corazon
## Maria Corazon Sumulong Cojuangco Aquino; https://en.wikipedia.org/wiki/Corazon_Aqui
no
dn: cn=corazon,ou=Users,dc=example,dc=com
cn: Maria Corazon
sn: Sumulong Cojuangco Aquino
objectClass: inetOrgPerson
objectClass: posixAccount
objectClass: shadowAccount
uid: corazon

######################
## Groups
######################
# Citizen > Politicians > Presidents > corazon (depth = 3)
dn: cn=citizens,ou=Users,dc=example,dc=com
objectClass: groupOfNames
description: Citizens
member: cn=politicians,ou=Users,dc=example,dc=com

# Politicians > Presidents > corazon (depth = 2)
dn: cn=politicians,ou=Users,dc=example,dc=com
objectClass: groupOfNames
description: Politicians
member: cn=presidents,ou=Users,dc=example,dc=com

# Presidents > corazon (depth = 1, direct group)
dn: cn=presidents,ou=Users,dc=example,dc=com
objectClass: groupOfNames
description: Presidents
member: cn=corazon,ou=Users,dc=example,dc=com
```

User `corazon` has roles `Presidents` and `Politicians`. However, the search stops at depth 2, so they do not have the role `Citizens`, which requires a depth greater or equal to 3.

SAML (experimental)

Caution

Support for SAML providers is experimental.

For SAML providers only autoconfiguration through `metadataURI` is supported.

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
# ...
spec:
  identityProviders:
  - name: my-saml-provider
    saml:
      metadataURI: https://saml.example.com/sso/saml/metadata # required
      displayName: "My SAML provider" # optional
      idToken: # optional
        claims:
          - fromUpstream: "" # SAML attribute
            toClaim: ""      # claim that is part of an AppSSO id_token
```

- `.saml.displayName` (optional): A user-friendly display name for the provider that is rendered on the login page.
- `.saml.idToken.claims`: Allows for mapping a SAML attribute from an upstream SAML identity provider to the current authorization server. For more information, see Identity token claims mapping.

SAML external groups mapping

Service operators may map the identity provider's "groups" (or equivalent) attribute to the `roles` claim within an `AuthServer`'s identity token.

Note

Read more about roles claim mapping and filtering here

Configure `AuthServer` with SAML role attribute:

```
spec:
  identityProviders:
    - name: "saml-idp"
      saml:
        roles:
          fromUpstream:
            attribute: "saml-group-attribute"
```

For every ClientRegistration that has the `roles` scope listed, the identity token will be populated with the `roles` claim:

```
kind: ClientRegistration
metadata:
```

```
  name: my-client-registration
spec:
  scopes:
    - name: openid
    - name: roles
  # ...
```

When groups are mapped (as described above), all the groups provided by the identity provider are retrieved, and the relevant groups that the logged-in user is part of are appended to the `roles` claim of an `id_token`. To filter the available roles within an `id_token`, see Roles claim filtering section.

Note for registering a client with the identity provider

The `AuthServer` will set up SSO and metadata URLs based on the provider name in the configuration. For example, for a SAML provider with `name: my-provider`, the SSO URL will be `{spec.issuerURI}/login/saml2/sso/my-provider`. The metadata URL will be `{spec.issuerURI}/saml2/service-provider-metadata/my-provider`. `spec.issuerURI` is the externally accessible issuer URI for an `AuthServer`, including scheme and port. If the `AuthServer` is accessible on `https://appsso.company.example.com:1234/`, the SSO URL registered with the identity provider should be `https://appsso.company.example.com:1234/login/saml2/sso/my-provider`.

InternalUnsafe

> **Caution**
>
> The internal provider is **unsafe** and **must not** be used in production environments.

`InternalUnsafe` must be explicitly allowed by setting the annotation `sso.apps.tanzu.vmware.com/allow-unsafe-identity-provider: ""`.

During development, static users can be useful for testing purposes.

You cannot configure more than one `internalUnsafe` identity provider.

For example:

```
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  annotations:
    sso.apps.tanzu.vmware.com/allow-unsafe-identity-provider: "" # required annotation
when using the internal unsafe provider
  # ...
spec:
  identityProviders:
    - name: test-users
      internalUnsafe:
        users:
          - username: ernie
            password: "password" # plain text
            roles:
              - "silly"
            claims: # custom identity token claims
              given_name: "Bert"
              family_name: "Muppet"
              middle_initial: "H"
              email: "bert@muppets.example.com"
              alt_address: "123 Sesame Street"
```

```
          - username: bert
            password: "{bcrypt}$2a$10$201z9o/tHlocFsHFTo0plukh03ApBYe4dRiXcqeyRQH6CNNt
S8jWK" # bcrypt-hashed "password"
            roles:
              - "grumpy"
            claims: # custom identity token claims
              alt_address: "456 Fake Street"
              middle_initial: "T"
  # ...
```

The passwords can be plain text or bcrypt-hashed. Bcrypt-hashing passwords must be prefixed with `{bcrypt}`. For more information about the bcrypt-hash string, see Generating a bcrypt hash from a plain-text password.

Verify the configuration by visiting the `AuthServer`'s issuer URI in your browser and logging in as `ernie/password` or `bert/password`.

To use custom claims defined within `.internalUnsafe.users[*].claims`, you must include the `profile` scope within your `ClientRegistration` resource.

Generating a bcrypt hash from a plain-text password

There are multiple options for generating bcrypt hashes:

1. Use an online bcrypt generator
2. On Unix platforms, use `htpasswd`. Note, you may need to install it, for example on Ubuntu by running `apt install apache2-utils`

   ```
   htpasswd -bnBC 12 "" your-password-here | tr -d ':\n'
   ```

Identity token claims mapping

Note

This section is applicable to OpenID, LDAP, and SAML (experimental) identity provider configurations.

Service Operators can control which claims appear in an `AuthServer`-issued `id_token`, and how to obtain this value from an upstream identity provider.

For example, consider the following configuration:

```
spec:
  identityProviders:
  - name: my-identity-provider
    openid:
      idToken:
        claims:
          - fromUpstream: "title"
            toClaim: "job_title"
```

With this, if the upstream OpenID identity provider makes a `"title"` claim available with the value `"developer"`, the corresponding AuthServer-issued `id_token` contains a claim `"job_title": "developer"`.

This field also allows for mapping the standard OpenID claims, such as `given_name`, `family_name`, and non-standard claim, such as the `job_title` claim in the earlier example. When mapping the standard claims, the field types are preserved according to the original OpenID specification. For example, the `given_name` claim is defined as a string in the OpenID specification, so if a custom

claim is mapped into this field, the value of the custom claim is coerced into a string type. If the custom claim is an array type, the first value of the array is used.

Important

For the custom claims defined `.spec.identityProviders[*].{openid,ldap,saml}.idToken.claims` to be available in `AuthServer`-issued `id_token`s, App Operators must include the `profile` scope within their `ClientRegistration` resource.

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
# ...
spec:
  identityProviders:
  - name: my-identity-provider
    {openid,ldap,saml}:
      idToken: # optional
        claims:
          - fromUpstream: "" # identity provider claim name
            toClaim: ""      # claim that is part of an AppSSO id_token
```

Constraints

You must adhere to the following identity token mapping constraints:

- Multiple upstream identity provider claims cannot be mapped to a single `AuthServer` identity token claim.
- The value of `claims.fromUpstream` is case-insensitive for LDAP identity providers, and is case-sensitive for OpenID and SAML identity providers.
- `idToken.claims.toClaim` is case-sensitive.
- Application Single Sign-On collects claims only from the upstream `id_token` and, for OpenID identity providers, from the `userinfo` endpoint defined in `.openID.userinfoUri`.
- Reserved claims can not be mapped to. Reserved claims are listed as follows:

Reserved Claim Names
`roles`
`acr`
`amr`
`at_hash`
`auth_time`
`azp`
`c_hash`
`nonce`
`aud`
`exp`
`iat`

Reserved Claim Names
`iss`
`jti`
`nbf`
`sub`

Roles claim filtering

Note

This section is applicable to OpenID, LDAP, and SAML (experimental) identity provider configurations.

Once an external groups mapping has been applied (as described per identity provider above), AppSSO is able to retrieve all the groups from an identity provider. An identity provider may have hundreds of groups, and any particular user may be part of a large subset of those groups. When a user logs in, those groups will be appended to their `id_token`'s `roles` claim. This section describes how to filter the `roles` claim.

To filter groups, for a supported identity provider, apply:

```
spec:
  identityProviders:
    - name: my-provider
      <idp>:
        roles:
          filterBy:
            - exactMatch: ""
            - regex: ""
```

where `<idp>` may be `openid`, `ldap`, or `saml`.

Filters are disjunctive ("OR" operator), so each filter is applied to the entire set of groups, and merged into a set of unique filtered groups values. See filter examples for more information.

Roles claim filters

Available filters are:

- `exactMatch` - match the groups exactly. This filter is **case-sensitive**. e.g. `exactMatch: "developer"` will match only the group named "developer" and no other.
- `regex` - match groups according to the defined regular expression pattern. , and This filter is **case-insensitive**. e.g. `regex: ^admin` will match groups starting with the word "admin".
    - The regular expression pattern syntax used is RE2
    - Expressions should not be surrounded by forward slashes (`/`) and should only contain the pattern (e.g. `.*`, `^dev`, `\w+`).

Roles claim filter examples

Given an example set of groups retrieved from a hypothetical identity provider:

```
it-admin
it-developer
devops-user
```

```
devops-admin
devops-developer
product-user
product-developer
org-user
hr-user
hr-admin
```

Basic exact match filters

```
- exactMatch: "product-user"
- exactMatch: "org-user"
```

returns:

```
product-user
org-user
```

Basic regular expression (RegEx) filters

```
- regex: ".*-developer"
```

returns:

```
it-developer
devops-developer
product-developer
```

Multiple regular expression (RegEx) filters

```
- regex: ".*-developer"
- regex: "^it"    # starts with "it"
- regex: "admin$" # ends with "admin"
- regex: "\w+"    # at least one word or more
```

returns:

```
it-admin
it-developer
devops-admin
devops-developer
product-developer
hr-admin
```

Note

filters are disjunctive and so multiple filters can filter down the same values, but the resulting set will always have unique values.

Exact match and regular expression (RegEx) filters

```
- exact-match: "hr-admin"
- exact-match: "org-user"
- regex: "developer$"    # ends with "developer"
```

returns:

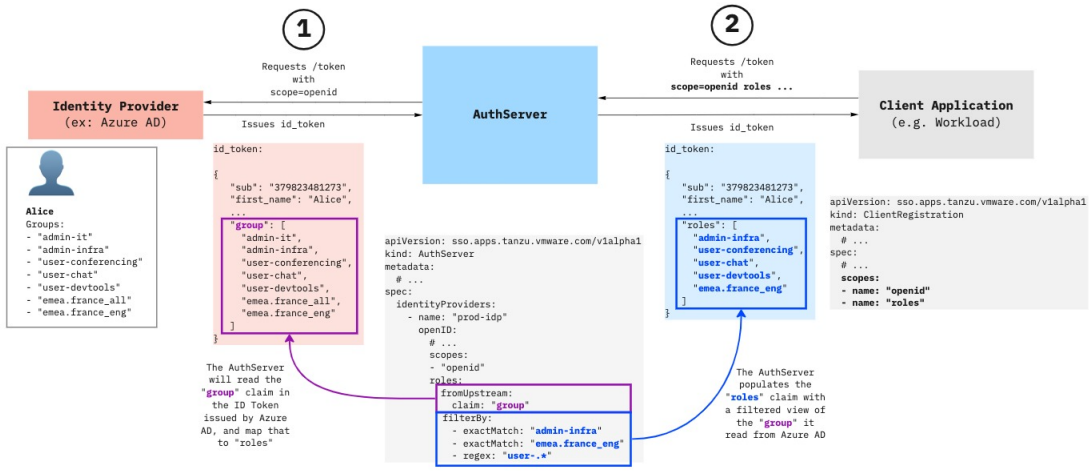
```
it-developer
devops-developer
```

```
product-developer
org-user
hr-admin
```

Roles claim mapping and filtering explained

When issuing an `id_token`, OpenID providers may include a (non-standard) claim describing the "groups" the user belongs to, the "roles" of the user, or something similar. This claim is identity provider specific. For example, Azure AD uses the "group" claim by default, and allows administrators to select the name of the claim.

Service Operators may choose to make these "groups", "roles", or equivalent, available in the id_token issued by an AppSSO `AuthServer`, in the `roles` claim, with filtering rules applied.



Restrictions

Each identity provider has a declared `name`. The following conditions apply:

- the names must be unique
- the names must not be blank
- the names must follow Kubernetes' DNS Subdomain Names guidelines
  - contain no more than 253 characters
  - contain only lowercase alphanumeric characters, '-' or '.'
  - start with an alphanumeric character
  - end with an alphanumeric character
- the names may not start with `client` or `unknown`

There can be at most one of each `internalUnsafe` and `ldap`.

Configure authorization for AppSSO

This topic tells you how to configure authorization for Application Single Sign-On (commonly called AppSSO).

Note

This topic is applicable to Internal, OpenID, LDAP, and SAML (experimental) identity provider `AuthServer` configurations. For more information, see AuthServer.

Overview

An application or `Workload` can protect certain resources based on user's level of authorization. Within OAuth 2, the application with protected resources, the Resource Server, verifies if the access token provided contains the scopes to perform an action on a protected resource.

The following excerpt is from a Spring Boot application, OAuth2 Resource Server, protecting its message API endpoints `/message/**`:

```
http.authorizeExchange(exchanges -> exchanges
                        .pathMatchers("/message/**").hasAuthority("SCOPE_message.rea
d")
                        .anyExchange().authenticated()
        )
```

The access token to access any endpoint under `/message/` path must have `message.read` scope within its access token.

For full example, see Spring Security documentation.

The following sections describe how to configure the mapping of user roles to authorization scopes at `AuthServer` identity provider and `ClientRegistration` levels.

Retrieving external groups or roles

Important

Skip this section if you work with an internal unsafe provider. External groups mapping is not required because roles are defined in the specifications.

To configure authorization for an identity provider, you must define from which claim or attribute the upstream identity provider supplies the groups or roles that a user is part of:

- OpenID external groups mapping
- LDAP external groups mapping
- SAML (experimental) external groups mapping

After external groups mapping is complete, and groups or roles are retrievable, you can optionally filter the roles that are appended to an identity token. For more information about how to filter roles, see Roles claim filtering.

Mapping individual roles into authorization scopes

After external groups or roles are mapped to AppSSO's `roles` claim, and optionally filtered for the desired set of retrieved roles, you can map each role to the desired authorization scopes.

For example, given a retrieved role "hr", any client authorizing by using `my-openid-provider` can request scopes `hr.read` or `hr.write`, provided that the client registered the scopes in `ClientRegistration.spec.scopes`:

```
kind: AuthServer
# ...
spec:
```

```
  identityProviders:
    - name: my-openid-provider
      openid:
        accessToken:
          scope:
            rolesToScopes:
              - fromRole: "hr" # -> Role "hr" is mapped to the "hr.read" and "hr.writ
e" scopes.
                toScopes:      #    Only users with the "hr" role can be issued access
token with these scopes.
                  - "hr.read"  # ^^
                  - "hr.write" # ^^
```

For example, given that a `ClientRegistration` is applied to include `hr.read` or `hr.write`:

```
kind: ClientRegistration
# ...
spec:
    scopes:
    - name: "roles" # Must request special 'roles' scope.
    - name: "hr.read"
    - name: "hr.write"
```

Any client can request an access token with the scopes, but an access token can be issued with those scopes only if the user that is being authorized has the role `hr` in the upstream identity provider.

If the user has the role `hr`, he or she must consent to allow the application to request the scopes. After the consent is provided, the user can access resources limited to the `hr.read` and `hr.write` scopes within the application by using their access token.

Default authorization scopes

You can define authorization scopes that are automatically granted to all users within an identity provider, regardless of user role.

For example, given an `AuthServer` with an OpenID provider, with defined authorization scope defaults:

```
kind: AuthServer
# ...
spec:
    identityProviders:
    - name: my-openid-provider
      openid:
        accessToken:
            scope:
                defaults:
                - "developer.read"
                - "developer.write"
                - "developer.delete"
```

For example, given that a `ClientRegistration` is applied to include any of the default scopes:

```
kind: ClientRegistration
# ...
spec:
    scopes:
    - name: "roles" # Must request special 'roles' scope.
    - name: "developer.read"
```

When an application or `Workload` is registered by using the `ClientRegistration`, that application, on behalf of the user, can request and be granted with the scope `developer.read` automatically within the issued access token. The user must consent to allow the application to request the scope. After the consent is provided, the user can access resources limited to the `developer.read` scope within the application by using their access token.

The following is a full sample of authorization configurations and the accompanying `ClientRegistration` configurations to allow clients to request the scopes:

