VMware Tanzu Greenplum on vSphere	264
Supported Platforms	264
Overview	265
Getting Started	265
VMware Tanzu Greenplum on vSphere Architecture	266
Layered Architecture	266
Provider Layer	266
Infrastructure Layer	266
Virtual Machine Cluster Layer	266
Greenplum Layer	267
Planning VMware vSphere with Greenplum	268
Calculating the Greenplum Database Size and ESXi Hosts	268
Determining the RAID Type	268
Determining the Number of Virtual Machines	269
Sizing the Greenplum Virtual Machine	270
Putting It All Together	270
Dell EMC VxRail Reference Architecture	271
Next Steps	271
Prerequisites	271
Greenplum Cluster	271
VMware vSphere	271
Network	272
Next Steps	272

Setting Up VMware vSphere Network	272
Verifying the Distributed Virtual Switch Settings	273
Creating the Distributed Port Groups	273
Configuring the Distributed Port Groups	274
Principles of VMware Vsphere Distributed Switch to Uplink Assignment	274
Using Four 100GbE Links	275
Enabling VMware Vsphere Distributed Switch (vDS) Health Check	275
Next Steps	276
Setting Up VMware vSphere DRS and HA	276
Enabling DRS	276
Enabling HA	277
Next Steps	279
Setting Up VMware Vsphere Storage	280
Configuring vSAN	280
Creating the Storage Policies	281
Next Steps	284
Setting Up VMware vSphere Encryption	284
Virtual Machine Encryption versus vSAN Encryption	285
Enabling Encryption on Greenplum	285
Prerequisites	285
Option 1: Enabling Virtual Machine Encryption	286
Option 2: Enabling vSAN Encryption	288
Step 1: Enabling vSAN encryption	288
Step 2: Creating the VMware vSphere storage policy	289
Next Steps	292
Validating VMware vSphere Setup Performance with HCIBench	292
Deploying the HCIBench Virtual Machine	292
Using HCIBench	294
Reviewing the Results	297
Next Steps	297
Creating the Jumpbox Virtual Machine	297
Uploading the ISO Image to vCenter	297
Deploying the Jumpbox Virtual Machine	297
Initializing the Jumpbox Virtual Machine	298
Installing VMware Tools	299

Installing Terraform	300
Next Steps	300
Choosing your Deployment Option	300
Option 1: Deploying Greenplum Using a Pre-built OVA	300
Downloading the Greenplum Database to a local machine	300
Deploying the Greenplum Database Template OVA	301
Modifying Resources	301
Validating the Virtual Machine Template	302
Provisioning the Virtual Machines	302
Monitoring the Greenplum Deployment	304
Setting Up the GPCC Login User	304
Next Steps	304
Option 2: Deploying Greenplum Using Your Own Template	304
Creating the Virtual Machine Template	305
Preparing the Virtual Machine	305
Performing System Configuration	306
Installing the Greenplum Database Software	312
Creating the Greenplum Template	313
Validating the Template	313
Creating a Test Virtual Machine	313
Verifying the Test Virtual Machine Settings	314
Allocating the Virtual Machines with Terraform	317
Provisioning the Virtual Machines	317
Terraform timeout	319
Validating the Deployment	319
Deploying Greenplum	320
Deploying a Greenplum Database Cluster	321
Next Steps	322
Validating the Greenplum Installation	322
Managing Single Host Failures in VMware vSphere	323
How DRS and HA protect a running Greenplum cluster	323
Single Host Failure Scenarios	324
Mirror Segment Failure	324
Primary Segment Failure	324
Standby Master Failure	325

Master Failure	326
After Host Recovery	326
Best Practices for Greenplum HA	326
Appendix: Grace Period for a Downed Segment	327
Planning Downtime for Maintenance	327
Bringing the ESXi Host Down	327
Bringing the ESXi Host Back Up	328
Performance Impact of Host Maintenance	328
Installing and Upgrading Greenplum	329
Estimating Storage Capacity	330
Calculating Usable Disk Capacity	330
Calculating User Data Size	331
Calculating Space Requirements for Metadata and Logs	331
Configuring Your Systems	332
Disable or Configure SELinux	333
Disable or Configure Firewall Software	333
Recommended OS Parameters Settings	334
The hosts File	335
The sysctl.conf File	335
System Resources Limits	337
Core Dump	338
XFS Mount Options	338
Disk I/O Settings	338
Networking	340
Transparent Huge Pages (THP)	340
IPC Object Removal	341
SSH Connection Threshold	341
Synchronizing System Clocks	342
To configure NTP	342
Creating the Greenplum Administrative User	343
Next Steps	344
Installing the Greenplum Database Software	344
Installing Greenplum Database	345
Downloading the Greenplum Database Server Software (VMware Tanzu Greenplum)	345
Verifying the Greenplum Database Software (VMware Tanzu Greenplum)	345

Installing the Greenplum Database Software	345
(Optional) Installing to a Non-Default Directory	346
Enabling Passwordless SSH	347
Confirming Your Installation	348
About Your Greenplum Database Installation	348
Next Steps	349
Verifying the VMware Tanzu Greenplum Software Download	349
Creating the Data Storage Areas	349
Creating Data Storage Areas on the Master and Standby Master Hosts	350
To create the data directory location on the master	350
Creating Data Storage Areas on Segment Hosts	350
To create the data directory locations on all segment hosts	350
Next Steps	351
Validating Your Systems	351
Validating Network Performance	351
Validating Disk I/O and Memory Bandwidth	352
To run the disk and stream tests	352
Initializing a Greenplum Database System	352
Overview	353
Initializing Greenplum Database	353
Creating the Initialization Host File	354
To create the initialization host file	354
Creating the Greenplum Database Configuration File	354
To create a gpinitssystem_config file	354
Running the Initialization Utility	355
To run the initialization utility	355
Troubleshooting Initialization Problems	356
Using the Backout Script	356
Setting the Greenplum Database Timezone	356
Setting Greenplum Environment Variables	357
To set up the gpadmin environment for Greenplum Database	357
Next Steps	358
Allowing Client Connections	358
Creating Databases and Loading Data	358
Installing Optional Extensions (Tanzu Greenplum)	358

Procedural Language, Machine Learning, and Geospatial Extensions	358
Python Data Science Module Package	359
Python Data Science Modules	359
Installing the Python Data Science Module Package	362
Uninstalling the Python Data Science Module Package	363
R Data Science Library Package	363
R Data Science Libraries	363
Installing the R Data Science Library Package	364
Uninstalling the R Data Science Library Package	365
Greenplum Platform Extension Framework (PXF)	366
Installing Additional Supplied Modules	366
Configuring Timezone and Localization Settings	367
Configuring the Timezone	367
About Locale Support in Greenplum Database	367
Locale Behavior	369
Troubleshooting Locales	369
Character Set Support	369
Setting the Character Set	371
Character Set Conversion Between Server and Client	371
Upgrading to Greenplum 6	373
Upgrading from an Earlier Greenplum 6 Release	374
Prerequisites	374
Upgrading from 6.x to a Newer 6.x Release	375
Troubleshooting a Failed Upgrade	377
PXF Upgrade and Migration	377
Migrating PXF from Greenplum 5.x to 6.x	377
Prerequisites	378
Step 1: Complete PXF Greenplum Database 5.x Pre-Migration Actions	378
Step 2: Migrating PXF to Greenplum 6.x	379
Migrating gpdfs External Tables to PXF	381
Preparing for the Migration	381
Setting Up PXF	382

Creating a PXF External Table	383
Mapping the LOCATION Clause	384
Mapping the FORMAT Options	385
Example gphdfs to pxf External Table Mapping for an HDFS Text File	385
Verifying Access with PXF	386
Removing the gphdfs External Tables	386
Revoking Privileges to the gphdfs Protocol	386
 Upgrading PXF When You Upgrade from a Previous Greenplum Database 6.x Version	 386
Step 1: PXF Pre-Upgrade Actions	387
Step 2: Registering or Upgrading PXF	387
 Migrating Data from Greenplum 4.3 or 5 to Greenplum 6	 388
Preparing the Greenplum 6 Cluster	388
Preparing Greenplum 4.3 and 5 Databases for Backup	389
About Migrating Views Created with lag()/lead() Functions	392
Backing Up and Restoring a Database	393
Completing the Migration	394
Working With Hash Operator Classes in Greenplum 6	394
 Enabling iptables (Optional)	 396
How to Enable iptables	396
Example iptables Rules	396
Example Master and Standby Master iptables Rules	397
Example Segment Host iptables Rules	398
 Installation Management Utilities	 398
 Greenplum Environment Variables	 399
Required Environment Variables	399
GPHOME	399
PATH	399
LD_LIBRARY_PATH	399
MASTER_DATA_DIRECTORY	399
Optional Environment Variables	400
PGAPPNAME	400
PGDATABASE	400
PGHOST	400
PGHOSTADDR	400
PGPASSWORD	400

PGPASSFILE	400
PGOPTIONS	400
PGPORT	400
PGUSER	400
PGDATESTYLE	401
PGTZ	401
PGCLIENTENCODING	401
Example Ansible Playbook	401
Ansible Playbook - Greenplum Database Installation for CentOS 7	402
Greenplum Database Security Configuration Guide	404
Securing the Database	404
Accessing a Kerberized Hadoop Cluster	405
Platform Hardening	405
Greenplum Database Ports and Protocols	405
Configuring Client Authentication	408
Allowing Connections to Greenplum Database	409
Editing the pg_hba.conf File	411
Authentication Methods	412
Basic Authentication	412
Basic Authentication Examples	413
GSSAPI Authentication	414
LDAP Authentication	415
SSL Client Authentication	416
SSL Authentication Parameters	416
OpenSSL Configuration	416
Creating a Self-Signed Certificate	417
Configuring postgresql.conf for SSL Authentication	417
Configuring the SSL Client Connection	418
PAM-Based Authentication	419
Radius Authentication	420
RADIUS Authentication Options	420
Limiting Concurrent Connections	420
Encrypting Client/Server Connections	421
Configuring Database Authorization	421
Access Permissions and Roles	421

Managing Object Privileges	422
About Object Access Privileges	423
About Password Encryption in Greenplum Database	423
Using SCRAM-SHA-256 Password Encryption	423
Setting the SCRAM-SHA-256 Password Hash Algorithm System-wide	423
Setting the SCRAM-SHA-256 Password Hash Algorithm for an Individual Session	424
Using SHA-256 Password Encryption	424
Setting the SHA-256 Password Hash Algorithm System-wide	424
Setting the SHA-256 Password Hash Algorithm for an Individual Session	425
Example	425
Restricting Access by Time	426
Example 1 – Create a New Role with Time-based Constraints	427
Example 2 – Alter a Role to Add Time-based Constraints	427
Example 3 – Alter a Role to Add Time-based Constraints	427
Dropping a Time-based Restriction	428
Auditing	428
Viewing the Database Server Log Files	428
Encrypting Data and Database Connections	431
Encrypting gpfdist Connections	432
Encrypting Data at Rest with pgcrypto	433
Creating PGP Keys	434
Encrypting Data in Tables using PGP	436
Key Management	440
Security Best Practices	440
System User (gpadmin)	441
Superusers	441
Login Users	441
Groups	441
Object Privileges	441
Operating System Users and File System	442
Managing Data	445
Defining Database Objects	445
Creating and Managing Databases	446
About Template and Default Databases	446

Creating a Database	446
Cloning a Database	447
Creating a Database with a Different Owner	447
Viewing the List of Databases	447
Altering a Database	447
Dropping a Database	447
 Creating and Managing Tablespaces	 448
Creating a Tablespace	448
Using a Tablespace to Store Database Objects	448
Viewing Existing Tablespaces	449
Dropping Tablespaces	450
Moving the Location of Temporary or Transaction Files	450
 Creating and Managing Schemas	 450
The Default “Public” Schema	450
Creating a Schema	451
Schema Search Paths	451
Setting the Schema Search Path	451
Viewing the Current Schema	451
Dropping a Schema	452
System Schemas	452
 Creating and Managing Tables	 452
Creating a Table	452
Choosing Column Data Types	453
Setting Table and Column Constraints	453
Check Constraints	453
Not-Null Constraints	454
Unique Constraints	454
Primary Keys	454
Foreign Keys	454
Choosing the Table Distribution Policy	454
Declaring Distribution Keys	455
Custom Distribution Key Hash Functions	456
Example Custom Hash Operator Class	456
 Choosing the Table Storage Model	 458
Heap Storage	458
Append-Optimized Storage	458

To create a heap table	459
Choosing Row or Column-Oriented Storage	459
To create a column-oriented table	460
Using Compression (Append-Optimized Tables Only)	460
To create a compressed table	461
Checking the Compression and Distribution of an Append-Optimized Table	461
Support for Run-length Encoding	462
Adding Column-level Compression	462
Default Compression Values	464
Precedence of Compression Settings	464
Optimal Location for Column Compression Settings	464
Storage Directives Examples	464
Example 1	464
Example 2	465
Example 3	465
Example 4	465
Example 5	465
Adding Compression in a TYPE Command	466
Choosing Block Size	467
Altering a Table	467
Altering Table Distribution	467
Changing the Distribution Policy	467
Redistributing Table Data	467
Altering the Table Storage Model	468
Adding a Compressed Column to Table	468
Inheritance of Compression Settings	468
Dropping a Table	469
Partitioning Large Tables	469
About Table Partitioning	469
Table Partitioning in Greenplum Database	470
Deciding on a Table Partitioning Strategy	470
Creating Partitioned Tables	471
Defining Date Range Table Partitions	472
Defining Numeric Range Table Partitions	472
Defining List Table Partitions	473
Defining Multi-level Partitions	473
Partitioning an Existing Table	474
Limitations of Partitioned Tables	474
Loading Partitioned Tables	475

Verifying Your Partition Strategy	476
Troubleshooting Selective Partition Scanning	476
Viewing Your Partition Design	477
Maintaining Partitioned Tables	477
Adding a Partition	478
Renaming a Partition	478
Adding a Default Partition	479
Dropping a Partition	479
Truncating a Partition	479
Exchanging a Partition	480
Splitting a Partition	480
Modifying a Subpartition Template	481
Exchanging a Leaf Child Partition with an External Table	481
Example Exchanging a Partition with an External Table	482
Creating and Using Sequences	483
Creating a Sequence	484
Using a Sequence	484
Examining Sequence Attributes	484
Returning the Next Sequence Counter Value	484
Setting the Sequence Counter Value	484
Altering a Sequence	485
Dropping a Sequence	485
Specifying a Sequence as the Default Value for a Column	485
Sequence Wraparound	486
Using Indexes in Greenplum Database	486
To cluster an index in Greenplum Database	487
Index Types	487
About Bitmap Indexes	487
When to Use Bitmap Indexes	488
When Not to Use Bitmap Indexes	488
Creating an Index	488
Indexes on Expressions	489
Examining Index Usage	489
Managing Indexes	490
To rebuild all indexes on a table	490
Dropping an Index	490
Creating and Managing Views	490

Creating Views	491

Table 5. Advanced Aggregate Functions	
Function	Return Type
Description	MEDIAN (expr) timestamp, timestamptz, interval, float
MEDIAN (expression) Example: SELECT departmzent_id, MEDIAN(salary) FROM employees GROUP BY department_id; Can take a two-dimensional array as input. Treats such arrays as matrices. sum(array[]) smallint[], int[], bigint[], float[]	
sum(array[[1,2],[3,4]]) Example: CREATE TABLE mymatrix (myvalue int[]); INSERT INTO mymatrix VALUES (array[[1,2],[3,4]]); INSERT INTO mymatrix VALUES (array[[0,1],[1,0]]); SELECT sum(myvalue) FROM mymatrix; sum {{1,3}, {4,4}}	678
Performs matrix summation. Can take as input a two-dimensional array that is treated as a matrix. pivot_sum (label[], label, expr) int[], bigint[], float[]	
pivot_sum(array['A1','A2'], attr, value) A pivot aggregation using sum to resolve duplicate entries. unnest (array[]) set of anyelement unnest(array['one', 'row', 'per', 'item']) Transforms a one dimensional array into rows. Returns a set of anyelement, a polymorphic pseudo-type in PostgreSQL.

JSON Processing Functions	689

Table 7. JSON Processing Functions	Function	Return Type	Description	Example
Example Result	json_array_length(json)	jsonb_array_length(jsonb)	int	Returns the number of elements in the outermost JSON array. json_array_length('["1,2,3,{“f1”:1,“f2”:[5,6]},4]') 5
	json_each(json)	jsonb_each(jsonb)	setof key text, value json	setof key text, value jsonb
	select * from json_each('{“a”:“foo”, “b”:“bar”}')		Expands the outermost JSON object into a set of key/value pairs.	key value —+—
	a “foo”	b “bar”	json_each_text(json)	jsonb_each_text(jsonb)
			setof key text, value text	Expands the outermost JSON object into a set of key/value pairs. The returned values will be of type text. select * from json_each_text('{“a”:“foo”, “b”:“bar”}')
	a foo	b bar	json_extract_path(from_json json, VARIADIC path_elems text[])	jsonb_extract_path(from_json jsonb, VARIADIC path_elems text[])
			json	jsonb
			Returns the JSON value pointed to by path_elems (equivalent to #> operator).	json_extract_path('{“f2”:{“f3”:1,“f4”:{“f5”:99,“f6”:{“foo”}}}, “f4”:{“f5”:99,“f6”:{“foo”}}}
			json_extract_path_text(from_json json, VARIADIC path_elems text[])	jsonb_extract_path_text(from_json jsonb, VARIADIC path_elems text[])
			text	Returns the JSON value pointed to by