```
kind: AuthServer
# ...
spec:
  identityProviders:
    - name: my-openid-provider
      openid:
        roles:
          fromUpstream:
            claim: "groups"            # -> Map the upstream identity provider's exter
nal groups or roles claim.
          filterBy:                    # -> Optionally filter the groups or roles retr
ieved from identity provider.
            - exactMatch: "finance"    # ^^
            - exactMatch: "hr"         # ^^
            - exactMatch: "marketing"  # ^^
        accessToken:
          scope:
            defaults:                  # -> Optional default scopes granted to any use
r within the identity provider.
              - "developer.read"       # ^^
              - "developer.write"      # ^^
              - "developer.delete"     # ^^
            rolesToScopes:
            - fromRole: "hr"           # -> Role "hr" is mapped to "hr.read", "hr.writ
e" scopes.
              toScopes:                #    Only users with "hr" role can be issued ac
cess token with these scopes.
                - "hr.read"            # ^^
                - "hr.write"           # ^^
            - fromRole: "finance"      # -> Role "finance" is mapped to "finance" scop
e.
              toScopes:                #    Only users with "finance" role can be issu
ed an access token with this scope.
                - "finance"            # ^^
            - fromRole: "marketing"    # -> Role "marketing" is mapped to "marketing-r
eader", "marketing-writer" scopes.
              toScopes:                #    Only users with "marketing" role can be is
sued an access token with these scopes.
                - "marketing-reader"   # ^^
                - "marketing-writer"   # ^^
```

```
kind: ClientRegistration
# ...
spec:
  scopes:
    - name: "roles" # Must request special 'roles' scope.
    - name: "developer.read"
    - name: "developer.write"
    - name: "developer.delete"
    - name: "hr.read"
    - name: "hr.write"
    - name: "finance"
    - name: "marketing-reader"
    - name: "marketing-writer"
```

Public clients and CORS for AppSSO

This topic tells you how to configure Application Single Sign-On (commonly called AppSSO) to use public clients.

Overview

A public client is a client application that does not require credentials to obtain tokens, such as single-page apps (SPAs) or mobile devices. Public clients rely on Proof Key for Code Exchange (PKCE) Authorization Code flow extension.

Follow these steps to configure an `AuthServer` and `ClientRegistration`s for use with public clients:

1. Specify allowed HTTP origin (one or more) by using the `AuthServer.spec.cors` API.

   The authorization server relaxes the same-origin policy for the specified domain (one or more), enabling browser-based, single-page applications to interact with the designated authorization server. For more information, see CORS configuration.

2. Set `clientAuthenticationMethod` to `none` within `ClientRegistration` resource.

   Native applications and browser-based applications are considered public clients and must not rely on client credentials. Instead, PKCE must be used. Setting `clientAuthenticationMethod: none` ensures client credentials are not used, and makes PKCE mandatory for those clients. For more information, see Client authentication.

CORS configuration

A browser-based public client can interact with an `AuthServer` if the `AuthServer` has the public clients' origin (one or more) specified in `AuthServer.spec.cors`.

VMware recommends designating specific origins as follows:

```
kind: AuthServer
# ...
spec:
  cors:
    allowOrigins:
    - "https://example.com"         # Specific domain.
    - "https://mydept.example.com" # Specific subdomain.
    - "https://*.example.com"       # Subdomain wildcard notation.
    - "https://*.apps.example.com" # Subdomain wildcard notation.
```

You can also designate that all origins are allowed as follows:

```
kind: AuthServer
metadata:
  annotations:
    sso.apps.tanzu.vmware.com/allow-unsafe-cors: ""
spec:
  cors:
    allowAllOrigins: true
```

Caution

Do not allow all origins in production environments.

You must use the `allow-unsafe-cors` annotation when allowing all origin allowance. The `AuthServer` sends the `Access-Control-Allow-Origin: *` HTTP response header.

Requirements for allowed origin designations include:

- Only `allowOrigins` or `allowAllOrigins` is allowed to be set.
- When using `allowAllOrigins`, you must explicitly set the annotation `sso.apps.tanzu.vmware.com/allow-unsafe-cors: ""`. This is an acknowledgement that using `allowAllOrigins` is inherently unsafe.

Client authentication

When configuring a `ClientRegistration` for a public client, you must set your client authentication method to `none` and ensure that your public client supports Authorization Code with PKCE. With PKCE, the client does not authenticate, but presents a code challenge and subsequent code verifier to establish trust with the authorization server.

To set Client Authentication Method to `none`, ensure your `ClientRegistration` resource defines the following:

```
kind: ClientRegistration
# ...
spec:
  clientAuthenticationMethod: none
```

Public clients supporting Authorization Code with PKCE flow ensure that:

- On every OAuth `authorize` request, parameters `code_challenge` and `code_challenge_method` are provided. Only `code_challenge_method=S256` is supported.
- On every OAuth `token` request, parameter `code_verifier` is provided. Public clients do not provide a Client Secret because they are not tailored to retain any secrets in public view.

For public clients, the `AuthServer` only supports the Authorization Code Flow: `response_type=code`, because public clients such as single-page apps cannot safely store sensitive information such as client secrets.

Client credentials code grant

Some single-page applications require obtaining a token by using the `client_credentials`. This is not a recommended practice because a browser-based app cannot protect its `client_secret`.

In this scenario, the `ClientRegistration` cannot use `none` as its `clientAuthenticationMethod`. It must use either `client_secret_basic` or `client_secret_post`. For example:

```
kind: ClientRegistration
# ...
spec:
  authorizationGrantTypes:
  - client_credentials
  clientAuthenticationMethod: client_secret_basic
```

Additional CORS configuration

When you define either `allowOrigins` or `allowAllOrigins`, default values are set for other CORS-related headers. VMware provides configuration options to customize some of these headers. The following is the full CORS configuration using `allowOrigins`:

```
kind: AuthServer
# ...
spec:
  cors:
```

```
    allowOrigins:
    - "https://example.com"
    allowMethods:
    - GET
    - POST
    - OPTIONS
    allowHeaders:
    - Authorization
    exposeHeaders: []
    allowCredentials: false
```

- `allowMethods` defines the list of HTTP methods allowed. The values are sent back in the response to pre-flight requests, in the `Access-Control-Allow-Methods` header. When a pre-flight request is issued with the `Access-Control-Request-Method` header set, the value is checked against `allowMethods`. If it matches, the request completes. If it does not match, the server answers with an HTTP 403 Unauthorized status. The valid values are either `["*"]` or any combination of `[GET, HEAD, POST, PUT, PATCH, DELETE, OPTIONS, TRACE]`. The values are case-sensitive and default to `["GET", "POST", "OPTIONS"]`.
- `allowHeaders` defines the list of headers allowed. When a client issues a pre-flight request with values in the `Access-Control-Request-Headers` header, only the values that are also present in `AllowHeaders` are sent back in the response's `Access-Control-Allow-Headers` header. The values are case-insensitive and default to `["Authorization"]`.
- `exposeHeaders` defines the values of the `Access-Control-Expose-Headers` header in the response to a CORS request. The default value is `[]`.
- `allowCredentials` defines the value of the `Access-Control-Allow-Credentials` header in the response to a CORS request. The default value is `false`.

Token settings for Application Single Sign-On

This topic tells you how to configure token expiry settings for Application Single Sign-On (commonly called AppSSO).

Token expiry

AppSSO allows you to optionally configure the token expiry settings in your `AuthServer` resource.

The default token expiry settings are as follows:

Token type	Lifetime
Access token	12 hours
Identity token	12 hours
Refresh token	720 hours or 30 days

VMware recommends setting a shorter lifetime for access tokens, typically measured in hours, and a longer lifetime for refresh tokens, typically measured in days. Refresh tokens acquire new access tokens, so they have a longer lifespan.

To override the token expiry settings, configure the following in your `AuthServer` resource:

```
kind: AuthServer
# ...
spec:
  token:
    accessToken:
      expiry: "12h"
    idToken:
      expiry: "12h"
    refreshToken:
      expiry: "720h"
```

`expiry` field examples:

Type	Example	Definition
Seconds	`10s`	10 seconds
Minutes	`10m`	10 minutes
Hours	`10h`	10 hours

Note

The `expiry` field adheres to the duration constraints of the Go standard time library and does not support durations in units beyond hours, such as days or weeks. For more information, see the Go documentation.

Constraints

The token expiry constraints are as follows:

- The duration of the `expiry` field cannot be negative or zero.
- The refresh token's expiration time cannot be the same as or shorter than that of the access token.

Verify token settings

After you set up an Application Single Sign-On `AuthServer`, you can verify that the token received by applications looks as expected. For this purpose, you can create a simple application consuming your `AuthServer`. The following YAML file creates such an application. When you access its URL, it enables you to log in by using your `AuthServer` and displays the token it receives.

Caution

- The simple application is not intended for production use. It only serves a tool to help you verify your setup.
- The following YAML file pulls an unvetted public image `bitnami/oauth2-proxy:7.3.0`
- This section does not apply to an air-gapped environment.

If you stored the following YAML in a file named `token-viewer.yaml`, you can apply it to your cluster by running the following command:

```
  ytt -f token-viewer.yaml --data-value ingress_domain=YOUR-INGRESS-DOMAIN --data-valu
e-yaml 'authserver_selector=YOUR-AUTHSERVER-SELECTOR' | kubectl apply -f-
```

Where `YOUR-AUTHSERVER-SELECTOR` is the label name and its value. For example: `{"name": "ci"}`.

A full example is as follows:

```
#!
#! Token viewer
#!
#! usage:
#!
#! ytt -f token-viewer.yaml --data-value ingress_domain=example.com --data-value-yaml
'authserver_selector={"name": "ci"}'
#!
#! Then navigate to http://token-viewer.<INGRESS_DOMAIN>
#!

#@ load("@ytt:data", "data")
#@ fqdn = "token-viewer." + data.values.ingress_domain
#@ redirect_uri = "http://" + fqdn + "/oauth2/callback"
#@ namespace = data.values.namespace if "namespace" in data.values else "default"

Manage token signature keys for Application Single Sign-On

This topic tells you how to manage token signature keys for Application Single Sign-On (commonly called AppSSO).

Overview

An `AuthServer` must have token signature keys configured to be able to mint tokens.

For more information about token signatures, see About token signatures.

To learn how to manage keys of an `AuthServer`:

- Creating keys
- Rotating keys
- Revoking keys

Important

"Token signature key" or just "key" is AppSSO's wording for a public/private key pair that is tasked with signing and verifying JSON Web Tokens (JWTs). For more information, please refer to the following resources:

- JSON Web Signature (JWS) spec
- JSON Web Algorithms (JWA) spec
- JSON Web Token (JWT) spec

Creating keys

You can deploy an `AuthServer` without `spec.tokenSignature` but it won't be able to mint tokens. Therefore, keys must be configured to make it fully operational. The following describe how to create and apply a keys for an `AuthServer`.

An RSA key can be created multiple ways. Below are two recommended approaches – choose one.

Using secretgen-controller

Important

> This section assumes you have Tanzu Application Platform running on your cluster with `secretgen-controller` installed.

An RSAKey CR allows for expedited creation of a Secret resource containing PEM-encoded public and private keys required by an `AuthServer`.

1. Create an `AuthServer` with `RSAKeys` as follows:

```
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
 name: authserver-sample
 namespace: default
spec:
 tokenSignature:
   signAndVerifyKeyRef:
     name: my-token-signing-key
   extraVerifyKeyRefs:
     - name: my-token-verification-key
 # ...
---
apiVersion: secretgen.k14s.io/v1alpha1
kind: RSAKey
metadata:
 name: my-token-signing-key
 namespace: default
spec:
 secretTemplate:
   type: Opaque
   stringData:
     key.pem: $(privateKey)
     pub.pem: $(publicKey)
---
apiVersion: secretgen.k14s.io/v1alpha1
kind: RSAKey
metadata:
 name: my-token-verification-key
 namespace: default
spec:
 secretTemplate:
   type: Opaque
   stringData:
     key.pem: $(privateKey)
     pub.pem: $(publicKey)
```

2. Observe the creation of an underlying `Secrets`. The name of the each `Secret` is the same as the `RSAKey` names:

```
# Verify Secret exists
kubectl get secret my-token-signing-key

# View the base64-encoded keys
kubectl get secret my-token-signing-key -o jsonpath='{.data}'
```

   You should be able to see two fields within the Secret resource: `key.pem` (private key) and `pub.pem` (public key).

3. Verify that the `AuthServer` serves its keys

```
curl -s authserver-sample.default/oauth2/jwks | jq
```

If you encounter any issues with this approach, see Carvel Secretgen Controller documentation.

Using OpenSSL

You can generate an RSA key yourself using OpenSSL. Here are the steps:

1. Generate a PEM-encoded RSA key pair

   This guide references the freely published OpenSSL Cookbook and the approaches mentioned therein around generating a public and private key pair.

   ```
   # Generate an 4096-bit RSA key
   openssl genpkey -out privatekey.pem -algorithm RSA -pkeyopt rsa_keygen_bits:409
   6
   # -> privatekey.pem
   # The resulting private key output is in the PKCS#8 format

   # Next, extract the public key
   openssl pkey -in privatekey.pem -pubout -out publickey.pem
   # -> publickey.pem
   # The resulting public key output is in the PKCS#8 format

   # To view details of the private key
   openssl pkey -in privatekey.pem -text -noout
   ```

   For OpenSSL key generation examples, see the OpenSSL documentation.

   

   Important

   The minimum key size for an `Authserver` is 2048.

2. Create a secret resource by using the key generated earlier in this procedure:

   ```
   kubectl create secret generic my-key \
   --from-file=key.pem=privatekey.pem \
   --from-file=pub.pem=publickey.pem \
   --namespace default
   ```

3. Apply your `AuthServer`:

   ```
   apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
   kind: AuthServer
   metadata:
     name: authserver-sample
     namespace: default
   spec:
     tokenSignature:
       signAndVerifyKeyRef:
         name: my-key
     # ...
   ```

4. Verify that the `AuthServer` serves its keys

   ```
   curl -s authserver-sample.default/oauth2/jwks | jq
   ```

Rotating keys

This section describes how to “rotate” token signature keys for an `AuthServer`.

The action of “rotating” means moving the active token signing key into the set of token verification keys, generating a new cryptographic key, and assigning it to be the designated token signing key.

Assuming that you have an `AuthServer` with token signature keys configured, rotate keys as follows:

1. Generate a new token signing key first. See creating keys. Verify that the new `Secret` exists before proceeding to the next step.
2. Edit `AuthServer.spec.tokenSignature`, append the existing `spec.tokenSignature.signAndVerifyKeyRef` to `spec.tokenSignature.extraVerifyKeys` and set your new key as `spec.tokenSignature.signAndVerifyKeyRef`.

   For example:

   ```
   # Before
   ---
   apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
   kind: AuthServer
   metadata:
    name: authserver-sample
    namespace: default
   spec:
    tokenSignature:
      signAndVerifyKeyRef:
        name: old-key
      extraVerifyKeys: []
    # ...
   ```

   ```
   # After
   ---
   apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
   kind: AuthServer
   metadata:
    name: authserver-sample
    namespace: default
   spec:
    tokenSignature:
      signAndVerifyKeyRef:
        name: new-key
      extraVerifyKeys:
        - name: old-key
    # ...
   ```

   Once you apply your changes, key rotation is effective immediately.

Moving the active token signing key to be a token verification key is an *optional* step – check out the Revoking keys section for more.

Revoking keys

This section describes how to “revoke” token signature keys for an `AuthServer`.

The action of “revoking” a key means to entirely remove the key from circulation by an `AuthServer`, whether it be a token signing key or a token verification key. This action might be needed if your organization requires a complete key refresh where older keys are never retained. Another scenario might be in the case of an emergency in which a key or a session has been compromised and a complete revocation is warranted.

To revoke an existing key or keys, you may remove any references to the keys in the `spec.tokenSignature` resource. By removing the reference to the key, the system shall no longer acknowledge that the key is used for signing or verifying JWTs.