path_elems as text. Equivalent to #>> operator. json_extract_path_text('{“f2”: {“f3”:1}, “f4”: {“f5”:99, “f6”: “foo”}}, “f4”, “f6”) foo json_object_keys(jsonb_object_keys(jsonb) setof text Returns set of keys in the outermost JSON object. json_object_keys('{“f1”: “abc”, “f2”: {“f3”: “a”, “f4”: “b”}}) json_object_keys f1 f2 json_populate_record(base anyelement, from_json json) jsonb_populate_record(base anyelement, from_json jsonb) anyelement Expands the object in from_json to a row whose columns match the record type defined by base. See Note 1. select * from json_populate_record(null::myrowtype, ‘{“a”:1, “b”:2}’) a b —+— 1 2 json_populate_recordset(base anyelement, from_json json) jsonb_populate_recordset(base anyelement, from_json jsonb) setof anyelement Expands the outermost array of objects in from_json to a set of rows whose columns match the record type defined by base. See Note 1. select * from json_populate_recordset(null::myrowtype, ‘[{“a”:1, “b”:2}, {“a”:3, “b”:4}]’) a b —+— 1 2 3 4 json_array_elements(json) jsonb_array_elements(jsonb) setof json setof jsonb Expands a JSON array to a set of JSON values. select * from json_array_elements('[1,true, [2,false]]') value 1 true [2,false] 689 json_array_elements_text(json) jsonb_array_elements_text(jsonb) setof text Expands a JSON array to a set of text values. select * from json_array_elements_text(['foo', 'bar']) value foo bar json_typeof(json) jsonb_typeof(jsonb) text Returns the type of the outermost JSON value as a text string. Possible types are object, array, string, number, boolean, and null. See Note 2. json_typeof('123.4') number json_to_record(json) jsonb_to_record(jsonb) record Builds an arbitrary record from a JSON object. See Note 1. As with all functions returning record, the caller must explicitly define the structure of the record with an AS clause. select * from json_to_record('{“a”:1, “b”: [1,2,3], “c”: “bar”}') as x(a int, b text, d text) a b d —+—+—+— 1 [1,2,3] json_to_recordset(json) jsonb_to_recordset(jsonb) setof record Builds an arbitrary set of records from a JSON array of objects See Note 1. As with all functions returning record, the caller must explicitly define the structure of the record with an AS clause. select * from json_to_recordset('{[“a”:1, “b”: “foo”], [“a”: “2”, “c”: “bar”]}') as x(a int, b text); a b —+—+— 1 foo 2 Note: The examples for the functions json_populate_record(), json_populate_recordset(), json_to_record() and json_to_recordset() use constants. However, the typical use would be to reference a table in the FROM clause and use one of its json or jsonb columns as an argument to the function. The extracted key values can then be referenced in other parts of the query. For example the value can be referenced in WHERE clauses and target lists. Extracting multiple values in this way can improve performance over extracting them separately with per-key operators. JSON keys are matched to identical column names in the target row type. JSON type coercion for these functions might not result in desired values for some types. JSON fields that do not appear in the target row type will be omitted from the output, and target columns that do not match any JSON field will be NULL. The json_typeof function null return value of null should not be confused with a SQL NULL. While calling json_typeof('null'::json) will return null, calling json_typeof(NULL::json) will return a SQL NULL.

About the Greenplum Database Release Version Number	865
Starting and Stopping Greenplum Database	865
Starting Greenplum Database	865
Restarting Greenplum Database	866

Reloading Configuration File Changes Only	866
Starting the Master in Maintenance Mode	866
Stopping Greenplum Database	867
Stopping Client Processes	867
Managing Greenplum Database Access	868
Configuring Client Authentication	868
Allowing Connections to Greenplum Database	869
Editing the pg_hba.conf File	870
Editing pg_hba.conf	871
Limiting Concurrent Connections	871
To change the number of allowed connections	872
Encrypting Client/Server Connections	872
Creating a Self-signed Certificate without a Passphrase for Testing Only	873
Using LDAP Authentication with TLS/SSL	874
Enabling LDAP Authentication with STARTTLS and TLS	874
Enabling LDAP Authentication with a Secure Connection and TLS/SSL	875
Configuring Authentication with a System-wide OpenLDAP System	875
Notes	876
Examples	876
Using Kerberos Authentication	876
Prerequisites	877
Procedure	877
Creating Greenplum Database Principals in the KDC Database	877
Installing the Kerberos Client on the Master Host	878
Configuring Greenplum Database to use Kerberos Authentication	878
Mapping Kerberos Principals to Greenplum Database Roles	880
Configuring JDBC Kerberos Authentication for Greenplum Database	881
Installing and Configuring a Kerberos KDC Server	881
Configuring Kerberos for Linux Clients	883
Requirements	883
Prerequisites	883
Required Software on the Client Machine	883
Setting Up Client System with Kerberos Authentication	884
Running psql	884
To connect to Greenplum Database with psql	884

Running a Java Application	884
Configuring Kerberos For Windows Clients	885
Installing and Configuring Kerberos on a Windows System	885
Running the psql Utility	887
Creating a Kerberos Keytab File	887
Example gpload YAML File	888
Issues and Possible Solutions	888
Managing Roles and Privileges	889
Security Best Practices for Roles and Privileges	889
Creating New Roles (Users)	890
Altering Role Attributes	890
Role Membership	891
Managing Object Privileges	892
Simulating Row Level Access Control	894
Encrypting Data	894
Protecting Passwords in Greenplum Database	894
About MD5 Password Hashing	895
About SCRAM-SHA-256 Password Hashing	895
About SHA-256 Password Hashing	896
Time-based Authentication	896
Accessing the Database	896
Establishing a Database Session	896
Supported Client Applications	897
Greenplum Database Client Applications	897
Connecting with psql	898
Using the PgBouncer Connection Pooler	899
Overview	899
Migrating PgBouncer	900
Configuring PgBouncer	900
PgBouncer Authentication File Format	901
Configuring HBA-based Authentication for PgBouncer	902
Starting PgBouncer	902
Managing PgBouncer	903
Mapping PgBouncer Clients to Greenplum Database Server Connections	904

Database Application Interfaces	904
Troubleshooting Connection Problems	905
Configuring the Greenplum Database System	905
About Greenplum Database Master and Local Parameters	906
Setting Configuration Parameters	906
Setting a Local Configuration Parameter	906
Setting a Master Configuration Parameter	906
Setting Parameters at the System Level	907
Setting Parameters at the Database Level	907
Setting Parameters at the Role Level	907
Setting Parameters in a Session	908
Viewing Server Configuration Parameter Settings	908
Configuration Parameter Categories	908
Enabling Compression	908
Configuring Proxies for the Greenplum Interconnect	909
Example	909
Setting the Interconnect Proxy Addresses	910
Testing the Interconnect Proxies	911
Setting Interconnect Proxies for the System	912
Enabling High Availability and Data Consistency Features	912
Overview of Greenplum Database High Availability	912
Hardware level RAID	913
Data storage checksums	913
Segment Mirroring	914
Master Mirroring	914
Dual Clusters	914
Backup and Restore	915

Overview of Segment Mirroring	915
About Segment Mirroring Configurations	916
Overview of Master Mirroring	917
Enabling Mirroring in Greenplum Database	918
Enabling Segment Mirroring	919
To add segment mirrors to an existing system (same hosts as primaries)	919
To add segment mirrors to an existing system (different hosts from primaries)	919
Enabling Master Mirroring	920
To add a standby master to an existing system	920
To check the status of the master mirroring process (optional)	920
How Greenplum Database Detects a Failed Segment	920
How a Segment Failure is Detected and Managed	921
Configuring FTS Behavior	921
Checking for Failed Segments	922
Check for failed segments using gpstate	922
Check for failed segments using the gp_segment_configuration table	922
Check for failed segments by examining log files	922
To check the log files	923
Understanding Segment Recovery	923
Segment Recovery Basics	923
Segment Recovery: Flow of Events	924
Rebalancing After Recovery	924
Simple Failover and Recovery Example	924
Incremental versus Full Recovery	925
Recovering from Segment Failures	925
Prerequisites	926
Recovery Scenarios	926
Recover In-Place to Current Host	926
Incremental Recovery	926
Full Recovery	927
Recover to A Different Host within the Cluster	927
Recover to A New Host, Outside of the Cluster	928

Requirements for New Host	928
Steps to Recover to a New Host	928
Post-Recovery Tasks	929
Recovering a Failed Master	929
To activate the standby master	929
Restoring Master Mirroring After a Recovery	930
To restore the master mirroring after a recovery	930
To restore the master and standby instances on original hosts (optional)	930
To check the status of the master mirroring process (optional)	931
Backing Up and Restoring Databases	931
Parallel Backup with gpbackup and gprestore	932
Non-Parallel Backup with pg_dump	932
Expanding a Greenplum System	932
System Expansion Overview	933
Planning Greenplum System Expansion	936
System Expansion Checklist	936
Planning New Hardware Platforms	937
Planning New Segment Initialization	938
Planning Mirror Segments	938
Increasing Segments Per Host	939
About the Expansion Schema	939
Planning Table Redistribution	939
Managing Redistribution in Large-Scale Greenplum Systems	940
Table Redistribution Methods	940
Systems with Abundant Free Disk Space	940
Systems with Limited Free Disk Space	940
Redistributing Append-Optimized and Compressed Tables	940
Redistributing Partitioned Tables	941
Redistributing Indexed Tables	941
Preparing and Adding Hosts	941
Adding New Hosts to the Trusted Host Environment	941
To exchange SSH keys as root	942
To create the gpadmin user	942
To exchange SSH keys as the gpadmin user	943

Validating Disk I/O and Memory Bandwidth	943
To run gpcheckperf	943
Integrating New Hardware into the System	943
Initializing New Segments	943
Creating an Input File for System Expansion	944
Creating an input file in Interactive Mode	944
To create an input file in interactive mode	944
Expansion Input File Format	945
Running gpexpand to Initialize New Segments	946
To run gpexpand with an input file	946
Monitoring the Cluster Expansion State	947
Rolling Back a Failed Expansion Setup	947
Redistributing Tables	947
Ranking Tables for Redistribution	947
Redistributing Tables Using gpexpand	948
To redistribute tables with gpexpand	948
Monitoring Table Redistribution	948
Viewing Expansion Status	948
Viewing Table Status	949
Post Expansion Tasks	949
Removing the Expansion Schema	949
Setting Up PXF on the New Host	949
PXF 5	949
PXF 6	950
Migrating Data with gpcopy	950
Monitoring a Greenplum System	950
Monitoring Database Activity and Performance	950

Table 8. JSON Processing Functions

Function	Return Type	Description	Example
<code>json_array_length(json)</code>	<code>int</code>	Returns the number of elements in the outermost JSON array.	<code>json_array_length('["1,2,3,{\"f1\":1,\"f2\":[5,6]},4]')</code> 5
<code>jsonb_array_length(jsonb)</code>	<code>int</code>	Returns the number of elements in the outermost JSON array.	<code>jsonb_array_length('["1,2,3,{\"f1\":1,\"f2\":[5,6]},4]')</code> 5
<code>json_each(json)</code>	<code>setof key text, value jsonb</code>	Expands the outermost JSON object into a set of key/value pairs.	<code>select * from json_each('{\"a\":\"foo\", \"b\":\"bar\"}')</code>
<code>jsonb_each(jsonb)</code>	<code>setof key text, value jsonb</code>	Expands the outermost JSON object into a set of key/value pairs.	<code>select * from jsonb_each('{"a":"foo", \"b\":\"bar\"}')</code>
<code>json_each_text(json)</code>	<code>setof key text, value text</code>	Expands the outermost JSON object into a set of key/value pairs. The returned values will be of type text.	<code>select * from json_each_text('{\"a\":\"foo\", \"b\":\"bar\"}')</code>
<code>jsonb_each_text(jsonb)</code>	<code>setof key text, value text</code>	Expands the outermost JSON object into a set of key/value pairs. The returned values will be of type text.	<code>select * from jsonb_each_text('{"a":"foo", \"b\":\"bar\"}')</code>
<code>json_extract_path(from_json json, VARIADIC path_elems text[])</code>	<code>jsonb</code>	Returns the JSON value pointed to by path_elems (equivalent to #> operator).	<code>json_extract_path(from_json('{"f2\":{\"f3\":1,\"f4\":{\"f5\":99,\"f6\":\"foo\"}}'}, 'f4') '{"f5\":99,\"f6\":\"foo\"}')</code>
<code>jsonb_extract_path(from_jsonb jsonb, VARIADIC path_elems text[])</code>	<code>jsonb</code>	Returns the JSON value pointed to by path_elems (equivalent to #> operator).	<code>jsonb_extract_path(from_jsonb('{"f2\":{\"f3\":1,\"f4\":{\"f5\":99,\"f6\":\"foo\"}}'}, 'f4') '{"f5\":99,\"f6\":\"foo\"}')</code>
<code>json_extract_path_text(from_json json, VARIADIC path_elems text[])</code>	<code>text</code>	Returns the JSON value pointed to by path_elems as text.	<code>json_extract_path_text(from_json('{"f2\":{\"f3\":1,\"f4\":{\"f5\":99,\"f6\":\"foo\"}}'}, 'f4') 'f6')</code>
<code>jsonb_extract_path_text(from_jsonb jsonb, VARIADIC path_elems text[])</code>	<code>text</code>	Returns the JSON value pointed to by path_elems as text.	<code>jsonb_extract_path_text(from_jsonb('{"f2\":{\"f3\":1,\"f4\":{\"f5\":99,\"f6\":\"foo\"}}'}, 'f4') 'f6')</code>
<code>json_object_keys(json)</code>	<code>setof text</code>	Returns set of keys in the outermost JSON object.	<code>json_object_keys('{"f2\":{\"f3\":1,\"f4\":{\"f5\":99,\"f6\":\"foo\"}}')</code>
<code>jsonb_object_keys(jsonb)</code>	<code>setof text</code>	Returns set of keys in the outermost JSON object.	<code>jsonb_object_keys('{"f2\":{\"f3\":1,\"f4\":{\"f5\":99,\"f6\":\"foo\"}}')</code>

object. json_object_keys({'f1':"abc", "f2":{"f3":"a", "f4":"b"}}) json_object_keys f1 f2 json_populate_record(base anyelement, from_json json)	
jsonb_populate_record(base anyelement, from_json jsonb) anyelement	
Expands the object in from_json to a row whose columns match the record type defined by base. See Note 1. select * from	
json_populate_record(null::myrowtype, {'a':1, 'b':2}) a b --+-- 1 2	
json_populate_recordset(base anyelement, from_json json)	
jsonb_populate_recordset(base anyelement, from_json jsonb) setof anyelement	
Expands the outermost array of objects in from_json to a set of rows whose columns match the record type defined by base. See Note 1. select * from	
json_populate_recordset(null::myrowtype, [{'a':1, 'b':2}, {'a':3, 'b':4}]) a b --+-- 1 2 3 4 json_array_elements(json) jsonb_array_elements(jsonb) setof json	
setof jsonb Expands a JSON array to a set of JSON values. select * from	1501
json_array_elements('[1,true, [2,false]]') value 1 true [2,false]	
json_array_elements_text(json) jsonb_array_elements_text(jsonb) setof text	
Expands a JSON array to a set of text values. select * from	
json_array_elements_text('["foo", "bar"]') value foo bar json_typeof(json)	
jsonb_typeof(jsonb) text Returns the type of the outermost JSON value as a text string. Possible types are object, array, string, number, boolean, and null. See	
Note 2 json_typeof('-123.4') number json_to_record(json)	
jsonb_to_record(jsonb) record Builds an arbitrary record from a JSON object. See Note 1. As with all functions returning record, the caller must explicitly	
define the structure of the record with an AS clause. select * from	
json_to_record({'a':1, 'b':[1,2,3], 'c':"bar"}) as x(a int, b text, d text) a b d --+-- 1 [1,2,3] json_to_recordset(json) jsonb_to_recordset(jsonb) setof	
record Builds an arbitrary set of records from a JSON array of objects See Note 1. As with all functions returning record, the caller must explicitly define the	
structure of the record with an AS clause. select * from	
json_to_recordset(['{"a":1, "b":"foo"}, {"a":2, "c":"bar"}']) as x(a int, b text); a b --+-- 1 foo 2 Note: The examples for the functions json_populate_record(),	
json_populate_recordset(), json_to_record() and json_to_recordset() use	
constants. However, the typical use would be to reference a table in the FROM	
clause and use one of its json or jsonb columns as an argument to the function.	
The extracted key values can then be referenced in other parts of the query. For	
example the value can be referenced in WHERE clauses and target lists.	
Extracting multiple values in this way can improve performance over extracting	
them separately with per-key operators. JSON keys are matched to identical	
column names in the target row type. JSON type coercion for these functions	
might not result in desired values for some types. JSON fields that do not appear	
in the target row type will be omitted from the output, and target columns that	
do not match any JSON field will be NULL. The json_typeof function null return	
value of null should not be confused with a SQL NULL. While calling	
json_typeof('null'::json) will return null, calling json_typeof(NULL::json) will	
return a SQL NULL.	
f1 f2	1502
1 true [2,false]	1503
Window Functions	1505
Advanced Aggregate Functions	1506