For example, if you have a token signing key and a few verification keys:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  name: authserver-sample
  namespace: default
spec:
  tokenSignature:
    signAndVerifyKeyRef:
      name: key-3
    extraVerifyKeys:
      - name: key-2
      - name: key-1
  # ...
```

To revoke an existing verification key, remove it from the `extraVerifyKeys` list. In the example above, you can remove “key-2” and “key-1” from the list; JWTs signed with those keys will no longer be verifiable.

To revoke an existing token signing key, remove it from `signAndVerifyKeyRef` field. However, if you remove an existing token signing key without a replacement key, the `AuthServer` will not be able to issue access tokens until a valid token signing key is provided. In the example above, “key-3” would be removed; the system will not be able to sign or verify JWTs.

Session settings for AppSSO

This topic tells you how to configure the session expiry settings for Application Single Sign-On (commonly called AppSSO).

Session expiry

AppSSO allows you to optionally configure the session expiry settings in your `AuthServer` resource.

The default expiry time for an AppSSO session is 15 minutes, according to the STIG guidelines.

To override the session expiry settings, configure the following in your `AuthServer` resource:

```
kind: AuthServer
# ...
spec:
  session:
    expiry: "30m"
```

`expiry` field examples:

Type	Example	Definition
Minutes	`10m`	10 minutes
Hours	`5h`	5 hours

Note

> The `expiry` field adheres to the duration constraints of the Go standard time library and does not support durations in units beyond hours, such as days or weeks. For more information, see the Go documentation.

Constraints

The session expiry constraints are as follows:

- The duration of the `expiry` field cannot be negative or zero.
- The duration must be at least 1 minute.

Storage for AppSSO

This topic tells you how to configure the storage for Application Single Sign-On (commonly called AppSSO).

Overview

AppSSOs `AuthServer` handles data pertaining to user's session, identity, access tokens and approved or rejected consents. For production environments, it is critical to provide your own storage source to enable enterprise functions such as data backup and recovery, auditing and long-term persistence according to your organization's data and security policies.

AppSSO currently only supports Redis `v6.0` or above as a storage solution. `v6.0` introduced TLS support to ensure encrypted client-server communication - AppSSO enforces TLS by default.

Storage provided by default refers to an `AuthServer` resource where `.spec.storage` is not set.

Although data in motion is encrypted by using TLS, data at rest is not encrypted by default through `AuthServer`. Each storage provider is responsible for encrypting their own data. See data types for more information about storage.

Securing Data at rest

To be compliant with HIPAA, FISMA, PCI and GDPR, you must encrypt data at rest. Securing the underlying infrastructure that Redis uses is crucial to protect against a potential attack. The National Institute for Standards and Technology – Federal Information Processing Standards (NIST-FIPS) sets the standard for best practice when it comes to data security in the US. Symmetric cryptography can be used to protect data at rest. This means that the same key encrypts and decrypts the data, so there is no need for a different private and public key. The Advanced Encryption Standard (AES) encryption algorithm is an industry standard for securing data at rest. For the highest level security, VMware recommends using a 256-bit key.

Configuring Redis

To configure Redis as authorization server storage, you must have the following information of your Redis server:

- **Server CA certificate** (optional): the Certificate Authority (CA) certificate to verify Redis TLS connections. It is not required if Redis Server certificate is signed by a public CA.
- **host** (required): the domain name, IP address, or host name of your Redis server.
- **port** (optional): the port number of your Redis server. It default to `6379` and must be a string.
- **username** (optional): the username to authenticate against your Redis server.

- **password** (optional): the password to authenticate against your Redis server.

AppSSO takes the secure-by-default approach and does not establish non-encrypted communication channels. The `AuthServer` resource enters an error state if a non-encrypted connection is attempted.

mTLS is not supported, however Vanilla Redis uses mTLS by default. It can be turned off by setting `tls-auth-clients no`. For more information, see Redis documentation.

The following steps introduce the path to configuring Redis with AppSSO:

1. Configuring Redis Server CA certificate
2. Configuring a Redis Secret
3. Attaching storage to an AuthServer

Configuring Redis Server CA certificate

If your Redis includes a custom or non-public Server CA certificate, you must instruct AppSSO to trust the CA certificate. This is required for the authorization server to communicate with your Redis over TLS. See CA certificates for more information about configuring a CA certificate with AppSSO.

Configuring a Redis Secret

To provide coordinates (the location details) of your Redis server, you must create a `Secret` resource that follows well-known Secret entries conventions. For more information, see Service Bindings 1.0.0 specification.

Example of a properly formatted `Secret` resource:

Important

The Secret must be created in the same namespace as your `AuthServer`.

```
apiVersion: v1
kind: Secret
metadata:
  name: redis-credentials
  namespace: my-authserver
type: servicebinding.io/redis        # optional, must equal 'servicebinding.io/redis'
if defined
stringData:
  type: "redis"                      # required, must equal 'redis'
  ssl: "true"                        # required, must equal 'true'
  host: "redis01.prod.example.com"   # required
  port: "6379"                       # optional, must be a string, defaults to "6379"
if left empty
  password: "!!veryStrongPassword!!" # optional
  username: "redis01-user"           # optional
```

Attaching storage to an AuthServer

After a Redis Secret resource is applied, you can reference the Secret in `.spec.storage`. An example of an AuthServer with a reference to a Redis Secret is as follows:

```
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  name: my-authserver-example
```

```
  namespace: my-authserver
spec:
  # ...
  storage:
    redis:
      serviceRef:
        apiVersion: "v1"
        kind: "Secret"
        name: redis-credentials
```

After `AuthServer` is applied, ensure its `Status` is `Ready`.

Inspecting storage of an AuthServer

You can inspect the status of an `AuthServer`'s storage as follows:

```
kubectl get authserver <authserver-name> \
  --namespace <authserver-namespace> \
  --output jsonpath="{.status.storage.redis}" | jq
```

Expect to see the following output with the actual Redis host and port:

```
{
  "redis": {
    "host": "ci-redis.authservers.svc.cluster.local",
    "port": "6379"
  }
}
```

Storage provided by default

If no storage is defined, an `AuthServer` provides its own short-lived ephemeral storage solution, Redis. The provided Redis is configured to never flush any data to any volume that might be attached to the pods that operate the authorization server.

Caution

The default storage configuration is desisged for prototyping or testing environments and must not be used in production environments.

To view details for Redis of an `AuthServer`:

```
# Get the Redis image
kubectl get authserver <authserver-name> \
  --namespace <authserver-namespace> \
  --output jsonpath="{.status.deployments.redis}" | jq

# Get the Redis host and port
kubectl get authserver <authserver-name> \
  --namespace <authserver-namespace> \
  --output jsonpath="{.status.storage.redis}" | jq
```

Data types

The following data is stored in Redis:

- Client information
    - Authorization grant type

    - Client id
- User session
    - Session token
    - Refresh token
- Identity and access tokens

Note

This is the data that carries the highest level risk.

    - Authentication token including the principal
        - Personally identifying information such as email and name
- Approved or rejected consents
    - A client identifier
    - A reference to the user
    - A list of the Authorities that the user has granted to this client

Known limitations of storage providers

Redis Cluster

When your storage is provided by Redis Cluster, additional settings might be required.

The nodes and the maximum number of redirects must be set in your Service Bindings' `Secret`. For example, in addition to the entries in Configuring a Redis Secret, you must provide `cluster` settings as follows:

```
apiVersion: v1
kind: Secret
metadata:
  name: redis-cluster-credentials
  namespace: authservers
type: servicebinding.io/redis
stringData:
  #...
  cluster.max-redirects: 5
  cluster.nodes: 100.90.1.10:6379,100.90.1.11:6379,100.90.1.12:6379
```

Important

`cluster.nodes` must be a comma-separated list of `<ip>:<port>`.

AuthServer readiness for AppSSO

This topic tells you how to use `AuthServer.status` as a reliable source to verify an `AuthServer`'s readiness for Application Single Sign-On (commonly called AppSSO).

You can verify your `AuthServer` by ensuring:

- there is at least one token signing key configured.

```
curl -X GET {spec.issuerURI}/oauth2/jwks
```

The response body should yield at least one key in the list. If there are no keys, please apply a token signing key

- OpenID discovery endpoint is available.

  ```
  curl -X GET {spec.issuerURI}/.well-known/openid-configuration
  ```

  The response body should yield a valid JSON body containing information about the `AuthServer`.

Client registration check

It is helpful to verify an `AuthServer` by running a test run with a test `ClientRegistration`. It ensures that app developers can register clients with the `AuthServer` successfully.

Follow the steps below to ensure that your installation can:

1. Add a test client.
2. Get an access token.
3. Invalidate/remove the test client.

Prerequisites

Ensure that you have successfully applied a token signing key to your `AuthServer` before proceeding.

Define and apply a test client

Apply a `ClientRegistration` to your cluster in a Namespace that the `AuthServer` should allow clients from:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: ClientRegistration
metadata:
  name: test-client
  namespace: default
spec:
  authServerSelector:
    matchLabels:
    # appropriate labels for your `AuthServer`
  authorizationGrantTypes:
    - client_credentials
  clientAuthenticationMethod: client_secret_basic
```

See the ClientRegistration API reference for more field definitions.

This defines a test `ClientRegistration` with the `client_credentials` OAuth grant type.

Apply the `ClientRegistration`:

```
kubectl apply -f appsso-test-client.yaml
```

Once the `ClientRegistration` is applied, inspects its status and verify it's ready.

Get an access token

You should be able to get a token with the client credentials grant for example:

```
# Get client id (`base64` command has to be available on the command line)
export APPSSO_TEST_CLIENT_ID=$(kubectl get secret test-client -n default -o jsonpath="
{.data['client-id']}" | base64 --decode)

# Get client secret (`base64` command has to be available on the command line)
export APPSSO_TEST_CLIENT_SECRET=$(kubectl get secret test-client -n default -o jsonpa
th="{.data['client-secret']}" | base64 --decode)

# Attempt to fetch access token
curl \
 --request POST \
 --location "{spec.issuerURI}/oauth2/token" \
 --header "Content-Type: application/x-www-form-urlencoded" \
 --header "Accept: application/json" \
 --data "grant_type=client_credentials" \
 --basic \
 --user $APPSSO_TEST_CLIENT_ID:$APPSSO_TEST_CLIENT_SECRET
```

You should see a response JSON containing populated field `access_token`. If so, the system is working as expected, and client registration check is successful.

Make sure to delete the test `ClientRegistration` once you are done.

Scale AuthServer for AppSSO

This topic tells you how to scale `AuthServer` for Application Single Sign-On (commonly called AppSSO).

The number of authorization server replicas for an `AuthServer` can be specified under `spec.replicas`.

Furthermore, `AuthServer` implements the `scale` subresource. That means you can scale an `AuthServer` with the existing tooling. For example:

```
kubectl scale authserver authserver-sample --replicas=3
```

The resource of the authorization server and Redis `Deployments` can be configured under `spec.resources` and `spec.redisResources` respectively. See the API reference for details.

Curate a service offering

This topic describes how you expose an `AuthServer` as a ready-to-claim service offering using a `ClusterWorkloadRegistrationClass`.

`ClusterWorkloadRegistrationClass` creates resources so that application operators can discover and claim credentials for an Application Single Sign-On service offering. A `ClusterWorkloadRegistrationClass` has a description that is shown when application operators discover services by running `tanzu service class list`. This allows you identify the offering as an Application Single Sign-On service.

Furthermore, `ClusterWorkloadRegistrationClass` carries a base `WorkloadRegistration`, which is the blueprint for claims against this service. This base selects the target `AuthServer`. It can optionally receive a custom domain template, labels, and annotations that all `WorkloadRegistration` inherit.

Prerequisites

Before you create a service offering, you must create and configure an `AuthServer`. For instructions, see the topics in the service operator guide.

Create a `ClusterWorkloadRegistrationClass`

For an `AuthServer` with the following labels:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  labels:
    sso.apps.tanzu.vmware.com/env: staging
    sso.apps.tanzu.vmware.com/ldap: ""
#! ...
```

You can expose it as a claimable service offering by configuring a `ClusterWorkloadRegistrationClass` as follows:

```
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: ClusterWorkloadRegistrationClass
metadata:
  name: demo
spec:
  base:
    spec:
      authServerSelector:
        matchLabels:
          sso.apps.tanzu.vmware.com/env: staging
          sso.apps.tanzu.vmware.com/ldap: ""
```

After you apply this resource, application operators can discover it by running `tanzu service class list`, for example:

```
$ tanzu service class list
  NAME  DESCRIPTION
  demo  Login by AppSSO
```

Application operators can claim credentials for this service either by running the command `tanzu service class-claim create` or with a `ClassClaim` resource.

When a claim is created, a `WorkloadRegistration` is created from the base and it targets the `AuthServer`.

Customize the `ClusterWorkloadRegistrationClass`

Each `WorkloadRegistration` has `https://` redirect URIs templated. The default template is configured with `default_workload_domain_template`. If `spec.workloadDomainTemplate` is omitted, the default template is used. For more information, see default_workload_domain_template. Otherwise, you can customize it by setting a template on the base, for example, `"{{.Name}}-{{.Namespace}}.demo.{{.Domain}}"`.

You can further customize each `WorkloadRegistration` by setting labels and annotations for them.

The default description of an Application Single Sign-On service offering is `"Login by AppSSO"`, but you can customize this. Consider using a good name and description. For more information, see Names and descriptions later in this topic.

For example, if you want the `WorkloadRegistration` to template redirect URIs from a custom template and with both `https://` and `http://`, and you want to say that in the service's description, edit the `ClusterWorkloadRegistrationClass` as follows:

```
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: ClusterWorkloadRegistrationClass
metadata:
  name: demo
spec:
  description:
    short: Login by AppSSO with LDAP for apps in the "demo" subdomain
  base:
    metadata:
      annotations:
        sso.apps.tanzu.vmware.com/template-unsafe-redirect-uris: ""
    spec:
      workloadDomainTemplate: "{{.Name}}-{{.Namespace}}.demo.{{.Domain}}"
      authServerSelector:
        matchLabels:
          sso.apps.tanzu.vmware.com/env: staging
          sso.apps.tanzu.vmware.com/ldap: ""
```

Names and descriptions

When choosing a name and a description for a `ClusterWorkloadRegistrationClass` consider the following:

- When the name of a service is stable across environments, for example, from dev to production, application operators can use the same `ClassClaim` in all environments.
- The description of a service must clearly communicate its flavor and provider. The default description of a `ClusterWorkloadRegistrationClass` is `"Login by AppSSO"`.

  If there is a single Application Single Sign-On service offering the default description is usually good enough.

  To customize the description for your `ClusterWorkloadRegistrationClass`, consider prefixing it with `"Login by AppSSO - "`, for example, `"Login by AppSSO - LDAP and GitHub`.

Application Single Sign-On for App Operators

The following topics explain how to consume an Application Single Sign-On service:

- Discover AppSSO services
- Claim credentials for an AppSSO service
- Secure a workload
- Secure a Spring Boot workload
- Secure a single-page app workload

Discover Application Single Sign-On service offerings

This topic describes the recommended method for you to discover Application Single Sign-On service offerings.

VMware recommends that you consume Application Single Sign-On by claiming credentials for an Application Single Sign-On service using Services Toolkit. Service operators are responsible for curating service offerings.

You can discover the available service offerings with the Tanzu Service CLI:

```
tanzu service class list
```

The output contains a list of services you can claim credentials for, for example:

```
$ tanzu service class list
  NAME                    DESCRIPTION
  mysql-unmanaged         MySQL by Bitnami
  postgresql-unmanaged    PostgreSQL by Bitnami
  rabbitmq-unmanaged      RabbitMQ by Bitnami
  redis-unmanaged         Redis by Bitnami
  sso                     Login by AppSSO - LDAP
  sso-demo                Login by AppSSO - user:password - UNSAFE FOR PRODUCTION!
```

By looking at the `DESCRIPTION` you can identify two of the services as being for Application Single Sign-On: `sso` and `sso-demo`.

Claim credentials for an Application Single Sign-On service offering

This topic describes the recommended method for you to consume Application Single Sign-On service offerings, which is by using a class claim.

When you create a claim for an Application Single Sign-On service, you receive your service credentials through service bindings. This makes it easier to load the credentials into a workload running on Tanzu Application Platform.

To learn about the different levels of Application Single Sign-On service consumption, see The three levels of Application Single Sign-On consumption.

Discover available parameters

To create a claim for an Application Single Sign-On service, target the specific service and provide the required and optional parameters. These parameters allow you to configure the OAuth2 client according to your needs.

To discover the parameter schema for a service, run:

```
tanzu service class get NAME
```

For example:

```
$ tanzu service class get sso

NAME:           app-sso
DESCRIPTION:    Login by AppSSO - OAuth2
READY:          true

PARAMETERS:
  KEY                          DESCRIPTION  TYPE     DEFAULT                REQUIRED
  authorizationGrantTypes      [...]        array    [authorization_code]   false
  clientAuthenticationMethod   [...]        string   client_secret_basic    false
  displayName                  [...]        string   <nil>                  false
  redirectPaths                [...]        array    <nil>                  false
  requireUserConsent           [...]        boolean  true                   false
  scopes                       [...]        array    [map[...]]             false
  workloadRef.name             [...]        string   <nil>                  true
```

Here you can see all the parameters with a brief description, their types, default values, and whether they are required or not. The only required parameter is `workloadRef.name`.

Claim credentials

To claim credentials you can either use the `tanzu service class-claim create` command or create a `ClassClaim` directly.

- **If using the Tanzu CLI,** claim credentials by running:

  ```
  tanzu service class-claim create CLAIM-NAME \
    --class SERVICE-NAME \
    --namespace NAMESPACE \
    --parameter workloadRef.name=WORKLOAD-NAME \
    --parameter PARAMETER
  ```

  Where:

  - `CLAIM-NAME` is a name you choose for your claim.
  - `SERVICE-NAME` is the name of the service that you want to claim.
  - `NAMESPACE` is the namespace that your workload is in.
  - `WORKLOAD-NAME` is the name of your workload.
  - (Optional) `PARAMETER` is a parameter that you choose in the format `KEY=VALUE`. You can add more than one optional parameter. For how to discover parameters you can add, see Discover available parameters.

  For example:

  ```
  $ tanzu service class-claim create my-class-claim \
    --class app-sso \
    --namespace my-namespace \
    --parameter workloadRef.name=my-workload \
    --parameter displayName='My sample app' \
    --parameter redirectPaths='["/login/oauth2/code/sso"]' \
    --parameter authorizationGrantTypes='["client_credentials", "authorization_co
  de"]' \
    --parameter requireUserConsent=false
  ```

- **If using a `ClassClaim`,** create a YAML file similar to the following example:

  ```
  ---
  apiVersion: services.apps.tanzu.vmware.com/v1alpha1
  kind: ClassClaim
  metadata:
    name: my-class-claim
    namespace: my-namespace
  spec:
    classRef:
      name: app-sso
    parameters:
      workloadRef:
        name: my-workload
      displayName: "My sample app"
      redirectPaths:                        # Optional
        - /login/oauth2/code/sso
      authorizationGrantTypes:              # Optional
        - client_credentials
        - authorization_code
      requireUserConsent: false             # Optional
  ```

Important

When iterating on your `ClassClaim`, you must recreate it when you make changes. Updates to an existing `ClassClaim` have no effect. For more information, see Class claims compared to resource claims.

Inspect the progress of your claim

You can inspect the progress of your claim creation by running:

```
tanzu service class-claim get MY-CLAIM-NAME --namespace MY-NAMESPACE
```

or

```
kubectl get classclaim MY-CLAIM-NAME --namespace MY-NAMESPACE --output yaml
```

Caution

It can take approximately 60 to 120 seconds for your Application Single Sign-On credentials to propagate into your service bindings secret.

Next steps

You now have service credentials that you can use to secure your workload with SSO. To learn about the specific client settings and how you can use a claim to secure a workload with Application Single Sign-On, see Secure a workload. For tutorials that show how to secure specific types of workloads with Application Single Sign-On, see Secure a single-page app workload and Secure a Spring Boot workload.

If you have problems claiming credentials for an Application Single Sign-On service, learn how to troubleshoot. For more information about the `tanzu service` command, classes, and claims, see the Tanzu CLI Command Reference documentation.

Secure a workload with Application Single Sign-On

This tutorial tells you how to secure a `Workload` running on Tanzu Application Platform with Application Single Sign-On (commonly called AppSSO).

For specific stack implementations, see Secure a single-page app workload and Secure a Spring Boot workload.

The Getting Started topic explains how to obtain OAuth2 client credentials for an authorization server by claiming them from an Application Single Sign-On service offering. You can enable this by running the `tanzu service class-claims create` command or by using a `ClassClaim` resource. In either case, you can customize your OAuth2 client settings by providing parameters within your claim. To secure your `Workload`, you must provide the appropriate parameters relevant to the given situation.

The following sections elaborate on each parameter in detail and guide the process of loading credentials into a `Workload`.

When editing your `ClassClaim`, you must recreate it in order for the changes to take effect. Updating an existing `ClassClaim` does not produce any impact. For more information, see Using a `ClassClaim`.

OAuth2 client parameters

A `ClassClaim` for an Application Single Sign-On service is the request for OAuth2 client credentials for an authorization server.

The following is an example of a claim for a service called `sso`, which customizes all available client parameters:

```
---
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ClassClaim
metadata:
  name: my-sso-client
  namespace: my-apps
spec:
  classRef:
    name: sso
  parameters:
    workloadRef:
      name: my-workload
    redirectPaths:
      - /login/oauth2/code/my-sso-client
    displayName: "My SSO client"
    scopes:
      - name: openid
      - name: email
      - name: profile
      - name: roles
      - name: coffee.make
        description: bestows the ultimate power
    authorizationGrantTypes:
      - client_credentials
      - authorization_code
      - refresh_token
    clientAuthenticationMethod: client_secret_basic
    requireUserConsent: true
```

To verify the status of this `ClassClaim`, run:

```
kubectl get classclaim my-sso-client --namespace my-apps
```

After a `ClassClaim` is applied and its status shows `Ready`, it can be consumed by a `Workload`. When the credentials are loaded into a `Workload`, your application code can use them to initiate OAuth2 flows.

`redirectPaths`

As a critical part of your client parameters, `redirectPaths` define the locations to which your application's end-users are redirected to after the authentication. Incorrect redirect URIs often cause errors for clients and are the most common source of such issues. When redirect URIs are not configured accurately, your application encounters errors and can not perform OAuth2 flows.

For servlet-based Spring Boot workloads using Spring Security OAuth 2 Client library, the default redirect path template looks as follows:

```
/login/oauth2/code/{ClassClaim.metadata.name}`
```

For more information about the format, see the Spring documentation.

For example, configure a single redirect path in `ClassClaim`:

```
spec:
  parameters:
```

```
    redirectPaths:
      - /login/oauth2/code/my-sso-client
```

Behind the scenes, your redirect paths are templated into the full redirect URIs including a scheme and fully-qualified domain name. For example, your actual redirect URI might look as follows:

```
https://my-workload.my-apps.example.com/login/oauth2/code/my-sso-client
```

The choice of scheme (`https` or `http`), the template for the subdomain and the ingress domain are under the control of your service operators and platform operators. If your redirect URIs do not template according to your needs, reach out to your service operators and platform operators and request adjustments to the templates.

Redirect paths are one of the values for templating redirect URIs. However, there is another parameter that needs to be considered, which leads us to the next parameter.

`workloadRef`

`workloadRef.name` is the name of the workload which acts as the OAuth2 client. You can use this value when templating the fully-qualified domain name of your redirect URIs.

```
spec:
  parameters:
    workloadRef:
      name: my-workload
```

Therefore, if you rename your workload from `my-workload` to a different name, you must update this parameter to align with the new name.

Note

`workloadRef` is not resolved to an actual `Workload` existing on the cluster. This means that the claim does not depend on the existence of a `Workload`.

Display name

An optional field to designate a user-friendly display name for your registered client. The display name is rendered on the authorization scope consent page if the field `.spec.parameters.requireUserConsent` is toggled on.

The display name must be between 2 and 32 characters in length.

`authorizationGrantTypes`

In OAuth2, a grant type is the way your application obtains tokens from the authorization server. There are different grant types. Some of them allow your application to act on behalf of an end user, but others do not.

The `authorizationGrantTypes` parameter denotes all the grant types your application can use:

```
spec:
  parameters:
    authorizationGrantTypes:
      - client_credentials
      - authorization_code
      - refresh_token
```

Application Single Sign-On supports the following OAuth2 grant types:

- Authorization Code: `authorization_code`

  Applications use this grant type to authenticate and authorize end users. An `AuthServer` issues identity and access tokens to applications to identify end users' identities and their level of access to the protected resources.

- Client Credentials: `client_credentials`

  Applications use this grant type to communicate directly to other protected applications through a client identifier and a client secret. For example, in service-to-service communication, an `AuthServer` issues access tokens that define the level of access that the requesting service has to the protected service they seek to communicate with.

  

  Note

  Use cases for the grant type `authorization_code` and `client_credentials` are typically different, so VMware recommends creating separate client registrations for each grant type.

- Refresh Token: `refresh_token`

  Applications use this grant type to obtain access tokens. If the `refresh_token` grant type is included, a refresh token is attached to every access token issued by an `AuthServer`. You can use the refresh token to fetch the new access tokens before the older ones expire to continue accessing the protected resources.

Client authentication method

A client authentication method defines how your application presents its credentials to the authorization server.

```
spec:
  parameters:
    clientAuthenticationMethod: client_secret_basic
```

There are three client authentication methods:

- `client_secret_basic`(default): Send the client credentials by using the HTTP "Basic" authentication scheme. This is the recommended method for authenticating server-based applications such as Spring Boot or .NET Core apps (confidential clients).
- `client_secret_post`: Send the client credentials in the body of an HTTP POST request.
- `none`: Do not send the client credentials. This is for browser-based single-page apps.

`scopes`

The `scopes` field defines the OAuth2 scopes requested by your application, including the standard OpenID claims.

```
spec:
  parameters:
    scopes:
      - name: openid # Standard OpenID scope, containing claims "sub" (subject), "aud"
(audience) and so on.
      - name: email # Standard OpenID scope, containing claims "email" and "email_veri
fied".
      - name: profile # Standard OpenID scope, containing claims "name", "given_name",
"family_name" and so on.
      - name: roles # AppSSO special scope, requesting the user roles or groups be pop
```

```
ulated in the "roles" claim.
      - name: coffee.make # Custom the authorization scope.
        description: bestows the ultimate power # With a custom description.
```

To activate the issuance of the users' identity tokens and authentication, you must include the `openid` scope.

To activate fetching of the user roles or groups, you must include the `roles` scope.

`requireUserConsent`

The `requireUserConsent` field defines the toggling scopes approved by the end users.

```
spec:
  parameters:
    requireUserConsent: true
```

If activated, the end users are prompted to consent to or reject the scopes that the client requests on behalf of them. If deactivated, all scopes that the client requests are auto-approved or consented to without prompting.

Behind the scenes

When you create a `ClassClaim` for an Application Single Sign-On service, several resources are created behind the scenes. These resources can be helpful for debugging purposes.

- You create a `ClassClaim` for an Application Single Sign-On service with your parameters.
- An `XWorkloadRegistration` with your parameter is created in the same namespace.
- A `WorkloadRegistration` with your parameter is created in the same namespace. The `WorkloadRegistration` templates your redirect URIs.
- A `ClientRegistration` with your parameters and the templated redirect URIs are created in the same namespace.
- The `ClientRegistration` receives the client credentials and passes them all the way to your `ClassClaim`.

Loading client credentials into a `Workload`

Now that you have a client credentials for your application, you can reference the `ClassClaim` from your `Workload`.

An example `Workload` in `my-apps` namespace is as follows:

```
apiVersion: carto.run/v1alpha1
kind: Workload
metadata:
  labels:
    apps.tanzu.vmware.com/workload-type: web
  name: my-workload
  namespace: my-apps
spec:
  serviceClaims:
    - name: my-sso-client # Must match the name of the referenced `ClassClaim`.
      ref:
        apiVersion: services.apps.tanzu.vmware.com/v1alpha1
        kind: ClassClaim
        name: my-sso-claim
  #! ...
```

Alternatively, you can refer to your `ClassClaim` when deploying your workload with the Tanzu CLI:

```
tanzu apps workload create my-workload \
  --service-ref "my-sso-client=services.apps.tanzu.vmware.com/v1alpha1:ClassClaim:my-sso-claim" \
  # ...
```

Important

The service ref name must match the name of the referenced `ClassClaim`.

Thanks to service bindings, your credentials are provided to your `Workload`'s `Pod` (one or more) by mounting a volume containing your client credentials.

The credentials provided by the claim are:

- `client-id`: The identifier of your `Workload` that Application Single Sign-On is registered with. This is a unique identifier.
- `client-secret`: The secret string value used by Application Single Sign-On to verify your client. Keep this value secret.
- `issuer-uri`: The web address of the Application Single Sign-On `AuthServer` and the primary location that your `Workload` goes to when interacting with Application Single Sign-On.
- `authorization-grant-types`: A list of the desired OAuth 2 grant types.
- `client-authentication-method`: The method in which the client is authenticated when requesting an identity or access token.
- `scope`: A list of the desired scopes that your application's users have access to.

These credentials are mounted onto your `Workload`'s `Pod`(one or more) as individual files at the following locations:

```
/bindings
  /<name-of-service-claim>
    /client-id
    /client-secret
    /issuer-uri
    /authorization-grant-types
    /client-authentication-method
    /scope
```

Following the earlier example, you can find the location of mounted credentials on every `Pod` at:

```
/bindings/my-sso-client
```

Given these auto-generated values, your `Workload` can now load them at runtime and bind to an Application Single Sign-On authorization server at startup time. Reading the values from the file system is left to the implementer.

Trusting an authorization server

Your application makes a request to the authorization server. The authorization server serves traffic using TLS. If your company uses non-public certificate authority (CA), you must explicitly trust the authorization server or rather the certificate authority. For more information, see Configure Workloads to trust a custom certificate authority.

Summary

This concludes the tutorial explaining how to claim the client credentials for an Application Single Sign-On authorization server and how to secure a workload.

Secure a Spring Boot workload

This tutorial tells you how to secure a sample Spring Boot `Workload` with Application Single Sign-On (commonly called AppSSO), which runs on Tanzu Application Platform (commonly called TAP).

Follow these steps to deploy a sample Spring Boot `Workload`:

1. Get the sample application.
2. Create a namespace for workloads.
3. Claim client credentials.
4. (Optional) Ensure `Workload` trusts `AuthServer`.
5. Deploy the workload.

Get the sample application

Follow these steps to fetch the Application Single Sign-On Spring Boot application source code:

1. Download the Application Single Sign-On Starter Java accelerator from the Tanzu Developer Portal accelerators located on your Tanzu Application Platform cluster:
    - Option 1: Use the Tanzu Developer Portal dashboard through the browser.

      Navigate to Application Accelerators and download the “AppSSO Starter Java” accelerator.
    - Option 2: Use the Tanzu Accelerator CLI.

      Download the zip file of the accelerator source code by running:

      ```
      tanzu accelerator generate appsso-starter-java --server-url TAP_GUI_SERVE
      R_URL
      ```
2. Unzip the resulting `.zip` file into the `appsso-starter-java` directory in your workspace.

    ```
    unzip appsso-starter-java
    ```
3. With the resulting project, create an accessible remote Git repository and push your accelerator to the Git remote repository.

Create a namespace for workloads

You must create a namespace for your workloads for the `Workload` resources to function properly. If you have a workloads namespace already, you can skip this step.

```
kubectl create namespace my-apps
kubectl label namespaces my-apps apps.tanzu.vmware.com/tap-ns=""
```

For more information about provisioning namespaces for workloads, see Set up developer namespaces.

Claim client credentials

Follow these steps to claim credentials for an Application Single Sign-On service so that you can secure your workload:

1. Discover the available Application Single Sign-On services with the Tanzu Service CLI:

   ```
   $ tanzu service class list
   NAME      DESCRIPTION
   sso       Login by AppSSO
   ```

   The actual names of your AppSSO services might be different. VMware assumes that there's one AppSSO service with the name `sso`.

2. Claim credentials for that service by creating a `ClassClaim` named `appsso-starter-java` in the `my-apps` namespace.

   ```
   ---
   apiVersion: services.apps.tanzu.vmware.com/v1alpha1
   kind: ClassClaim
   metadata:
     name: appsso-starter-java
     namespace: my-apps
   spec:
     classRef:
       name: sso
     parameters:
       workloadRef:
         name: appsso-starter-java
       redirectPaths:
         - /login/oauth2/code/appsso-starter-java
       scopes:
         - name: openid
       authorizationGrantTypes:
         - authorization_code
       clientAuthenticationMethod: client_secret_basic
   ```

3. Apply the `ClassClaim` and verify its status by running:

   ```
   kubectl get classclaim appsso-starter-java --namespace my-apps
   ```

Ensure `Workload` trusts `AuthServer`

For Tanzu Application Platform cluster with a custom or self-signed CA certificate, see Configure workloads to trust a custom Certificate Authority (CA).

Deploy the `Workload`

Follow these steps to deploy the `Workload`:

1. Create the Spring Boot accelerator `Workload` by running:

   ```
   tanzu apps workload create appsso-starter-java \
       --namespace my-apps \
       --type web \
       --label app.kubernetes.io/part-of=appsso-starter-java \
       --build-env "BP_JVM_VERSION=17" \
       --service-ref "appsso-starter-java=services.apps.tanzu.vmware.com/v1alpha1:
   ClassClaim:appsso-starter-java" \
       --service-ref "ca-cert=v1:Secret:tap-ca-cert" \
       --git-repo "<GIT_LOCATION_OF_YOUR_ACCELERATOR>" \
       --git-branch main \
       --live-update
   ```

Important

Although you can assign any name to the `ClassClaim`, the `Workload`'s service reference name must match the `ClassClaim`'s name.

```
--service-ref "**appsso-starter-java**=services.apps.tanzu.vmware.
com/v1alpha1:ClassClaim:appsso-starter-java"
```

If the service reference name does not match the `ClassClaim` name, the `Workload` generates a redirect URI that the authorization server will reject.

It might take a few minutes for the workload to become available through a browser-accessible URL.

2. Query the latest status of the workload by running:

```
tanzu apps workload get appsso-starter-java --namespace my-apps
```

3. Monitor the `Workload` logs:

```
tanzu apps workload tail appsso-starter-java --namespace my-apps
```

After the status of the workload reaches the `Ready` state, you can navigate to the provided URL, which looks similar to:

```
https://appsso-starter-java.my-apps.<TAP_CLUSTER_DOMAIN_NAME>
```

4. Open your preferred web browser and navigate to the URL.

Expect to see a large log-in button tailored for authenticating with AppSSO.

Cleaning up

Delete the running application by running the following commands:

1. Delete the sample application `Workload`:

```
tanzu apps workload delete appsso-starter-java --namespace my-apps
```

2. Delete the claim:

```
tanzu service class-claims delete appsso-starter-java --namespace my-apps
```

Secure a single-page app workload

This tutorial tells you how to secure a sample single-page Angular app `Workload` with Application Single Sign-On (commonly called AppSSO), which runs on Tanzu Application Platform (commonly known as TAP).

Follow these steps to deploy a sample single-page app `Workload`:

1. Get the sample application.
2. Create a namespace for workloads.
3. Claim client credentials.
4. Verify application authentication settings.

5. Start a sample back end.
6. Deploy the Workload.

Get the sample application

Follow these steps to fetch the single-page Angular app source code:

1. Download the Angular Frontend accelerator from the Tanzu Developer Portal accelerators located on your Tanzu Application Platform cluster:
    - Option 1: Use the Tanzu Developer Portal dashboard by using a browser.

      Navigate to Application Accelerators and choose the **Angular Frontend** accelerator and then select the **Single Sign-on** option.
    - Option 2: Use the Tanzu Accelerator CLI.

      Download the zip file of the accelerator source code and identify your `AuthServer` Issuer URI by running:

      ```
      kubectl get authserver -A
      ```

      Generate the accelerator by using the `tanzu accelerator` CLI:

      ```
      tanzu accelerator generate angular-frontend \
        --server-url TAP-GUI-SERVER-URL \
        --options '{
          "useSingleSignOn": true,
          "authority": "AUTHSERVER-ISSUER-URI",
          "namespace": "my-apps",
          "authorityLabelKey": "my-sso",
          "authorityLabelValue": "true"
        }'
      ```
2. Unzip the resulting `.zip` file into the `angular-frontend` directory in your workspace:

    ```
    unzip angular-frontend
    cd angular-frontend
    git init
    git branch -M main
    git remote add origin YOUR-ACCELERATOR-GIT-REPOSITORY
    git push origin main -u
    ```

    For public clients, the `AuthServer` only supports the Authorization Code Flow: `response_type=code`, because public clients such as single-page apps cannot safely store sensitive information such as client secrets.
3. Push the resulting directory to the remote Git repository.

Create a namespace for workloads

You must create a namespace for your workloads for the `Workload` resources to function properly. If you have a workloads namespace already, you can skip this step.

```
kubectl create namespace my-apps
kubectl label namespaces my-apps apps.tanzu.vmware.com/tap-ns=""
```

For more information about provisioning namespaces for running `Workloads`, see Set up developer namespaces.

Claim the client credentials

Follow these steps to claim the credentials for an Application Single Sign-On service so that you can secure your workload:

1. Discover the available Application Single Sign-On services with the Tanzu Service CLI:

   ```
   $ tanzu service class list
     NAME      DESCRIPTION
     sso       Login by AppSSO
   ```

   The actual names of your Application Single Sign-On services might be different. VMWare assumes that there's one Application Single Sign-On service with the name `sso`.

2. Claim the credentials for that service by creating a `ClassClaim` named `angular-frontend` in the `my-apps` namespace.

   ```
   ---
   apiVersion: services.apps.tanzu.vmware.com/v1alpha1
   kind: ClassClaim
   metadata:
     name: angular-frontend
     namespace: my-apps
   spec:
     classRef:
       name: sso
     parameters:
       workloadRef:
         name: angular-frontend
       redirectPaths:
         - /user-profile
         - /customer-profiles/list
         - /
       scopes:
         - name: openid
         - name: email
         - name: profile
         - name: message.read
         - name: message.write
       authorizationGrantTypes:
         - authorization_code
       clientAuthenticationMethod: none
   ```

3. Apply the `ClassClaim` and verify the status is `Ready` by running:

   ```
   kubectl get classclaim angular-frontend --namespace my-apps
   ```

Verify application authentication settings

Within the single-page Angular app accelerator, authentication configuration settings are located in `src/assets/auth.conf.json`. After generating the accelerator, expect to observe the populated settings.

Open the file and verify that it adheres to the following structure:

```
{
  "authority": "ISSUER-URI",
  "clientId": "CLIENT-ID",
  "scope": [ "openid", "profile", "email", "message.read", "message.write" ]
}
```

Retrieve your client id by running:

```
kubectl get secret \
  $(kubectl get classclaim -n my-apps angular-frontend -o jsonpath='{.status.binding.name}') \
  --namespace my-apps \
  --template='{{ index .data "client-id" | base64decode}}'
```

Retrieve your issuer URI by running:

```
kubectl get secret \
  $(kubectl get classclaim -n my-apps angular-frontend -o jsonpath='{.status.binding.name}') \
  --namespace my-apps \
  --template='{{ index .data "issuer-uri" | base64decode}}'
```

Start a sample back end

Important

You can skip this step if you have a `java-rest-service` back end running already.

The `angular-frontend` sample application requires a back end application to start properly:

1. Start a sample simulated back end by running:

   ```
   kubectl run sample-backend --image nginx:NGINX-VERSION -n my-apps
   kubectl expose pod sample-backend --port 80 -n my-apps
   ```

2. In the `angular-frontend` source code, edit the `.server.location[/api/].proxy_pass` field in the `nginx.conf` file at the root of the source directory.

3. After updating the value, commit the changes to the Git remote repository:

   ```
   server {
    # ...
    location /api/ {
      proxy_pass http://sample-backend.my-apps/api/;
    }
    # ...
   }
   ```

Deploy the `Workload`

Follow these steps to deploy the `Workload`:

1. Create the `angular-frontend` accelerator `Workload` by running:

   ```
   tanzu apps workload create angular-frontend \
       --namespace my-apps \
       --type web \
       --param "clusterBuilder=base" \
       --param "annotations=autoscaling.knative.dev/minScale: \"1\"" \
       --label app.kubernetes.io/part-of=angular-frontend \
       --git-repo "GIT-LOCATION-OF-YOUR-ACCELERATOR" \
       --git-branch main
   ```

   

   Note

> As an alternative approach to creating the workload, you can declaratively define a `Workload` resource by using `config/workload.yaml` within the source repository.

It might take a few minutes for the workload to become available through a browser-accessible URL.

2. Query the latest status of the workload by running:

```
tanzu apps workload get angular-frontend --namespace my-apps
```

3. Monitor the `Workload` logs:

```
tanzu apps workload tail angular-frontend --namespace my-apps
```

After the status of the workload reaches the `Ready` state, you can navigate to the provided URL, which looks similar to:

```
https://angular-frontend.my-apps.TAP-CLUSTER-DOMAIN-NAME/user-profile
```

4. Open your preferred web browser and navigate to the URL.

Expect to be prompted to sign in by using AppSSO. After successfully signing in, the profile page displays your identifying information.

Clean up

Delete the running application by running these commands:

1. Delete the sample application `Workload`:

```
tanzu apps workload delete angular-frontend --namespace my-apps
```

2. Delete the claim:

```
tanzu service class-claims delete angular-frontend --namespace my-apps
```

3. Delete the sample back end if was previously applied:

```
kubectl delete svc sample-backend --namespace my-apps
kubectl delete pod sample-backend --namespace my-apps
```

Troubleshoot Application Single Sign-on

This topic tells you how to troubleshoot Application Single Sign-On (commonly called AppSSO).

Why is my AuthServer not working?

Generally, `AuthServer.status` is designed to provide you with helpful feedback to debug a faulty `AuthServer`.

Find all `AuthServer` related Kubernetes resources

Identify all `AuthServer` components with Kubernetes common labels. For more information, see Kubernetes documentation.

Query all related `AuthServer` sub-resources by using `app.kubernetes.io/part-of` label. For example:

```
kubectl get all,ingress,service -A -l app.kubernetes.io/part-of=<authserver-name>
```

See logs of all AuthServers

With stern, you can tail the logs of all AppSSO managed `Pods` inside your cluster with:

```
stern --all-namespaces --selector=app.kubernetes.io/managed-by=sso.apps.tanzu.vmware.com
```

Wait for change propagation

When applying changes to an `AuthServer`, changes to issuer URI, IdP (identity provider), server and logging configuration take a moment to be effective as the operator rolls out the authorization server `Deployment`.

Set up debug logs

Caution

Debug logs display all identity information from the upstream identity providers, for example, all LDAP attributes for a user. VMware recommends not using debug logs in production.

An `AuthServer` can display more information related to configuration or claim mappings. To enable debug logs, update your configuration with:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  # ...
spec:
  # ...
  # Do not forget the pipe character and preserve the indentation.
  logging: |
    level:
      com.vmware.tanzu.apps.sso: DEBUG
      appsso: DEBUG
```

Misconfigured `clientSecret`

Problem:

When attempting to sign in, you see `This commonly happens due to an incorrect [client_secret].` It might be because the client secret of an identity provider is misconfigured.

Solution:

Validate the `AuthServer.spec.openid.clientSecretRef`.

Misconfigured redirect URI

Problem:

You see `Error: [invalid_request] OAuth 2.0 Parameter: redirect_uri` when signing in.

Solution:

The `redirectURIs` of a `ClientRegistration` must refer to the URI (one or more) of the registered `Workload`. It does not refer to the URI of the AuthServer. For more information, see Redirect URIs.

Unsupported `id_token_signed_response_alg` with openid `identityProviders`

Problem:

When trying to log in with an OpenID Connect `identityProvider`, you are unable to sign in and observe the following error in the logs:

```
[invalid_id_token] An error occurred while attempting to decode the Jwt: Signed JWT re
jected: Another algorithm expected, or no matching key(s) found.
```

Solution:

Verify the `identityProvider`'s discovery endpoint at `ISSUER-URI/.well-known/openid-configuration` where `ISSUER-URI` is the value set at `spec.identityProviders.openid.issuerURI`.

The value of `id_token_signing_alg_values_supported` must include `RS256`. If it is not in the list, your identity configuration might not support AppSSO.

If `RS256` is present, expect to see a `jwks_uri` key in the discovery endpoint. If you visit the URL stored in this key, it must return at least one RSA key. Otherwise, your identity provider might be misconfigured.

Refer to your identity provider's documentation to enable `RS256` token signing.

Misconfigured identity provider clientSecret

Problem:

- When attempting to sign in, you see `<WORKLOAD_URL> redirected you too many times.` It might be because the client secret of an identity provider is misconfigured.
- If you have access to the authserver logs, verify if there is an entry with the text `"error":"[invalid_client] Client authentication failed: client_secret"`.

Solution:

Validate the secret referenced by the `clientSecretRef` for this particular identity provider in your `authserver.spec`.

Missing scopes

Problem:

When attempting to fetch data after signing in to your application by using AppSSO, you see `[invalid_scope] OAuth 2.0 Parameter: scope`.

Solution:

Add the required scopes into your `ClientRegistration` yaml under `spec.scopes`.

Changes to the secret do not propagate to the `ClientRegistration`. If you recreated the `Secret` that contains the `clientSecret`, you must re-deploy the `ClientRegistration`.

Misconfigured `sub` claim

Problem:

The `sub` claims in `id_token`s and `access_token`s follow the `<providerId>_<userId>` pattern. The previous `<providerId>/<userId>` pattern might cause bugs in URLs without proper URL-encoding in client applications.

Solution:

If your client application stores `sub` claims, you must update the `sub` claims to match the new pattern `<providerId>_<userId>`.

Troubleshoot a `ClassClaim` for an AppSSO service

Problem:

The service binding secret of a `ClassClaim` for an Application Single Sign-On service is empty.

Solution:

Be patient as it can take up to `~60-120s` for the client credentials to be propagated into the claim's service binding secret.

If you have waited for a considerable amount of time and the credentials still haven't appeared, see the Services Toolkit documentation for more troubleshooting information.

Application Single Sign-On Reference

This topic provides you with the following reference documentation of Application Single Sign-On (commonly called AppSSO):

- API
- Known issues
- OpenShift
- Package configuration
- RBAC
- AuthServer audit logs

AppSSO APIs

This topic provides you with detailed information about the following APIs of Application Single Sign-On (commonly called AppSSO):

- AuthServer
- ClientRegistration
- ClusterUnsafeTestLogin
- ClusterWorkloadRegistrationClass

- WorkloadRegistration
- XWorkloadRegistration

AuthServer API for AppSSO

In Application Single Sign-On (commonly called AppSSO), `AuthServer` represents the request for an OIDC authorization server. It causes the deployment of an authorization server backed by Redis over mutual TLS if no storage is defined.

An `AuthServer` should have labels which allow to uniquely match it amongst others. `ClientRegistration` selects an `AuthServer` by label selector and needs a unique match to be successful.

To allow `ClientRegistrations` only from a restricted set of `Namespaces`, you must set the annotation `sso.apps.tanzu.vmware.com/allow-client-namespaces`. Its value is a comma-separated list of allowed `Namespaces`, for example, `"app-team-red,app-team-green"`. If the annotation is missing, the default value is `*`, denoting that all client namespaces are allowed.

The issuer URI, which is the point of entry for clients and end-users, is constructed through the package's `domain_template`. You can view the issuer URI by running `kubectl get authserver -n authservers`.

See Issuer URI & TLS for more information.

Token signature keys are configured by using `spec.tokenSignature`. This is a required field. See Token signatures for more context.

You can configure identity providers under `spec.identityProviders`. If there is none, end-users can not log in. For more information about configuring identity providers, see Identity providers.

The deployment can be further customized by configuring replicas, resources, http server and logging properties.

Spec

```
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: AuthServer
metadata:
  name: ""
  namespace: ""
  labels: { } # required, must uniquely identify this AuthServer
  annotations:

```

Alternatively, you can interactively discover the spec with:

```
kubectl explain authservers.sso.apps.tanzu.vmware.com
```

Status & conditions

The `.status` subresource helps you to learn the `AuthServer`'s readiness, resulting deployments, attached clients and to troubleshoot issues.

`.status.issuerURI` is the templated issuer URI. This is the entry point for any traffic.

`.status.tls` is the actual TLS configuration.

`.status.tokenSignatureKeyCount` is the number of currently configured token signature keys.

`.status.clientRegistrationCount` is the number of currently registered clients.

`.status.deployments.authServer` describes the current authorization server deployment by listing the running image, its replicas, the hash of the current configuration and the generation which has last resulted in a restart.

`.status.deployments.redis` describes the current provided Redis deployment by listing its running image. This field is nil if storage is defined explicitly by using `.spec.storage`.

`.status.storage.redis` describes the configured Redis storage such as host name and port number.

`.status.conditions` documents each step in the reconciliation:

- `Valid`: Is the spec valid?
- `ImagePullSecretApplied`: Has the image pull secret been applied?
- `SignAndVerifyKeyResolved`: Has the single sign-and-verify key been resolved?

- `ExtraVerifyKeysResolved`: Have the single extra verify keys been resolved?
- `IdentityProvidersResolved`: Has all identity provider configuration been resolved?
- `ConfigResolved`: Has the complete configuration for the authorization server been resolved?
- `AuthServerConfigured`: Has the complete configuration for the authorization server been applied?
- `IssuerURIReady`: Is the authorization server yet responding to `{.status.issuerURI}/.well-known/openid-configuration`?
- `Ready`: whether all the previous conditions are “True”

The super condition `Ready` denotes a fully successful reconciliation of a given `ClientRegistration`.

If everything goes well you will see something like this:

```
issuerURI: "https://..."
observedGeneration: 1
tokenSignatureKeyCount: 0
clientRegistrationCount: 0
caCerts:
  - cert:
      subject: ""

    status: "True"
    type: Valid
```

RBAC

The `ServiceAccount` of the authorization server has a `Role` with the following permissions:

```
- apiGroups:
    - ""
  resources:
    - secrets
  verbs:
    - get
    - list
    - watch
  resourceNames:
    - { name }-auth-server-keys
    - { name }-auth-server-clients
```

Example

This example requests an authorization server with two token signature keys and two identity providers.

Note

The label used for matching to ClientRegistrations must be unique across namespaces.

```

ClientRegistration API for AppSSO

In Application Single Sign-On (commonly called AppSSO), `ClientRegistration` is the request for client credentials for an AuthServer.

`ClientRegistration` is created automatically during the process of claiming credentials. However, there is also the option of creating it manually.

It implements the Service Bindings `ProvisionedService`. The credentials are returned as a Service Bindings `Secret`.

A `ClientRegistration` must uniquely identify an `AuthServer` by using `spec.authServerSelector`. If it matches none, too many or a disallowed `AuthServer`, it does not get credentials. The other fields are for the configuration of the client on the `AuthServer`.

Spec

```
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: ClientRegistration
metadata:
  name: ""
  namespace: ""
spec:
  authServerSelector: # required
    matchLabels: { }
  redirectURIs: # optional
    - ""
  scopes: # optional
    - name: ""
      description: ""
  displayName: "" # optional, must be between 2 and 32 chars in length
  authorizationGrantTypes: # optional
    - client_credentials
    - authorization_code
    - refresh_token
  clientAuthenticationMethod: "" # optional, values accepted are described in Client a
```

```
uthentication methods section
  requireUserConsent: false # optional
status:
  authServerRef:
    apiVersion: ""
    issuerURI: ""
    kind: ""
    name: ""
    namespace: ""
  binding:
    name: ""
  clientID: ""
  clientSecretHelp: ""
  conditions:
    - lastTransitionTime: ""
      message: ""
      reason: ""
      status: "True" # or "False"
      type: ""
  observedGeneration: 0
```

Alternatively, you can interactively discover the spec with:

```
kubectl explain clientregistrations.sso.apps.tanzu.vmware.com
```

Scopes

The following scopes must be included for the issuance of identity tokens:

- `openid` must be included for the identity tokens to be issued.
- `profile` must be included so the custom-mapped claims are included in an issued identity token, for example, `AuthServer.identityProviders[*].{openID,ldap,saml}.idToken.claims`. For more information, see Identity token claims mapping.
- `email` must be included to retain the `email` and `email_verified` claims.
- `address` must be included to retain the `address` claim.
- `phone` must be included to retain the `phone_number` and `phone_number_verified` claims.
- `roles` must be included to retrieve the user role information from an upstream identity provider. For more information, see Configure authorization.

Client authentication methods

Client authentication methods supported by `ClientRegistration` resource are:

- `client_secret_basic`: HTTP header based client authentication (default).
- `client_secret_post`: HTTP POST body based client authentication.
- `none`: No client authentication. Required for public clients. For more information, see Public clients and CORS.

Status & conditions

The `.status` subresource helps you to learn about your client credentials, the matched `AuthServer` and to troubleshoot issues.

`.status.authServerRef` identifies the successfully matched `AuthServer` and its issuer URI.

`.status.binding.name` is the name of the Service Bindings `Secret` which contains the client credentials.

`.status.conditions` documents each step in the reconciliation:

- `Valid`: Is the spec valid?
- `AuthServerResolved`: Has the targeted `AuthServer` been resolved?
- `ClientSecretResolved`: Has the client secret been resolved?
- `ServiceBindingSecretApplied`: Has the Service Bindings Secret with the client credentials been applied?
- `AuthServerConfigured`: Has the resolved `AuthServer` been configured with the client?
- `Ready`: whether all the previous conditions are “True”

The super condition `Ready` denotes a fully successful reconciliation of a given `ClientRegistration`.

If everything goes well you will see something like this:

```
status:
  authServerRef:
    apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
    issuerURI: http://authserver-sample.default
    kind: AuthServer
    name: authserver-sample
    namespace: default
  binding:
    name: clientregistration-sample
  clientID: default_clientregistration-sample
  clientSecretHelp: 'Find your clientSecret: ''kubectl get secret clientregistration-s
ample --namespace default'''
  conditions:
    - lastTransitionTime: "2022-05-13T07:56:41Z"
      message: ""

      status: "True"
      type: Valid
  observedGeneration: 1
```

Example

```
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: ClientRegistration
metadata:
  name: my-client-registration
  namespace: app-team
spec:
  displayName: "My sample app"
  authServerSelector:
    matchLabels:
      for: app-team
      ldap: "true"
  redirectURIs:
    - "https://127.0.0.1:8080/authorized"
    - "https://my-application.com/authorized"
  requireUserConsent: false
  clientAuthenticationMethod: client_secret_basic
  authorizationGrantTypes:
    - "authorization_code"
    - "refresh_token"
  scopes:
    - name: "openid"
      description: "To indicate that the application intends to use OIDC to verify the
user's identity"
    - name: "email"
      description: "The user's email"
    - name: "profile"
      description: "The user's profile information"
```

The client is registered with the authorization server with the given `spec`. The resulting client credentials are available in a `Secret` that the `ClientRegistration` owns.