Table 10. Advanced Aggregate Functions Function Return Type Full Syntax	
Description MEDIAN (expr) timestamp, timestamptz, interval, float MEDIAN	
(expression) Example: SELECT department_id, MEDIAN(salary) FROM	
employees GROUP BY department_id; Can take a two-dimensional array as	
input. Treats such arrays as matrices. PERCENTILE_CONT (expr) WITHIN	
GROUP (ORDER BY expr [DESC/ASC]) timestamp, timestamptz, interval, float	
PERCENTILE_CONT(percentage) WITHIN GROUP (ORDER BY expression)	
Example: SELECT department_id, PERCENTILE_CONT (0.5) WITHIN GROUP	
(ORDER BY salary DESC) "Median_cont"; FROM employees GROUP BY	
department_id; Performs an inverse distribution function that assumes a	
continuous distribution model. It takes a percentile value and a sort specification	
and returns the same datatype as the numeric datatype of the argument. This	
returned value is a computed result after performing linear interpolation. Null are	
ignored in this calculation. PERCENTILE_DISC (expr) WITHIN GROUP (ORDER	
BY expr [DESC/ASC]) timestamp, timestamptz, interval, float	
PERCENTILE_DISC(percentage) WITHIN GROUP (ORDER BY expression)	1506
Example: SELECT department_id, PERCENTILE_DISC (0.5) WITHIN GROUP	
(ORDER BY salary DESC) "Median_desc"; FROM employees GROUP BY	
department_id; Performs an inverse distribution function that assumes a discrete	
distribution model. It takes a percentile value and a sort specification. This	
returned value is an element from the set. Null are ignored in this calculation.	
sum(array[]) smallint[]int[], bigint[], float[] sum(array[[1,2],[3,4]]) Example:	

CREATE TABLE mymatrix (myvalue int[]); INSERT INTO mymatrix VALUES (array[[1,2],[3,4]]); INSERT INTO mymatrix VALUES (array[[0,1],[1,0]]); SELECT sum(myvalue) FROM mymatrix; sum {{1,3},{4,4}} Performs matrix summation. Can take as input a two-dimensional array that is treated as a matrix. pivot_sum (label[], label, expr) int[], bigint[], float[] pivot_sum(array['A1','A2'], attr, value) A pivot aggregation using sum to resolve duplicate entries. unnest (array[]) set of anyelement unnest(array['one', 'row', 'per', 'item']) Transforms a one dimensional array into rows. Returns a set of anyelement, a polymorphic pseudotype in PostgreSQL.

VMware Tanzu™ Greenplum® 6.21 Documentation

This documentation describes how to install, configure, and use VMware Tanzu Greenplum, and provides links to related Tanzu products that work with Tanzu Greenplum.

Welcome to Tanzu Greenplum

Tanzu Greenplum is a massively parallel processing (MPP) database server that supports next generation data warehousing and large-scale analytics processing. By automatically partitioning data and running parallel queries, it allows a cluster of servers to operate as a single database supercomputer performing tens or hundreds times faster than a traditional database. It supports SQL, MapReduce parallel processing, and data volumes ranging from hundreds of gigabytes, to hundreds of terabytes.

Differences Compared to Open Source Greenplum Database

VMware Tanzu Greenplum 6 includes all of the functionality in the open source [Greenplum Database project](#) and adds:

- Product packaging and installation script
- Support for QuickLZ compression. QuickLZ compression is not provided in the open source version of Greenplum Database due to licensing restrictions.
- Support for data connectors:
 - ◊ Greenplum-NiFi Connector
 - ◊ Greenplum-Spark Connector
 - ◊ Greenplum-Informatica Connector
 - ◊ Greenplum-Kafka Integration
 - ◊ Greenplum Streaming Server
- Support for Greenplum-sourced or enhanced contrib modules:
 - ◊ advanced_password_check
 - ◊ diskquota
 - ◊ gp_array_agg
 - ◊ gp_legacy_string_agg
 - ◊ gp_parallel_retrieve_cursor
 - ◊ gp_percentile_agg
 - ◊ gp_sparse_vector
 - ◊ greenplum_fdw
 - ◊ orafce

- Data Direct ODBC/JDBC Drivers
- Greenplum PostGIS Extension
- [gpcopy](#) utility for copying or migrating objects between Greenplum systems
- Support for managing Greenplum Database using VMware Tanzu Greenplum Command Center
- Support for full text search and text analysis using VMware Tanzu GPText
- Greenplum backup plugin for DD Boost
- Backup/restore storage plugin API

VMware Tanzu Greenplum 6.x Release Notes

This document contains release information about VMware Tanzu Greenplum Database 6.x releases. For previous versions of the release notes for Greenplum Database, go to [VMware Tanzu Greenplum Database Documentation](#). For information about Greenplum Database end of life, see [VMware Tanzu Greenplum Database end of life policy](#).

VMware Tanzu Greenplum 6 software is available for download from the VMware Tanzu Greenplum page on [VMware Tanzu Network](#).

VMware Tanzu Greenplum 6 is based on the open source [Greenplum Database project](#) code.

Upgrading Greenplum

See [Upgrading to Greenplum 6](#) to upgrade your existing Greenplum software.

Release 6.21

Release 6.21.2

Server

32358

Index creation is now allowed on partitioned tables containing external partitions. Creating a non-unique index on a partitioned table will ignore external partitions, but fail if any of the indexes is a constraint index.

32293

Updates the index `VACUUM` strategy for Append-Optimized tables to correctly determine when an index entry can be removed. An index entry is now removed only after ensuring that the entry points to a droppable segment, and is therefore already invisible.

31941

LDAP bind credentials that were leaked to the log after failed login attempts are no longer a security risk.

13860

The EPQ routine for AO/AOCS relations and DML node has been disallowed.

13699

Duplicate `gp_fastsequence` values (`ctid`) no longer appear in AO tables.

Query Processing

32348

Non-optimal plans that caused queries to hang were fixed by setting the number of rebinds (rescans) correctly when statistics are copied.

Release 6.21.1

Features

Greenplum Database 6.21.1 includes a new metrics collector extension that is compatible with Greenplum Command Center 6.8.

Resolved Issues

Server

13881

Resolves an issue in transaction processing where transactions were erroneously rolled back because gang processes were being deleted.

12690

Resolves an issue where, when a memory limit was hit, a query was throwing errors without calling the correct cleanup function.

13874

Resolves an error handling issue that caused PANIC errors during query execution.

32237

Fixes for PostgreSQL CVE-2022-1552 have been backported to secure `Autovacuum`, `REINDEX`, and other commands that activate relevant protections too late or not at all.

32211

A `pg_upgrade` check for parent partitions with seg entries was added to prevent upgrade failure, and `logicalEOF` was added to `errdetail` in `OpenAOSegmentFile`.

32210

Primary now writes a special WAL at the place where the mirror is supposed to continue streaming the rest of the broken WAL.

31937

`pg_resetxlog` infrastructure is used to set the oldest xid instead of freezing the catalog, preventing CLOG truncation during a segment upgrade.

13706

Resolves an error, `FATAL: Unexpected internal error (list.c:395)`, that could occur when creating a plan for a correlated subquery against a partitioned table. The problem occurred in some queries when an `InitPlan` could not be created, and the planner generated copies of nested subplans in the wrong order. The fix ensures that first level subplans and nested subplans are generated correctly in this situation.

13696

Improves planning performance for DML queries by avoiding unnecessary planning for join tree relations, especially with complex subqueries.

13694

A fix for the logic in `pg_lock_status()` that keeps it from missing some rows and counting others twice has been backported.

13678

Resolves a problem where unnecessary checks were performed when `runaway_detector_activation_percent` was disabled (set to 100).

13675

An error is thrown when `COPY FROM/INSERT` will result in inserted data being invisible to user queries issued from master.

13669

Resolved an assertion failure, `"FATAL" error "Unexpected internal error (vmem_tracker.c:436)", "Process 399817 will wait for gp_debug_linger=120 seconds before termination`, that could occur during initialization when resource groups were enabled.

11662

Appendoptimized materialized views now have invalid relfrozenxid.

6716

Resolves a problem where `CREATE EXTENSION WITH SCHEMA` failed because Tanzu Greenplum did not set up the `search_path` on both the Query Dispatcher and the Query Executor before executing the extension script.

Query Processing

32302

Prevents optimizer from crashing during query optimization due to lack of statistics.

32273

Adds a GUC that keeps queries on distributed replicated tables from hanging when using ORCA by controlling fallback for replicated tables.

32238

ORCA now requires an index type to properly cost bitmap scans before performing full table scans.

32233

Eliminates query performance difference between GPORCA and Postgres.

32125

The master logger process that was creating high load on master, causing segments to go down, was fixed by processing the string with two kinds of modification.

32061

ORCA now prevents creation of spill files by pushing cast operations below the join when safe.

13746

Fallback to Postgres optimizer when a target list in CTE producer is empty.

13683

Fixes incorrect addrefs that caused memory leaks.

Data Flow

32199

Resolves a problem in the fixed width formatting code that could cause the error `The line delimiter specified in the Formatter arguments: < 3> is not located in the data file` even though the text was formatted correctly. The problem occurred because the code did not handle the situation where the end of a buffer coincided with the end of the data (and therefore does not include an expected newline character).

32151

Resolves a `gpfdist` crash that could occur during session clean up if a session timed due to a disk full condition. Instead of crashing, `gpfdist` now logs an error for this condition.

Tanzu Greenplum on vSphere

1102

Resolved an issue where users were seeing WARNINGS in gpinitssystem logs when there was a mismatch between what the `hostname` utility reported and the actual segment host name.