```
apiVersion: v1
kind: Secret
type: servicebinding.io/oauth2
metadata:
  name: my-client-registration
  namespace: app-team
data: # fields below are base64-decoded for display purposes only
  type: oauth2
  provider: appsso
  client-id: default_my-client-registration
  client-secret: c2VjcmV0 # auto-generated
  issuer-uri: https://appsso.example.com
  client-authentication-method: client_secret_basic
  scope: openid,email,profile
  authorization-grant-types: client_credentials,refresh_token
```

ClusterUnsafeTestLogin API for Application Single Sign-On

`ClusterUnsafeTestLogin` is the recommended way to get started with Application Single Sign-On (commonly called AppSSO) in non-production environments, and it is not safe for production.

`ClusterUnsafeTestLogin` represents the request for an unsafe, ready-to-claim AppSSO service offering. It reconciles into an unsafe `AuthServer`, a token signing key `Secret`, and a `ClusterWorkloadRegistrationClass`. It is cluster-scoped and has no specifications.

Its `AuthServer` is `http` only, which allows all CORS origins and runs with a single replica. Its name is prefixed with `unsafe-`. Its issuer URI resembles `http://unsafe-demo.appsso.example.com`.

There is a single `user:password` login. That user has roles `user` and `test` and claims `first_name=First-Name`, `last_name=Last-Name` and `email=user@example.com`.

Its `ClusterWorkloadRegistrationClass` templates `WorkloadRegistration` with safe and unsafe redirect URIs. That means a redirect path is templated with both `https` and `http` as the scheme.

Its namespace-scoped resources are placed in the cluster resource namespace. The cluster resource namespace is configurable. The default cluster resource namespace is `appsso`.

Once created, you can discover it with the Tanzu Service CLI:

```
$ tanzu service class list
  NAME      DESCRIPTION
  <name>    Login by AppSSO - user:password - UNSAFE FOR PRODUCTION!
```

Specification

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: ClusterUnsafeTestLogin
metadata:
  name: "" #! required
status:
  issuerURI: ""
  clusterResourceNamespace: ""
  conditions:
  - lastTransitionTime: ""
    message: ""
    reason: ""
    status: ""
    type: AuthServerReady
  - lastTransitionTime: ""
    message: ""
    reason: ""
    status: ""
    type: ClusterWorkloadRegistrationClassReady
  - lastTransitionTime: ""
    message: ""
    reason: ""
    status: ""
    type: Ready
  - lastTransitionTime: ""
    message: ""
    reason: ""
    status: ""
    type: SignAndVerifyKeyConditionReady
  observedGeneration: 0
  tokenSignature:
    signAndverifyKey:
      name: ""
      pem: ""
```

Example

Due to the zero-configuration nature of the `ClusterUnsafeTestLogin` API, there exists only a single feasible example:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: ClusterUnsafeTestLogin
```

```
metadata:
  name: demo
```

ClusterWorkloadRegistrationClass API for Application Single Sign-On

In Application Single Sign-On (commonly called AppSSO), `ClusterWorkloadRegistrationClass` represents the request to expose an `AuthServer` as a claimable service offering. It is cluster-scoped and is identified by its short name `cwrc`.

`ClusterWorkloadRegistrationClass` optionally receives a free-form description which explains the offering to those which discover it with the Tanzu CLI. It also receives a base `WorkloadRegistration` section.

`ClusterWorkloadRegistrationClass` reconciles into a Crossplane `Composition` and a Services Toolkit `ClusterInstanceClass`.

The `Composition` defines how to create a `WorkloadRegistration` for an `AuthServer`. The `Composition` is for the composite resource `XWorkloadRegistration`. It relies on Crossplane's provider-kubernetes.

The `ClusterInstanceClass` is applied with its description and a selector for the `Composition`. Instances of this class are claimed by using Services Toolkit's `ClassClaim`. For more information, see claims.

The available parameters of the `ClusterInstanceClass` are those of `XWorkloadRegistration`. For more information about the fields, see XWorkloadRegistration.

The base `WorkloadRegistration` section is the blueprint for claims to this class. It is the base `Object` for the `Composition`. This base is patched with the parameters from claims. Setting fields on the base sets the fields on all claimed `WorkloadRegistration`. This is how they can match a certain `AuthServer`, or have labels and annotations.

The base is a partial projection of `WorkloadRegistration`'s specification. It is limited to the fields `metadata.labels`, `metadata.annotations`, `spec.workloadDomainTemplate`, and `spec.authServerSelector`. For more information about the fields, see WorkloadRegistration.

After the offering is created, you can discover it with the Tanzu Service CLI:

```
$ tanzu service class list
  NAME     DESCRIPTION
  <name>   <description>
```

You can also discover the service's parameters with the Tanzu Service CLI:

```
$ tanzu service class get <name>
NAME:           <name>
DESCRIPTION:    <description>
READY:          true

PARAMETERS:
  KEY                          DESCRIPTION  TYPE     DEFAULT               REQUIRED
  authorizationGrantTypes      [...]        array    [authorization_code]  false
  clientAuthenticationMethod   [...]        string   client_secret_basic   false
  displayName                  [...]        string   <nil>                 false
  redirectPaths                [...]        array    <nil>                 false
  requireUserConsent           [...]        boolean  true                  false
  scopes                       [...]        array    [map[...]]            false
  workloadRef.name             [...]        string   <nil>                 true
```

`ClusterWorkloadRegistrationClass` aggregates the readiness of its children. It is not ready until its base's `authServerSelector` uniquely selects an `AuthServer`. When an `AuthServer` is matched, its reference is written to the status.

The `Composition` label selector is written to the status.

Specification

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: ClusterWorkloadRegistrationClass
metadata:
  name: "" #! required
spec:
  description:
    short: "" #! required, default to "Login by AppSSO"
  base:
    metadata:
      labels: {} #! optional
      annotations: {} #! optional
    spec:
      workloadDomainTemplate: "" #! optional
      authServerSelector:
        matchLabels: {} #! required
status:
  authServerRef:
    apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
    issuerURI: ""
    kind: AuthServer
    name: ""
    namespace: ""
  compositionSelector:
    matchLabels: {}
  conditions:
  - lastTransitionTime: ""
    message: ""
    reason: ""
    status: ""
    type: AuthServerResolved
  - lastTransitionTime: ""
    message: ""
    reason: ""
    status: ""
    type: ClusterInstanceClassReady
  - lastTransitionTime: ""
    message: ""
    reason: ""
    status: ""
    type: CompositionApplied
  - lastTransitionTime: ""
    message: ""
    reason: ""
    status: ""
    type: Ready
  observedGeneration: 1
```

Alternatively, you can interactively discover the API with:

```
kubectl explain cwrc
```

Examples

This is a minimal example that selects an `AuthServer` that is uniquely identified by the label `sso.apps.tanzu.vmware.com/env=dev`:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: ClusterWorkloadRegistrationClass
metadata:
  name: sample-minimal
spec:
  base:
    spec:
      authServerSelector:
        matchLabels:
          sso.apps.tanzu.vmware.com/env: dev
```

This is a full example that selects an `AuthServer` that is uniquely identified by the label `sso.apps.tanzu.vmware.com/env=dev`. It sets a custom `workloadDomainTemplate` on the base, a label and an annotation. The annotation triggers safe and unsafe redirect URI templating.

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: ClusterWorkloadRegistrationClass
metadata:
  name: sample-full
spec:
  description:
    short: Login by AppSSO with a custom domain template
  base:
    metadata:
      labels:
        app.kubernetes.io/part-of: service-claims
      annotations:
        sso.apps.tanzu.vmware.com/template-unsafe-redirect-uris: ""
    spec:
      workloadDomainTemplate: "{{.Namespace}}-{{.Name}}.apps.{{.Domain}}"
      authServerSelector:
        matchLabels:
          sso.apps.tanzu.vmware.com/env: staging
```

Claims

Instances of this class are claimed by using Services Toolkit's `ClassClaim`.

The class is identified by its name and the client registration's configuration is set as its parameters. The `spec` of parameters is the specification of XWorkloadRegistration.

For more information about the `ClassClaim` API, see ClusterInstanceClass and ClassClaim.

You can set the propagation time of client credentials to the `ClassClaim` up to `120s`.

Claims specification

This is the specification of a `ClassClaim` for a `ClusterWorkloadRegistrationClass`, not the specification of the `ClassClaim` API.

```
---
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ClassClaim
metadata:
  name: "" #! required
  namespace: #! required
spec:
```

```
  classRef:
    name: "" #! required
  parameters:
    workloadRef:
      name: "" #! required
    redirectPaths: #! optional
      - "" #! must be an absolute path
    scopes: #! optional
      - name: "" #! required
        description: "" #! optional
    authorizationGrantTypes: #! optional
      - "" #! must be one of "authorization_code", "client_credentials" or "refresh_to
ken"
    clientAuthenticationMethod: "" #! optional, must be one of "client_secret_post",
"client_secret_basic" or "none"
    requireUserConsent: false #! optional
```

Claims examples

If a claimable AppSSO service offering exists as follows:

```
$ tanzu service class list
  NAME               DESCRIPTION
  demo               Single Sign-On Demo
```

This is a minimal example claim for the AppSSO service offering `demo`:

```
---
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ClassClaim
metadata:
  name: sample-minimal
spec:
  classRef:
    name: demo
  parameters:
    workloadRef:
      name: sample-workload
    redirectPaths:
      - /redirect/uri/1
      - /redirect/uri/2
```

This is a fully configured example claim for the AppSSO service offering `demo`:

```
---
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ClassClaim
metadata:
  name: sample-full
spec:
  classRef:
    name: demo
  parameters:
    workloadRef:
      name: sample-workload
    redirectPaths:
      - /redirect/uri/1
      - /redirect/uri/2
    scopes:
      - name: openid
      - name: email
      - name: profile
      - name: roles
      - name: coffee.make
```

```
        description: bestows the ultimate power
    authorizationGrantTypes:
      - client_credentials
      - authorization_code
      - refresh_token
    clientAuthenticationMethod: client_secret_basic
    requireUserConsent: false
```

Claims updates

`ClassClaim` performs a point-in-time look-up, so updates to an existing `ClassClaim.spec.parameters` have no effect. For more information, see Class claims compared to resource claims.

When creating your `ClassClaim` with kapp, you can configure it to replace the resource instead of updating it when it changes:

```
---
apiVersion: kapp.k14s.io/v1alpha1
kind: Config
rebaseRules:
  - resourceMatchers:
      - apiVersionKindMatcher:
          { apiVersion: services.apps.tanzu.vmware.com/v1alpha1, kind: ClassClaim }
    path: [metadata, annotations, "classclaims.services.apps.tanzu.vmware.com/xrd-nam
e"]
    type: copy
    sources: [new, existing]

---
apiVersion: services.apps.tanzu.vmware.com/v1alpha1
kind: ClassClaim
metadata:
  annotations:
    kapp.k14s.io/update-strategy: always-replace
#! ...
```

WorkloadRegistration API for AppSSO

In Application Single Sign-On (commonly called AppSSO), `WorkloadRegistration` represents the request for client credentials for an AuthServer. It is a portable, higher-level abstraction over ClientRegistration. It is namespaced and is identified by its short name `workloadreg`.

`WorkloadRegistration` templates redirect URIs and reconciles into a ClientRegistration. For more information, see Redirect URI templating.

`WorkloadRegistration` exposes most of the fields of ClientRegistration. The exceptions are `spec.redirectPaths` (instead of `spec.redirectURIs`), `spec.workloadDomainTemplate` and `spec.workloadRef`.

By templating redirect URIs, a `WorkloadRegistration` is decoupled from a client workload's specific FQDN. As a result, it is portable across environments.

`spec.workloadDomainTemplate` is a golang text/template. It is optional with default value `{{.Name}}.{{.Namespace}}.{{.Domain}}`. You can change the default value to the package configuration value `default_workload_domain_template`.

The values for `{{.Name}}` and `{{.Namespace}}` are inherited from `spec.workloadRef`. The field `spec.workloadRef` is not resolved to an actual workload running on the cluster. It is a holder for template values which identify a workload.

The package configuration value `workload_domain_name` defines the value for `{{.Domain}}`.

Similar to `ClientRegistration`:

- `WorkloadRegistration` is bindable. It implements the Service Bindings `ProvisionedService`. The credentials are returned as a Service Bindings `Secret`.
- A `WorkloadRegistration` must uniquely identify an `AuthServer` by using `spec.authServerSelector`. If it matches none, too many or a disallowed `AuthServer`, it does not get credentials.

`WorkloadRegistration` aggregates the readiness of its child `ClientRegistration`.

Note

The term “workload” is meant to express the general notion of a workload. The overlap with Cartographer’s `Workload` API is therefore both incidental and accidental, because that API too is not opinionated as to what specific resources consolidat a “workload”.

`WorkloadRegistration` represents the client registration of any “workload” whose redirect URIs can be templated. It must not be a `Workload` or even be running on a Kubernetes cluster.

Specification

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: WorkloadRegistration
metadata:
  name: "" #! required
  namespace: "" #! required
  annotations:
    sso.apps.tanzu.vmware.com/template-unsafe-redirect-uris: "" #! optional
spec:
  workloadDomainTemplate: "" #! optional
  workloadRef:
    name: "" #! required
    namespace: "" #! required
  authServerSelector:
    matchLabels: {} #! required
  displayName: "" #! optional, must be between 2 and 32 chars in length
  redirectPaths: #! optional
    - "" #! must be an absolute path
  scopes: #! optional
    - name: "" #! required
      description: "" #! optional
  authorizationGrantTypes: #! optional
    - "" #! must be one of "authorization_code", "client_credentials" or "refresh_toke
n"
  clientAuthenticationMethod: "" #! optional, must be one of "client_secret_post", "cl
ient_secret_basic" or "none"
  requireUserConsent: false #! optional
status:
  authServerRef:
    apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
    issuerURI: ""
    kind: AuthServer
    name: ""
    namespace: ""
  binding:
    name: ""
  conditions:
  - lastTransitionTime: ""
```

```
    message: ""
    reason: ""
    status: ""
    type: ClientRegistrationReady
  - lastTransitionTime: ""
    message: ""
    reason: ""
    status: ""
    type: Ready
  observedGeneration: 0
  redirectURIs:
  - ""
  workloadDomainTemplate: ""
```

Alternatively, you can interactively discover the API with:

```
kubectl explain workloadreg
```

Examples

This is a minimal example which selects an `AuthServer` that is uniquely identified by the label `sso.apps.tanzu.vmware.com/env=dev`:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: WorkloadRegistration
metadata:
  name: sample-minimal
spec:
  workloadRef:
    name: test-workload-name
    namespace: test-workload-namespace
  authServerSelector:
    matchLabels:
      sso.apps.tanzu.vmware.com/env: dev
```

This is a full example which selects an `AuthServer` that is uniquely identified by label `sso.apps.tanzu.vmware.com/env=dev`. It uses all possible client configurations and sets a custom `workloadDomainTemplate` and an annotation. The annotation causes safe and unsafe redirect URI templating.