1042

Resolved an issue where “command not found” warnings were seen during deployment of Greenplum.

1034

Resolved an issue where deployment would fail if the segment count was equal to 1 or odd numbers for Mirrored Greenplum deployments.

844

Resolved an issue where a manual shutdown of the Guest OS would show a 'failed' state for the Greenplum Virtual Service.

Release 6.21.0

VMware Tanzu Greenplum 6.21.0 is a minor release that includes feature changes and resolves several issues.

Features

Greenplum Database 6.21.0 includes these new and changed features:

- The `LOCK TABLE` SQL command now includes a `MASTER ONLY` option; when enabled, Greenplum Database locks tables on the master only, rather than on the master and all of the segments. This option is particularly useful for metadata-only operations.
- The `gp_parallel_retrieve_cursor` contrib module is no longer Beta, it is promoted to a supported feature.
- The `greenplum_fdw` contrib module is no longer Beta, it is promoted to a supported feature.
- Greenplum Database now supports the `SET TRANSACTION SNAPSHOT` command.
- Greenplum Database 6.21.0 adds support for both the `SCRAM-SHA-256` password hashing algorithm and the `scram-sha-256` client authentication method. Refer to [Protecting Passwords in Greenplum Database](#) for more information.
- Greenplum Database now includes a configuration parameter — `gp_interconnect_address_type` — to specify the type of address binding strategy Greenplum Database uses for communication between segment host sockets. This allows users, if their configuration permits, to specify that Greenplum use a unicast address — rather than a wildcard address — for interconnect sockets. This reduces port usage on segment hosts and prevents interconnect traffic from being routed through unintended (and possibly slower) network interfaces.
- Log messages that are generated for connection checks between the Query Executor and Query Dispatcher now include the error number that was generated by the receiver.
- Greenplum Database introduces a new server configuration parameter, `gp_log_endpoints`, that you can use to enable logging of parallel retrieve cursor endpoint details.
- Greenplum Database introduces the new resource group server configuration parameter `gp_resource_group_enable_recalculate_query_mem`. The default value of this parameter is `false`; Greenplum Database calculates the maximum per-query memory based on the memory configuration and the number of primary segments on the master host. If the memory configuration on your Greenplum Database master and segment hosts differ and you prefer that the maximum per-transaction memory calculation be based on the segment host configuration, set the parameter to `true`.
- Greenplum Database 6.21.0 introduces a new module, `gp_percentile_agg`, that you can use to improve GPORCA plan generation performance for queries that include ordered-set aggregate functions such as `percentile_cont()`, `percentile_disc()`, and `median()`.
- Greenplum Database 6.21.0 includes version 2.0 of the `diskquota` module. This version introduces support for schema and role tablespace disk quotas as well as per-segment tablespace quotas. `diskquota` can also now enforce quota hard limits; if a query exceeds a disk quota during execution, `diskquota` terminates the query. Refer to the [module documentation](#) for more information and for upgrade instructions.
- The VMware Tanzu Greenplum Connector for Apache NiFi version 1.0.1 is available, which

includes a change. See the [Connector 1.0 Release Notes](#) for more information.

- The Greenplum Magic Tool (gpmt) family of tools now includes the `gp_storage_rca_collector` tool, which collects storage-related artifacts. See the [storage_rca_collector](#) topic for details.
- The gpmt `gp_log_collector` tool now collects PXF logs and `gpupgrade` logs. In addition, this tool has been enhanced to collect system initialization timestamps, `/var/log/dmesg` content, and output from `top` and `sar` commands.
- The PgBouncer distributed with Greenplum Database has been updated to version 1.16.1.
- Greenplum Streaming Server (GPSS) version 1.7.2 is included, which includes changes and bug fixes. Refer to the [Greenplum Streaming Server Documentation](#) for more information about this release and for upgrade instructions.
- For customers deploying Greenplum on vSphere, the following new features and changes have been introduced in this release:
 - ◊ The Greenplum Virtual Machine now provides a service running on the master VM that monitors the postmaster process and restarts the process if it fails. This improves the reliability and availability of the postmaster process. It is enabled by default.
 - ◊ The Greenplum Virtual Machine now provides a service running on each segment VM that monitors the segment process and restarts the process if it fails. This improves the reliability and availability of the segment process. It is enabled by default.
 - ◊ Greenplum on vSphere is now supported on vSphere 6.7 and higher.
 - ◊ Greenplum on vSphere now supports mirrorless Greenplum deployments.
 - ◊ The VxRail reference architecture has been updated to recommend 100GbE networking instead of 25GbE. Increasing the available network throughput significantly improves storage system performance and provides a more balanced system across resources.
- The PostGIS spatial database extension version `2.5.4+pivotal.7.build.1` is included, which contains updated `GEOS` and `EXPAT` dependencies. Because the `GEOS` geometry library is updated to version 3.10.2; PostGIS now includes support for the `ST_Subdivide`, `ST_ClipByBox2D`, `ST_VoronoiLines`, and `ST_VoronoiPolygons` functions.

Resolved Issues

Server

32247, [13532](#)

Prevents panic in Planner by not bringing a SegmentGeneral path that refs outer Params to SingleQE.

32229

Resolves a problem with TCP/UDP connections communicating across different subnets by adding a new GUC, `gp_interconnect_address_type`, which allows users to switch from the wildcard default to a unicast IP address to support motion communication. (Resolved by [PR-13344](#).)

32220

Moves incrementing `txns_using_rel` to follow ERROR reports to fix leaks in AppendOnlyHash entries. (Resolved by [PR-13570](#).)

32213, [13549](#)

Resolves wrong date behavior by rejecting ambiguous 5 digit date strings in non-standard

formats.

32173

Resolves slow intermittent query response by using hostname instead of an IP address to compute the host segments.

32067, 32141

Resolves an issue where OOM errors have occurred during queries by adding a new GUC, `gp_resource_group_enable_recalculate_query_mem`.

32066

Prevents `gp_tablespace_segment_location()` from executing on `entrydb` QE. (Resolved by [PR-13287](#).)

31957

Enhances OLAP performance by ensuring that both sides of the NOT-IN sublink `testexpr` are non-nullable. (Resolved by [PR-13420](#).)

13446

Fixes incorrect scan position during bitmap index words scans. (Resolved by [PR-13522](#).)

32205

Falls back to Planner from ORCA if a target list is empty.

13467

Resolves a cache lookup failure for attribute 0 of relation xxx from child inheritance/partition table to parent.

182378648

Enables recursion for utility mode connections to propagate ALTER OWNER commands to child tables during `pg_restore`, which must run in utility mode.

n/a

Reverts a problematic commit that enclosed a check for interrupts (CFI) in a try-catch statement. (Resolved by [PR-13568](#).)

n/a

Adds additional GUC defaults for ICW mirrorless tests. (Resolved by [PR-13563](#).)

n/a

Provides checks on fatal exit status and outputs file location for users of `pg_upgrade`. (Resolved by [PR-13475](#).)

n/a

Fixes double freeing during a debug build that caused Assertion failure. (Resolved by [PR-13472](#).)

n/a

Adds distributed snapshot support to `pg_export_snapshot`. (Resolved by [PR-13470](#).)

n/a

Allows LOCK TABLE to be conducted on MASTER ONLY to improve performance. (Resolved by [PR-13463](#).)

n/a

Preserves append-optimized options for tables without indexes when creating internal tables from query results. (Resolved by [PR-13461](#).)

n/a

Backports part of recovery TAP tests that can be supported on Greenplum 6 and related TAP framework changes. (Resolved by [PR-13375](#).)

n/a

Restores visibility of some GUCs that were hidden from users' `pg_settings`. (Resolved by [PR-13353](#).)

n/a

Resolves suboptimal plans by enabling a GatherMerge alternative for non-EstMaster singleton distribution. (Resolved by [PR-13294](#).)

n/a

Improves the authentication framework by backporting scram-sha256 to Greenplum 6.
(Resolved by [PR-13286](#).)

n/a

Resolves an issue where debug trace output was incorrectly reported at DEBUG3 level by adding an external boolean server configuration parameter, `gp_log_endpoints`, to print endpoints information to server log. (Resolved by [PR-13254](#).)

n/a

Upgrades `pgbouncer` to support scram-sha256 to provide a strong password hash for Greenplum. (Resolved by [PR-13146](#).)

n/a

Fixes queries with `mode()` aggregate crashes when `QueryFinishPending` is set to true. (Resolved by [PR-13096](#).)

Query Processing

31988

Resolves performance differences between ORCA and Planner by generating an alternative that pushes aggregates below Materialize.

31995

Adds support for ordered aggregates by preventing ORCA from falling back to Planner, which resulted in suboptimal performance for Madlib functions.

13242

Enables a check to redistribute tuples before updating, preventing wrong results for ORCA plans that use split updates.

181905507

Resolves an issue where Assertion failed in a debug build by accounting for the memory for the object.

32205

Resolves cases where improper handling of empty target lists results in a crash.