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: WorkloadRegistration
metadata:
  name: sample-full
  annotations:
    sso.apps.tanzu.vmware.com/template-unsafe-redirect-uris: ""
spec:
  workloadDomainTemplate: "hi-i-live-in-{{.Namespace}}-and-my-name-is-{{.Name}}.sampl
e.{{.Domain}}"
  workloadRef:
    name: test-workload-name
    namespace: test-workload-namespace
  authServerSelector:
    matchLabels:
      name: authserver-sample
      sample: "true"
  displayName: "Full sample app"
  redirectPaths:
    - /redirect/uri/1
    - /redirect/uri/2
```

```
  scopes:
    - name: openid
    - name: email
    - name: profile
    - name: roles
    - name: coffee.make
      description: bestows the ultimate power
  authorizationGrantTypes:
    - client_credentials
    - authorization_code
    - refresh_token
  clientAuthenticationMethod: client_secret_basic
  requireUserConsent: true
```

Redirect URI templating

Redirect URIs are templated as follows:

1. If `spec.redirectPaths` is empty, no further action is required.
2. Resolve the workload domain template by reading `spec.workloadDomainTemplate` or default it to `default_workload_domain_template` if omitted.
3. Resolve the values for `{{.Name}}` and `{{.Namespace}}` from `spec.workloadRef`.
4. Resolve the value for `{{.Domain}}` from `workload_domain_name`.
5. For each entry in `spec.redirectPaths`, template a full redirect URI by joining the path with the rendered workload domain template. Use `https` as the scheme.
6. If the annotation `sso.apps.tanzu.vmware.com/template-unsafe-redirect-uris` is present, template an additional unsafe redirect URI for each entry in `spec.redirectPaths` by using `http` as the scheme.

For example, if you set `workload_domain_name` to `tap.example.com`, a hypothetical `WorkloadRegistration` might look as follows:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: WorkloadRegistration
metadata:
  name: demo
  annotations:
    sso.apps.tanzu.vmware.com/template-unsafe-redirect-uris: ""
spec:
  workloadRef:
    name: my-workload
    namespace: my-ns
  redirectPaths:
    - /login/success
    - /login/error
  #! ...
status:
  redirectURIs:
    - https://my-workload.my-ns.tap.example.com/login/success
    - http://my-workload.my-ns.tap.example.com/login/success
    - https://my-workload.my-ns.tap.example.com/login/error
    - http://my-workload.my-ns.tap.example.com/login/error
  workloadDomainTemplate: '{{.Name}}.{{.Namespace}}.{{.Domain}}'
  #! ...
```

XWorkloadRegistration API for AppSSO

In Application Single Sign-On (commonly called AppSSO), `XWorkloadRegistration` is a cluster-scoped Crossplane XRD. It serves as an integration API between Services Toolkit, Crossplane and AppSSO.

Note

This API is not intended for direct usage. Although it is supported, VMware recommend using `ClassClaim`, `WorkloadRegistration`, or `ClientRegistration` instead when you need direct access to this API.

In most cases, when creating a `ClassClaim` for an AppSSO service offering, for example, ClusterWorkloadRegistrationClass, Services Toolkit creates an `XWorkloadRegistration`. By using a `Composition`, the `XWorkloadRegistration` is reconciled into a `WorkloadRegistration` with Crossplane's `provider-kubernete`'s `Object` as an intermediary.

The specification of `XWorkloadRegistration` is identical to WorkloadRegistration but without `spec.workloadRef.namespace` and `spec.authServerSelector`.

Specification

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: XWorkloadRegistration
metadata:
  name: "" #! required
spec:
  workloadRef:
    name: "" #! required
  redirectPaths: #! optional
    - "" #! must be an absolute path
  scopes: #! optional
    - name: "" #! required
      description: "" #! optional
  displayName: "" #! optional
  authorizationGrantTypes: #! optional
    - "" #! must be one of "authorization_code", "client_credentials" or "refresh_toke
n"
  clientAuthenticationMethod: "" #! optional, must be one of "client_secret_post", "cl
ient_secret_basic" or "none"
  requireUserConsent: false #! optional
status:
  authServerRef:
    apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
    issuerURI: ""
    kind: AuthServer
    name: ""
    namespace: ""
  binding:
    name: ""
```

Note

Crossplane's standard Crossplane Resource Model (commonly called XRM) fields are omitted.

Examples

If a `Composition` for `XWorkloadRegistration` exists, for example, by using a `ClusterWorkloadRegistrationClass`, this is a minimal example:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: XWorkloadRegistration
metadata:
  name: sample-minimal
spec:
  workloadRef:
    name: test-workload-name
```

This is a fully configured example:

```
---
apiVersion: sso.apps.tanzu.vmware.com/v1alpha1
kind: XWorkloadRegistration
metadata:
  name: sample-full
spec:
  workloadRef:
    name: test-workload-name
  redirectPaths:
    - /redirect/uri/1
    - /redirect/uri/2
  displayName: "Full sample app"
  scopes:
    - name: openid
    - name: email
    - name: profile
    - name: roles
    - name: coffee.make
      description: bestows the ultimate power
  authorizationGrantTypes:
    - client_credentials
    - authorization_code
    - refresh_token
  clientAuthenticationMethod: client_secret_basic
  requireUserConsent: true
```

Known issues for Application Single Sign-On

This topic describes known limitations and workarounds related to working with Application Single Sign-On (commonly called AppSSO). For further troubleshooting guidance, see Troubleshoot Application Single Sign-on.

Unregistration by deletion

You can only deregister an existing, ready `ClientRegistration` from its selected `AuthServer` by deleting it. Breaking the match between the two resources by updating either the labels of the `AuthServer` or the label selector on the `ClientRegistration` does not deregister the client from the authorization server.

Limited number of `ClientRegistrations` per `AuthServer`

The number of `ClientRegistration` for an `AuthServer` is limited to around 2,000. This is a soft limitation. If you attempt to apply more `ClientRegistration` resources than the limit, those clients applied past the limit will work. This is subject to change in future product versions.

LetsEncrypt: domain name for Issuer URI limited to 64 characters maximum

If you use LetsEncrypt to issue TLS certificates for an `AuthServer`, the domain name for the Issuer URI (excluding the `http{s}` prefix) cannot exceed 64 characters in length. If exceeded, you might receive a LetsEncrypt specific error during the certificate issuance process. You might observe this limitation when your base domain and subdomain joined together exceed the maximum limit.

If your default Issuer URI is too long, use the `domain_template` field in Application Single Sign-On values YAML to shorten the domain.

For example, you can forgo the namespace in the Issuer URI as follows:

```
domain_template: "{{.Name}}.{{.Domain}}"
```

Caution

By leaving out the namespace in your domain template, application routes might conflict if there are multiple `AuthServer`s with the same name but in different namespaces.

`ClassClaim` credential propagation time

It can take up to 60 to 120 seconds for the client credentials to propagate up into a `ClassClaim`'s service binding secret.

Application Single Sign-On for OpenShift clusters

On OpenShift clusters, AppSSO must run with a custom SecurityContextConstraint (SCC) to enable compliance with restricted Kubernetes Pod Security Standards. Tanzu Application Platform configures the following SCC for AppSSO controller and its `AuthServer` managed resources when you configure the `kubernetes_distribution: openshift` key in the `tap-values.yaml` file.

Specification follows:

```
---
kind: SecurityContextConstraints
apiVersion: security.openshift.io/v1
metadata:
  name: appsso-scc
allowHostDirVolumePlugin: false
allowHostIPC: false
allowHostNetwork: false
allowHostPID: false
allowHostPorts: false
allowPrivilegeEscalation: false
allowPrivilegedContainer: false
allowedCapabilities: null
defaultAddCapabilities: null
fsGroup:
  type: MustRunAs
priority: null
readOnlyRootFilesystem: false
requiredDropCapabilities:
  - KILL
  - MKNOD
  - SETUID
  - SETGID
```

```
runAsUser:
  type: MustRunAsNonRoot
seLinuxContext:
  type: MustRunAs
volumes:
  - configMap
  - downwardAPI
  - emptyDir
  - persistentVolumeClaim
  - projected
  - secret
seccompProfiles:
  - 'runtime/default'
```

AppSSO controller's `ServiceAccount` is given the following additional permissions, including a `use` permission for AppSSO SCC, so `AuthServer` can use the custom SCC:

```
- apiGroups:
    - security.openshift.io
  resources:
    - securitycontextconstraints
  verbs:
    - "get"
    - "list"
    - "watch"
```

```
- apiGroups:
    - security.openshift.io
  resourceNames:
    - appsso-scc
  resources:
    - securitycontextconstraints
  verbs:
    - "use"
```

Package configuration for Application Single Sign-On

In most cases, the Application Single Sign-on (commonly called AppSSO) package installation is configured by using the meta package installation of Tanzu Application Platform (commonly called TAP). The Tanzu Application Platform package has a `shared` top-level configuration key for sharing common configuration between the packages it installs.

Application Single Sign-on inherits the `shared.{ingress_domain, ingress_issuer, ca_cert_data, kubernetes_distribution}` configuration values from Tanzu Application Platform. You can override these values with Application Single Sign-On specific values under `appsso`. Application Single Sign-On specific configuration has precedence over the shared values of Tanzu Application Platform.

For example:

```
#! my-tap-values.yaml

shared:
# Shared configuration goes here.

appsso:
# AppSSO-specific configuration goes here.
```

Configuration values

The package installation of `sso.apps.tanzu.vmware.com` has the following configuration values:

`ca_cert_data`

You can configure trust for custom CAs by providing their certificates as a PEM bundle to `ca_cert_data`. As a result, all `AuthServer`s trust your custom CAs.

This is useful if you have Identity providers serving certificates from a custom CA and configuring AuthServer storage.

Alternatively, you can configure trust for a single AuthServer.

Note

Application Single Sign-on specific `ca_cert_data` is concatenated with `shared.ca_cert_data`. The resulting PEM bundle contains both.

`cluster_resource_namespace`

This setting designates the target namespace when the cluster-scoped APIs reconcile into namespace-scoped resources.

In particular, the cluster-scoped ClusterUnsafeTestLogin reconciles into namespace-scoped resources such as an `AuthServer`. These resources are placed in the `cluster_resource_namespace`.

The default value of `cluster_resource_namespace` is `appsso`.

Note

Updating the `cluster_resource_namespace` of an existing package installation delete or create namespace-scoped resources in the new namespace. This causes downtime for the impacted resources momentarily.

`default_authserver_clusterissuer`

You can denote a `cert-manager.io/v1/ClusterIssuer` as a default issuer for `AuthServer.spec.tls.issuerRef` and omit `AuthServer.spec.tls`. When the value of `AuthServer.spec.tls.issuerRef` is the empty string `""`, no default issuer is assumed and no `AuthServer.spec.tls` is required.

If you configured `shared.ingress_issuer` and omitted `default_authserver_clusterissuer` while installing Tanzu Application Platform, Application Single Sign-on uses the ingress issuer of Tanzu Application Platform and sets `default_authserver_clusterissuer` to `shared.ingress_issuer`.

`default_workload_domain_template`

This is the default template from which WorkloadRegistration renders redirect URIs. It is used when `WorkloadRegistration.spec.workloadDomainTemplate` is omitted.

This is a golang text/template. The default is `"{{.Name}}.{{.Namespace}}.{{.Domain}}"`.

The domain template is applied with the configured `workload_domain_name` and the name and namespace specified in `WorkloadRegistration.spec.workloadRef`. For more information, see Redirect URI templating.

VMware recommends maintaining consistency between the values of `default_workload_domain_template` and Cloud Native Runtimes' `domain_template`. Both values

share the same default configuration. However, for customization purposes, using the same value for both settings ensures that `Workloads` get the expected redirect URIs templated.

domain_name

The Application Single Sign-on package has one required configuration value, its `domain_name`. It templates the issuer URI for `AuthServer`. `domain_name` must be the shared ingress domain of your Tanzu Application Platform package installation. If your Tanzu Application Platform installation is configured with `shared.ingress_domain`, Application Single Sign-on inherits the correct configuration.

If omitted, `domain_name` is set to `shared.ingress_domain`.

domain_template

You can customize how Application Single Sign-on template's `issuerURIs` with the `domain_template` configuration. This is a golang text/template. The default value is `"{{.Name}}.{{.Namespace}}.{{.Domain}}"`.

The domain template is applied with the given `domain_name` and the `AuthServer`'s name and namespace:

- `{{.Domain}}` evaluates to the configured `domain_name`
- `{{.Name}}` evaluates to `AuthServer.metadata.name`
- `{{.Namespace}}` evaluates to `AuthServer.metadata.namespace`

To use a wild-card certificate, consider `"{{.Name}}-{{.Namespace}}.{{.Domain}}"`.

VMware recommends keeping the name and namespace sections of the template to avoid domain name collisions.

kubernetes_distribution

This setting toggles behavior for specific Kubernetes distributions. Currently, the only supported values are `""` and `openshift`.

It is processed in combination with `kubernetes_version`.

Application Single Sign-On installs OpenShift specific RBAC and resources. For more information, see Application Single Sign-On for OpenShift clusters.

If omitted, `kubernetes_distribution` is set to `shared.kubernetes_distribution`.

kubernetes_version

This setting toggles behavior for specific Kubernetes distributions. Currently, the only supported values are `""` or semantic versions in the form of `\d*\.\d*\.\d*`.

It is processed in combination with `kubernetes_distribution`.

Application Single Sign-On installs OpenShift specific RBAC and resources. For more information, see Application Single Sign-On for OpenShift clusters.

If omitted, `kubernetes_version` is set to `shared.kubernetes_version`.

workload_domain_name

This is used as the value for `{{.Domain}}` in WorkloadRegistration's domain template.

`workload_domain_name` defaults to the value of `domain_name`.

In most cases, the value of `workload_domain_name` matches the value of Cloud Native Runtimes' `domain_name`.

`replicas`

The controller is run with this many replicas. The default value is `1`.

The controller uses leader election so that there is only a single active replica at a time. Increasing this value does not improve the controller's performance.

`resources`

This is the value for the controller's `Deployment.spec.template.spec.containers[0].resources`.

See Configuration schema for more information about its structure and default values.

`resync_period`

This is the duration after which the controller re-synchronizes all resources. That means that every instance of a Application Single Sign-On API is reconciled at this point.

The default value is `2h`.

VMware does not recommend customizing this value in all practical scenarios.

Configuration schema

The package installation of `sso.apps.tanzu.vmware.com` has the following configuration schema:

```
---

#@schema/desc "Optional: Kubernetes platform distribution that this package is being i
nstalled on. Accepted values: ['','openshift']"
kubernetes_distribution: ""

#@schema/desc "Optional: Kubernetes platform version that this package is being instal
led on. Accepted format: ['x.x.x']"
kubernetes_version: ""

#@schema/desc "Domain name for AuthServers."
domain_name: "example.com"

#@schema/desc "Optional: Golang template/text string for constructing AuthServer FQDN
s."
domain_template: "{{.Name}}.{{.Namespace}}.{{.Domain}}"

#@schema/desc "Optional: A cert-manager.io/v1/ClusterIssuer for defaulting AuthServer
TLS."
default_authserver_clusterissuer: ""

#@schema/desc "Optional: Domain name for Workloads. Defaults to the value of domain_na
me."
workload_domain_name: ""

#@schema/desc "Optional: Golang template/text string for defaulting Workload FQDNs tem
plating."
default_workload_domain_template: "{{.Name}}.{{.Namespace}}.{{.Domain}}"

#@schema/desc "The namespace which children of cluster-scoped resources are located i
n."
cluster_resource_namespace: "appsso"

#@schema/desc "Optional: PEM-encoded certificate data for AuthServers to trust TLS con
```

```
nections with a custom CA."
ca_cert_data: ""

#@schema/desc "Optional: Interval at which the controller will re-synchronize applied
resources."
resync_period: "2h"

#@schema/desc "Optional: Number of controller replicas to deploy."
replicas: 1

#@schema/desc "Optional: Resource requirements of the controller deployment."
resources:
  requests:
    #@schema/desc "CPU request of the controller."
    cpu: "20m"
    #@schema/desc "Memory request of the controller."
    memory: "100Mi"
  limits:
    #@schema/desc "CPU limit of the controller."
    cpu: "500m"
    #@schema/desc "Memory limit of the controller."
    memory: "500Mi"
```

RBAC for AppSSO

The Application Single Sign-On (commonly called AppSSO) package aggregates the following permissions into Tanzu Application Platform's well-known roles. For more information, see Role descriptions for Tanzu Application Platform.

User aggregated rules

app-operator

```
apiGroups:
  - sso.apps.tanzu.vmware.com
resources:
  - clientregistrations
  - workloadregistrations
verbs:
  - '*'
```

app-editor

```
apiGroups:
  - sso.apps.tanzu.vmware.com
resources:
  - clientregistrations
  - workloadregistrations
verbs:
  - get
  - list
  - watch
```

app-viewer

```
apiGroups:
  - sso.apps.tanzu.vmware.com
resources:
  - clientregistrations
  - workloadregistrations
```

```
verbs:
  - get
  - list
  - watch
```

service-operator

```
apiGroups:
  - sso.apps.tanzu.vmware.com
resources:
  - authservers
  - clusterunsafetestlogins
  - clusterworkloadregistrationclasses
verbs:
  - '*'
```

Controller

To manage the life cycle of AppSSO's APIs, the AppSSO controller's `ServiceAccount` has a `ClusterRole` with the following permissions:

```
- apiGroups:
    - sso.apps.tanzu.vmware.com
  resources:
    - authservers
    - clientregistrations
    - clusterunsafetestlogins
    - clusterworkloadregistrationclasses
    - workloadregistrations
  verbs:
    - '*'
- apiGroups:
    - sso.apps.tanzu.vmware.com
  resources:
    - authservers/status
    - clientregistrations/status
    - clusterunsafetestlogins/status
    - clusterworkloadregistrationclasses/status
    - workloadregistrations/status
  verbs:
    - patch
    - update
- apiGroups:
    - sso.apps.tanzu.vmware.com
  resources:
    - authservers/finalizers
    - clientregistrations/finalizers
    - clusterunsafetestlogins/finalizers
    - clusterworkloadregistrationclasses/finalizers
    - workloadregistrations/finalizers
  verbs:
    - '*'
- apiGroups:
    - ""
  resources:
    - events
  verbs:
    - create
    - update
    - patch
- apiGroups:
    - coordination.k8s.io
  resources:
```

```
    - leases
  verbs:
    - create
    - get
    - update
- apiGroups:
    - ""
  resources:
    - secrets
    - configmaps
    - services
    - serviceaccounts
  verbs:
    - '*'
- apiGroups:
    - apps
  resources:
    - deployments
  verbs:
    - '*'
- apiGroups:
    - rbac.authorization.k8s.io
  resources:
    - roles
    - rolebindings
  verbs:
    - '*'
- apiGroups:
    - cert-manager.io
  resources:
    - certificates
    - issuers
  verbs:
    - '*'
- apiGroups:
    - cert-manager.io
  resources:
    - clusterissuers
  verbs:
    - get
    - list
    - watch
- apiGroups:
    - networking.k8s.io
  resources:
    - ingresses
  verbs:
    - '*'
- apiGroups:
    - servicebinding.io
  resources:
    - servicebindings
  verbs:
    - '*'
- apiGroups:
    - services.apps.tanzu.vmware.com
  resources:
    - clusterinstanceclasses
  verbs:
    - '*'
- apiGroups:
    - services.apps.tanzu.vmware.com
  resources:
    - clusterinstanceclasses
  verbs:
    - '*'
```

```
- apiGroups:
    - apiextensions.crossplane.io
  resources:
    - compositions
  verbs:
    - '*'
```

AppSSO also installs OpenShift specific RBAC and resources. For more information, see Application Single Sign-On for OpenShift clusters.