181707276

Resolves a DQA issue that did not include the aggregation stage in hash calculation.

n/a

Resolves an issue where ORCA pushed UDFs down to the segments, but made suboptimal cost comparisons between plans. (Resolved by [PR-13384](#).)

n/a

Correctly represents Table Value Function in ORCA as a constant value, preventing it from returning incorrect results. (Resolved by [PR-13535](#).)

n/a

Resolves an issue with incorrect results from replicated tables. (Resolved by [PR-13058](#).)

n/a

Resolves a performance issue with ORCA producing suboptimal plans. (Resolved by [PR-13327](#).)

Cluster Management

180823003

Resolves an issue where `gpstate` was incorrectly reporting mirror segments as not initialized when they had been initialized using `pg_ctl`. This was due to the mirror segment port number listed in `postgresql.conf` being out of sync with the number listed in the `gp_segment_configuration` table.

Data Flow

32209

Creates `gpload6` to update the data loading utility for Greenplum 6.x. (Resolved by [PR-13465](#).)

32179, 31372

Fixes a reported `gpfdist` error, `unknown meta type 108`. (Resolved by [PR-13457](#), [PR-13458](#).)

32169, [13448](#)

Fixes a crash that occurs when an error is thrown during `cdbdisp_destroyDispatcherState`.

Extensions

n/a

Fixes a memory leak in `SetupUDPIFCInterconnect_Internal()` with read-only transactions.
(Resolved by [PR-10314](#).)

Release 6.20

Release 6.20.5

Release Date: 2022-06-02

VMware Tanzu Greenplum 6.20.5 is a maintenance release that resolves two issues.

Resolved Issues

Query Optimizer

32142

Resolves an issue where a query on a partitioned table took longer to plan and execute with GPORCA than with the Postgres Planner. GPORCA planning time performance is improved by disabling partition constraint calculations for such queries.

Server

32119

Resolves an issue where a user-defined function was unable to access a replicated temporary table because the identifier of the session's temporary namespace was not dispatched to all gangs.

Release 6.20.4

Release Date: 2022-05-18

VMware Tanzu Greenplum 6.20.4 is a maintenance release that resolves a single issue.

Resolved Issues

Server

32229, 32204

The fix for 32140, added in Greenplum 6.20.3, introduced a regression. Interconnect failures could occur if multiple subnets were configured on the same host, but routing between the subnets was not enabled. This problem was resolved in version 6.20.4 by reverting the original fix.

Release 6.20.3

Release Date: 2022-04-08

VMware Tanzu Greenplum 6.20.3 is a maintenance release that resolves several issues.

Resolved Issues

Server

32133

Resolves an issue where an attempted failover to mirror segments resulted in a `PANIC` error on all primary segments because FTS was failing the primary over prematurely.

32140

Resolves an issue where queries were failing with the message “bind: Address already in use”. This was due to Greenplum Database running out of UDP ephemeral ports when creating listener and sender sockets for UDP interconnect, due to high concurrency (exacerbated by primary segment density – the number of acting primaries on a given segment host).

32111, [13245](#)

Greenplum Database crashed during the redistribution phase of cluster expansion when processing an AO table that had an index because Greenplum ignored the storage options on the original table. Greenplum now reconstructs the storage options of the original table during this operation rather than use the current default storage options.

[13920](#)

Removes platform-specific limitation from socket message type recognition logic by using `int`.

[13212](#)

Resolves an issue where the Postgres Planner returned the error `unexpected join qual in JOIN_LASJ_NOTIN join` while planning a query that included a multi-column `NOT IN` with a `NULL` constant value.

[13202](#)

Updates the Postgres Planner to allow direct dispatch of `gp_segment_id` and include it as a distributed column constraint.

Cluster Management

32160

Resolves an issue where rebalancing segments with `gprecoverseg -r` was failing with timeout errors. This has been resolved by increasing the timeout value for promoting mirror segments to primary.

Query Optimizer

32130

Resolves an issue where an `ANALYZE` operation on a table that included an `xml`-type column took a long time to complete because there is no equality operator for the type.

[13172](#)

Resolves an issue where GPORCA might crash when a strict function with zero arguments was used as a filter for NULL rejection.

181646913

Resolves a C++ compiler and `nullptr` usage mismatch by using `NULL` instead.

Data Flow

32076

Resolves an issue where Greenplum Database ignored the `ON MASTER` clause provided in a writable external table definition that specified the `s3` protocol. Greenplum now fully supports

`ON MASTER` for `s3` writable external tables.

31730

Improves `gpload` by choosing a better default distribution key for the staging table. `gpload` now uses the distribution key(s) of the target table as the distribution key(s) for the staging table. If the target table was created `DISTRIBUTED RANDOMLY`, `gpload` uses the `MATCH_COLUMNS` as the staging table's distribution key(s).

181229489

Resolves an issue where `gpload` did not recognize special characters like capital letters in a staging table name when the name was enclosed in double quotes.

13399

Adds SSL connection regression test cases.

Release 6.20.1

Release Date: 2022-03-25

VMware Tanzu Greenplum 6.20.1 is a maintenance release that resolves several issues.

Resolved Issues

VMware Tanzu Greenplum 6.20.1 resolves these issues:

Server

32136, [13292](#)

Resolves an issue where queries using recursive CTE with a window function or an ordered set aggregate function (special aggs) would cause a PANIC.

32123, [13265](#)

Resolves an issue where the result of an `UPDATE` query that included a `NOT IN` operator identified that one row was updated, when in fact the row was not updated.

32086, [13195](#)

Resolves an issue where `minirepro` returned the error `cache lookup failed for relation N` due to Greenplum's special handling of a type conversion from `unknown` to `text`.

32050

Resolves issues with error check with `pg_upgrade` check mode. Upgrade checks are now allowed to progress even if there are failures, and can also check the target cluster.

[13264](#)

Removes a memory leak in the dtx recovery process.

[12390](#)

Removes memory leaks.

181428106

Adds a check to error out when a `DECLARE ... PARALLEL RETRIEVE ...` command is invoked, but the `gp_parallel_retrieve_cursor` extension is not registered in the database.

Cluster Management

32018

Resolves an issue where running `gpstate -e` on the master generated the message `FATAL", "57P03", "connections to primary segments are not allowed.`

Query Optimizer

32126

Resolves an issue where GPORCA returned the error `could not determine which collation`

to use when a query used a Nested Loop Index join, and the join condition included a function like `upper()`; GPORCA now propagates collation information in this case.

32072

Resolves an edge case where GPORCA returned unexpected results on a query that included an immutable function returning a custom data type; Greenplum Database now falls back to the Postgres Planner.

12710

Resolves a performance issue that occurred when GPORCA generated an inefficient query plan for a query that included a common table expression (CTE) and where the result set was used more than once.

181647276

Resolves an issue where Greenplum Database crashed when it encountered a query using an `ALL` operator that had an implicit cast on the left-hand side of the expression.

181576677

Fixes an issue where a previous bug fix broke the printing of expression properties used to debug.

Release 6.20.0

VMware Tanzu Greenplum 6.20.0 is a minor release that includes feature changes and resolves several issues.

Features

Greenplum Database 6.20.0 includes these new and changed features:

- Greenplum Database 6.20 has been tested on and is supported for deployment to Red Hat Enterprise Linux 64-bit 8.x (RHEL8).

Note: For existing Tanzu Greenplum 6.20 or later deployments, VMware does not support upgrading the underlying operating system from RHEL7 or earlier to RHEL8 without also rewriting the database data. If you upgrade the operating system to RHEL8, you must also rewrite the Greenplum data by restoring a full backup that was created using `gpbbackup`, or by using the VMware Tanzu Greenplum Data Copy Utility (`gpcopy`).

- **PostGIS 2.5.4+pivot.6.build.1** is included to provide support for deployment on Red Hat Enterprise Linux 64-bit 8.x (RHEL8).
- MADlib version 1.19.0 is included to provide support for deployment on Red Hat Enterprise Linux 64-bit 8.x (RHEL8). This release includes additional fixes and features as described in the [MADlib Release Notes](#).
- Mirrors can now be added, recovered, or moved independently of each other. This has two consequences:
 - Previously, Greenplum Database required that when adding, recovering, or moving mirrors, all mirrors had to successfully complete the `pg_basebackup` phase before any mirrors could be marked as `up`. Now, mirrors that successfully complete `pg_basebackup` can be marked as `up` independently of other mirrors.
 - Previously, if adding, recovering, or moving mirrors failed during `pg_basebackup` then none of those mirrors would be marked as `up` and the user would have to re-run these operations for all mirrors. Now, the user only need re-run these operations for those mirrors that failed during `pg_basebackup`.
- The Console now provides more detailed information on failures during moving, recovering or adding mirrors. Specifically, it reports the hostname and port number of the mirrors that

failed to be moved/recovered/added. It also includes the location of log files for failed `pg_basebackup` and `pg_rewind` operations, and the location of the data directory for `pg_ctl` start failures.