AuthServer audit logs for AppSSO

This topic tells you how to use `AuthServer` audit logs in Application Single Sign-On (commonly called AppSSO).

Overview

`AuthServer`s perform the following tasks:

- Handle user authentication
- Issue `id_token` and `access_token`

Each audit event contains the following information:

- `ts` - date/time of the event
- `remoteIpAddress` - the IP of the user-authentication or if not attainable, the IP of the last proxy

Authentication

`AuthServer` produce the following authentication events:

- `AUTHENTICATION_SUCCESS`
  - **Trigger** successful authentication
  - **Data recorded** Username, Provider ID, Provider Type (INTERNAL, OPENID, ...)
- `AUTHENTICATION_LOGOUT`
  - **Trigger** successful logout
  - **Data recorded** Username, Provider ID, Provider Type (INTERNAL, OPENID, ...)
- `AUTHENTICATION_FAILURE`
  - **Trigger** failed authentication using either `internalUnsafe` or `ldap` identity provider
  - **Data recorded** Username, Provider ID, Provider Type (INTERNAL or LDAP)
- `INVALID_IDENTITY_PROVIDER_CONFIGURATION`
  - **Trigger** some cases of failed authentication with an `openId` or `saml` identity provider
  - **Data recorded** Provider ID, Provider Type, error
  - **Note** usually followed by a human-readable help message, with `"logger": "appsso.help"`

Token flows

`AuthServer` produce the following authorization_code and token events:

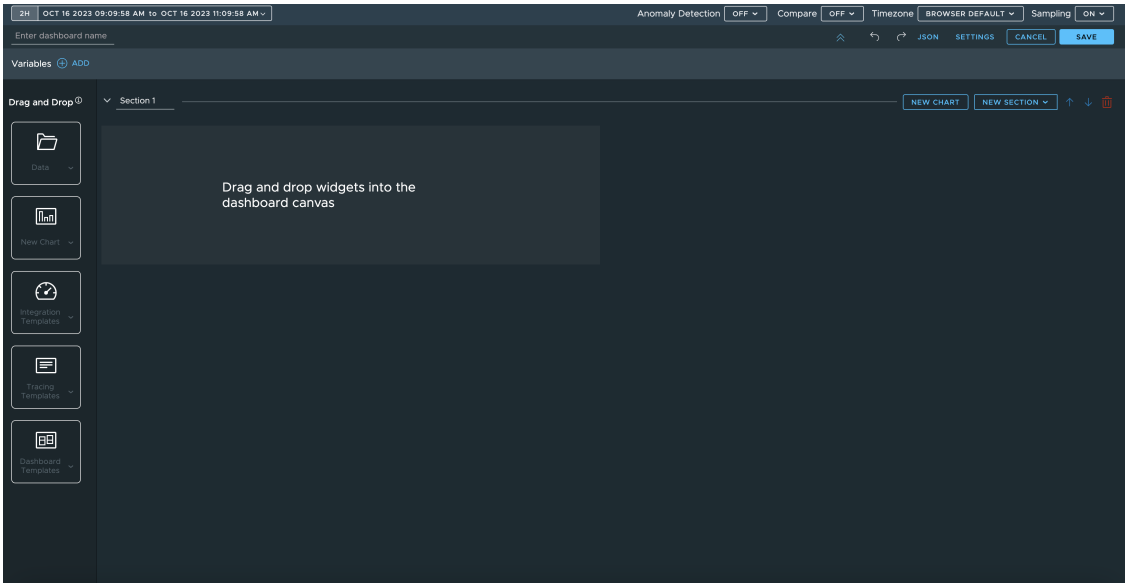
- `AUTHORIZATION_CODE_ISSUED`

    - **Trigger** `authorization_code` grant type, successful call to `/oauth2/authorize`
    - **Data recorded** Username, Provider ID, Provider Type, Client ID, Scopes requested, Redirect URI
- `AUTHORIZATION_CODE_REQUEST_REJECTED`
    - **Trigger** `authorization_code` grant type, unsuccessful call to `/oauth2/authorize`, for example invalid Client ID, invalid Redirect URI, ...
    - **Data recorded** Error, Error Code (ex: `invalid_scope`), Client ID, Scopes requested Redirect URI, Username (may be `anonymousUser`), Provider ID and Provider Type if available
- `TOKEN_ISSUED`
    - **Trigger** successful call to `/oauth2/token`
    - **Data recorded** Scopes, Client ID, Grant Type (`authorization_code` or `client_credentials`), Username
- `TOKEN_REQUEST_REJECTED`
    - **Trigger** unsuccessful call to `/oauth2/token`, for example invalid Client Secret
    - **Data recorded** Client ID, Scopes requested, Error

Overview of the Aria Operations for Applications dashboard for Tanzu Application Platform (beta)

The Aria Operations for Applications (AOA) dashboard helps you monitor the health of a cluster. The AOA dashboard shows whether the deployed Tanzu Application Platform (commonly known as TAP) components are behaving as expected.

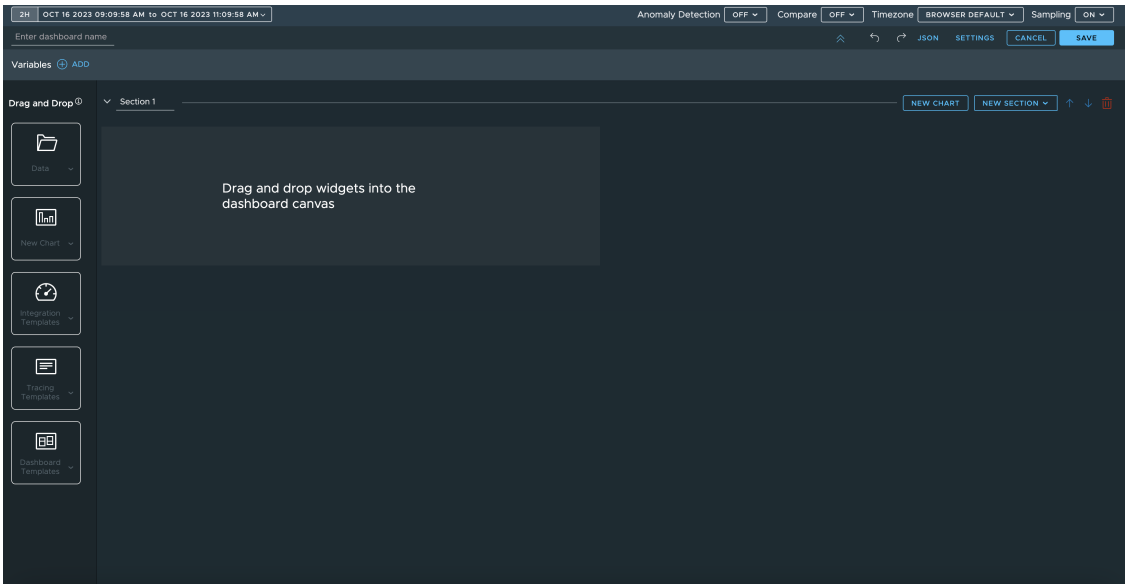
Aria Operations for Applications (formerly Tanzu Observability) powers AOA dashboard.



Overview of the Aria Operations for Applications dashboard for Tanzu Application Platform (beta)

The Aria Operations for Applications (AOA) dashboard helps you monitor the health of a cluster. The AOA dashboard shows whether the deployed Tanzu Application Platform (commonly known as TAP) components are behaving as expected.

Aria Operations for Applications (formerly Tanzu Observability) powers AOA dashboard.



Install the Aria Operations for Applications dashboard for Tanzu Application Platform (beta)

This topic tells you how to integrate a Kubernetes cluster of any distribution with Aria Operations for Applications (AOA) so that you can use the AOA dashboard. This topic also tells you how to set up and configure AOA dashboard for use with Tanzu Application Platform (commonly known as TAP).

Prerequisites

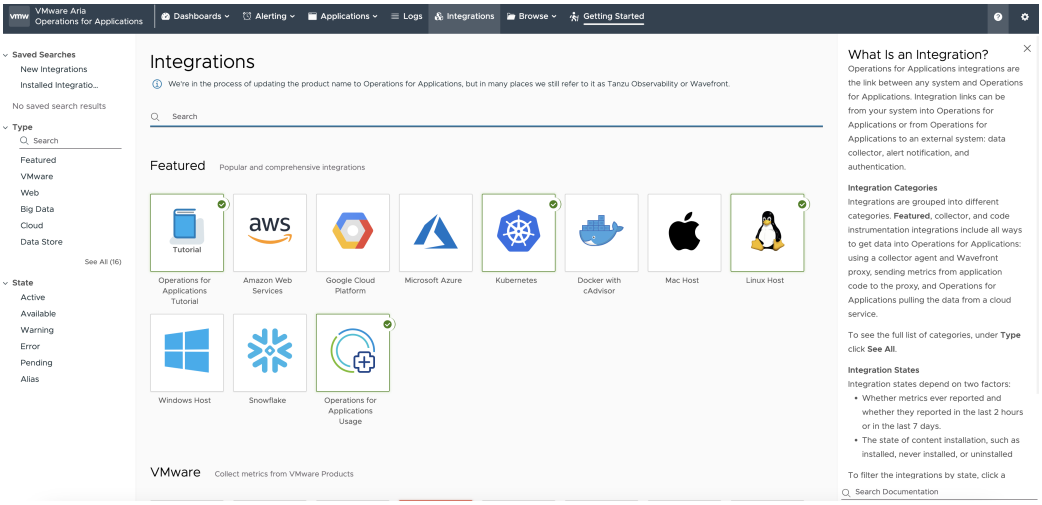
Before integrating a Kubernetes cluster with AOA you must have:

- AOA Wavefront access with permissions to integrate Kubernetes clusters and view dashboards
- A Kubernetes cluster with Tanzu Application Platform installed

Integrate with AOA Wavefront

To integrate with AOA Wavefront:

1. Log in to your AOA instance, click the **INTEGRATIONS** tab, and then click **Kubernetes**.



2. Click **ADD AN INTEGRATION INSTANCE** on the next page.

3. Fill out the **Kubernetes Integration Setup** page:
    1. Select **Kubernetes Cluster** as the distribution type.
    2. Type the cluster name in the **Cluster Name** text box.
    3. Enable **Logs**.
    4. Enable **Metrics**.
    5. Configure authentication. If the token is not listed, verify that you have AOA Wavefront access.
4. Run the kubectl commands in the **Deployment Script** text box on the cluster that you want to onboard.

Set up metrics collection in a cluster

Perform the following procedures to set up metrics collection in a cluster.

Download the dashboard and set up the cluster

To download the dashboard and set up the cluster:

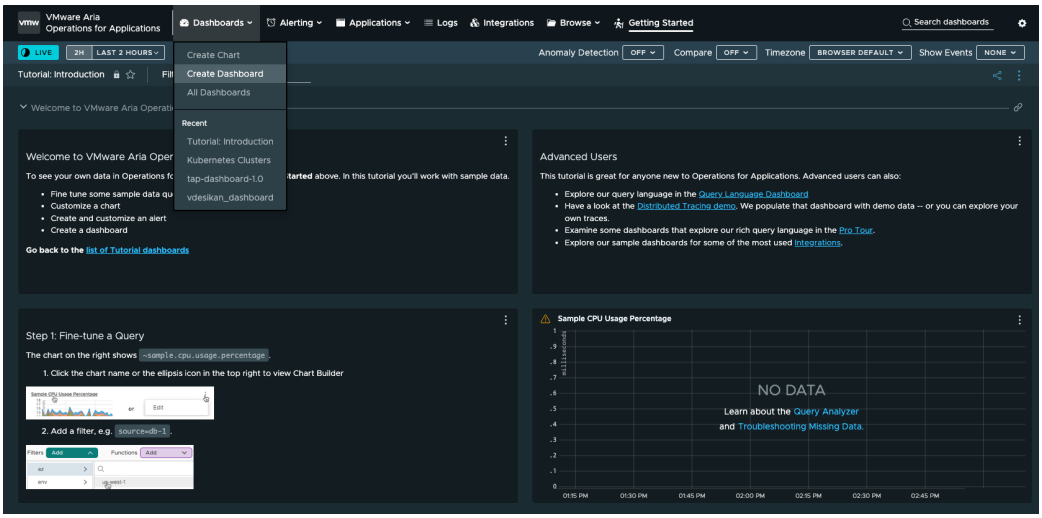
1. Download and install the Tanzu CLI binary file from the Tanzu Application Platform tile in VMware Tanzu Network if you have not already installed it.
2. Download the dashboard zip file from the tile in VMware Tanzu Network for Tanzu Application Platform v1.9.1 or later.
    - Click **Aria Operations for Applications Dashboard for Tanzu Application Platform (Beta)**.
    - Download the `aoa-dashboard-for-tap` zip file for your operating system.
3. Use an extraction tool to unpack the binary file.
4. Apply the included `tap-metrics.yaml` file to the onboarded cluster, which enables the collection of Tanzu Application Platform `CustomResource` metrics, by running:

    ```
    kubectl apply -f tap-metrics.yaml
    ```

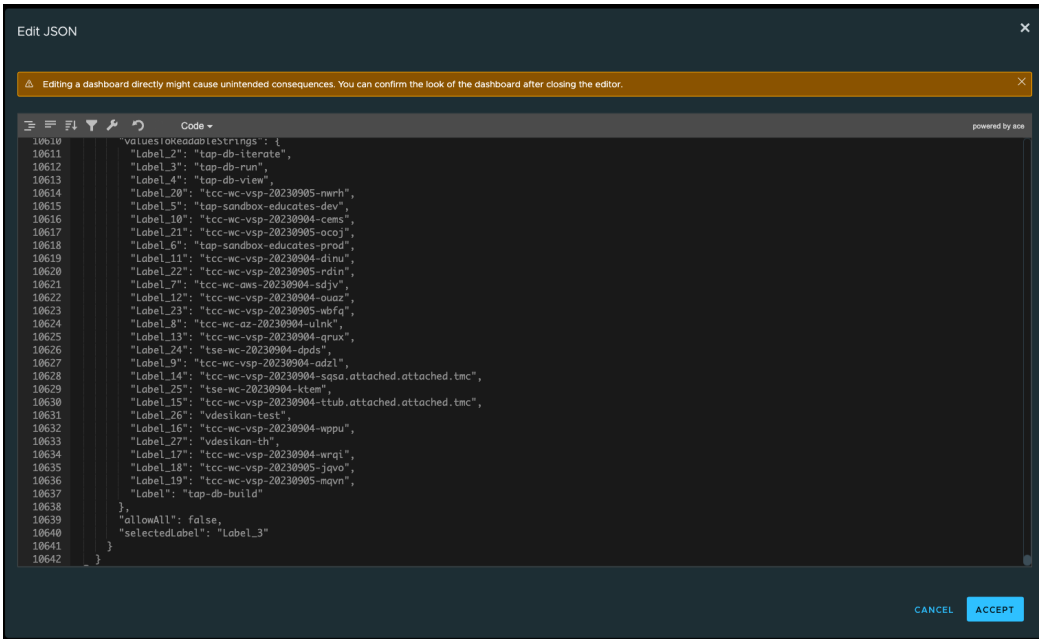
Create the dashboard in AOA Wavefront

To create a dashboard in AOA Wavefront:

1. Go to the AOA Wavefront home page and then click **Dashboards** > **Create Dashboard**.



2. Click **JSON** in the upper right corner.
3. Click **Tree** > **Code** and extract the downloaded content from `tap-health-dashboard.json`.
4. Copy the content from `tap-health-dashboard.json` into the code block and then click **ACCEPT**.



5. Click **SAVE** in the top right corner to save the dashboard.
6. In the search text box, type the name of the cluster that you onboarded and select it from the list of available clusters.

(Optional) Onboard additional clusters

The dashboard currently only supports monitoring one cluster at a time. But you can follow the steps in Set up metrics collection in a cluster to onboard additional clusters to AOA. The additional clusters then appear in the **Cluster** drop-down menu.

Use the Aria Operations for Applications dashboard for Tanzu Application Platform (beta)