- The `gpstate -e` command now includes an additional section in its output: “Segments in recovery.” This section reports on the progress of each segment’s recovery. Specifically, for each segment it reports:
 - ◊ the recovery type (incremental or full)
 - ◊ the number of completed bytes
 - ◊ the number of total bytes
 - ◊ the percentage of recovery the segment has completed
- `gp_log_collector` now collects data from `pg_db_role_setting` instead of `pg_settings` and now collects settings related to resource groups.
- The Query Optimizer (GPORCA) improves query performance by supporting query plan generation for ordered aggregates. You can configure GPORCA to generate query plans for ordered aggregates by setting the new `optimizer_enable_orderedagg` server configuration parameter to `true`.
- The Query Optimizer (GPORCA) now supports bitmap scans on partitioned tables that contain both heap and AO partitions.
- Greenplum 6.20.0 now bundles the `btree_gin` PostgreSQL contrib module. This module provides sample generalized inverted index (GIN) operator classes that implement B-tree equivalent behavior for certain data types.
- Greenplum 6.20.0 now bundles the `pg_trgm` PostgreSQL contrib module. This module provides functions and operators for determining the similarity of alphanumeric text based on trigram matching. The module also provides index operator classes that support fast searching for similar strings.
- The `pageinspect` module now includes support for bitmap indexes as described in the module documentation. If you are currently using the module in a database, you must upgrade the module to access the new functionality.
- Greenplum 6.20.0 introduces the new contrib module `gp_array_agg`. This module implements a parallel `array_agg()` aggregate function for Greenplum Database.
- Greenplum 6.20.0 introduces support for retrieving data, in parallel and on demand, directly from Greenplum Database segments via the new `gp_parallel_retrieve_cursor` (Beta) contrib module.
- Greenplum 6.20.0 introduces support for accessing data stored in one or more external Greenplum Database clusters via the new `greenplum_fdw` (Beta) contrib module, which implements a foreign-data wrapper.
- The `gp_sparse_vector` contrib module includes a bug fix. If you are currently using the module in a database, you must upgrade the module to obtain the fix.
- The `CREATE SERVER` command exposes a new `OPTIONS` named `num_segments`. The `greenplum_fdw` foreign-data wrapper supports this option; you use it to identify the number of segments in the remote Greenplum Database cluster.
- Greenplum Streaming Server (GPSS) version 1.7.0 is included, which includes new and changed features and bug fixes. Refer to the [Greenplum Streaming Server Documentation](#) for more information about this release and for upgrade instructions.
- The PXF version 6.3.0 distribution is available with this release; you can download it from the

Release Download directory named *Greenplum Platform Extension Framework* on [VMware Tanzu Network](#). Refer to the [PXF documentation](#) for information about this release and for installation and upgrade instructions.

- For customers deploying Greenplum on Dell EMC VxRail, the following enhancements have been introduced to the guidelines, and reference templates:
 - ◊ Greenplum Command Center (GPCC) is now included by default in the Greenplum Virtual Machine. After deploying Greenplum, GPCC will be accessible and ready to use. For details on the GPCC user account, see [Setting Up the GPCC Login User](#).
 - ◊ The Storage Policy has been updated from Stripe 1 to Stripe 4, to improve vSAN performance.
 - ◊ The Greenplum deployment via your own template now allows you to enable vApp options that will be used by Terraform during deployment. For details see [Installing the Greenplum Database Software](#)
 - ◊ This release adds documentation for changing the Data Disk size during the Greenplum Virtual Machine deployment. For details see [Modifying Resources](#).

Resolved Issues

VMware Tanzu Greenplum 6.20.0 resolves these issues:

Cluster Management

174741420

Resolves an issue where `gpstop` was throwing an error and failed to stop the cluster if the standby master host was unreachable.

Query Optimizer

31891

Resolves a query performance issue on a large table where GPORCA's default behaviour was to use a group aggregate. GPORCA now introduces the `gp_array_agg` hash aggregate that can be used in this circumstance.

Server

32038

Resolves an issue where `SELECT * from <view>` was intermittently failing with the message "FATAL: Internal error: Using fd > 65535 in MPP_FD_SET" .

32089

Resolves an issue where the server was failing to acquire resources on one or more segments due to shared snapshot collisions. The code now handles cleanup of worker processes differently during idle cleanup session timeouts.

31606

Resolves an issue where the identical query was running significantly more slowly in 6.x than in 5.28 because an incorrect amount of memory was allocated to the query.

32009, [12986](#)

Resolves an issue with the `gp_sparse_vector` module where using the `==` operator against a `NULL` operand generated a PANIC.

[12797](#)

Resolves an issue where index corruption could occur when an invalid snapshot was used with an AO table.

- Resolves an issue where calling the `gpmt` utility with the `primarymirror_lengths` option was failing due to unavailability of the `pg_filespace_entry` table. Queries have been updated to use the `gp_segment_configuration` table instead.
- Resolves an issue where calling the `gpmt` utility with the `tablecollect` option was failing because the `pg_class` table no longer has the `reltoastidxid` column.

Data Flow

31996, 7321

Resolves an issue where `gpload` occasionally failed and reported the error `GC object already tracked` due to a double-free of an object.

Release 6.19

Release 6.19.4

Release Date: 2022-03-11

VMware Tanzu Greenplum 6.19.4 is a maintenance release that resolves several issues.

Resolved Issues

VMware Tanzu Greenplum 6.19.4 resolves these issues:

Data Flow

32102, 8012

Resolved an issue where `gpfdist` would fail to load some data in a `.gz` data file if the file contained multiple end-of-file (EOF) flags. `gpfdist` code was modified so that it continues reading from a `.gz` data file until it reaches the actual EOF flag.

Server

32098, 32079

If the checkpointer process failed to open segment 1, the segment number was incorrectly reset to 0. This could cause an infinite loop of retries and failures and lead to the `pg_xlog` file growing in size with the checkpointer process hanging. The problem was resolved by ensuring that the segment number is not reset to 0 in this situation.

32095

Resolved an issue where `gpexpand` was failing with error “table has already been expanded partition prepare” . The `gpexpand` code has been modified so that the expand script – a two-stage process – can be run again in the second stage if it fails in the first stage.

Release 6.19.3

Release Date: 2022-02-25

VMware Tanzu Greenplum 6.19.3 is a maintenance release that resolves several issues.

Resolved Issues

VMware Tanzu Greenplum 6.19.3 resolves these issues:

Server

32056

Resolves an issue where querying the `gp_toolkit.gp_resgroup_status_per_segment` view returned the error `value ... is out of range for type integer` when the OID of a resource group was greater than 2^{31} .

32026

Resolves an issue where a `pg_upgrade` check for heterogeneous partition tables failed during a major version `gpupgrade` when a Greenplum Database 5.x partitioned table included a dropped column(s).

31977

Resolves an issue where `ALTER TABLE ... SET WITH (REORGANIZE=false) DISTRIBUTED RANDOMLY` incorrectly triggered a data redistribution.

13107

Resolves an issue where disk space for a dropped relation was not freed on transaction commit; Greenplum Database now truncates the files.

13105

Resolves a file descriptor leak on AO segment files.

13044

Resolves an issue where the access of an incorrect variable could cause a crash on an out-of-page read.

12936

Resolves an issue where a `CREATE TABLE .. AS (...) WITH NO DATA` could crash the server when `pg_attribute_encoding` was omitted.

12054

Resolves an issue where the execution of a multi-level correlated query with a high level of nesting could cause a segfault or provide incorrect results.

Query Optimizer

32074

Resolves a performance issue that was observed when GPORCA planned a query on a partitioned table with a large number of columns and indexes.

179048211

In some cases, the Query Optimizer generated incorrect results when the query included an `=ALL` operator. This issue is resolved.

Data Flow

32080

Resolves an issue where `gpload`, when `REUSE_TABLES: true`, could not find a staging table to reuse, and failed to create the staging table in the `public` schema. This issue is resolved; `gpload` now creates staging tables in the same schema as specified by `EXTERNAL: SCHEMA:.`

PostGIS

178647728

The latest PostGIS release fixes the `RPATH` values for PostGIS and dependent library (`.so`) files. With this fix, you can use `gpupgrade` on systems that have data of PostGIS-defined types including `geometry`, `geography`, etc., provided that the latest build of **PostGIS 2.1.5+pivot.3** is installed on both the Greenplum Database 5 and Greenplum Database 6 clusters.

Release 6.19.2

Release Date: 2022-02-11

VMware Tanzu Greenplum 6.19.2 is a maintenance release that resolves several issues.

Changed Features

Greenplum Database 6.19.2 includes these changes:

- Greenplum 6.19.2 introduces a change to WAL record replay for AO tables to enable *future* support of archive recovery.

Resolved Issues

VMware Tanzu Greenplum 6.19.2 resolves these issues:

Server

32068

Resolves an issue where Greenplum Database generated a PANIC and the error `ERRORDATA_STACK_SIZE exceeded` during the execution of certain queries after an upgrade to version 6.19.0 or 6.19.1.

32002

Resolves an issue where incremental recovery failed because `pg_rewind` was erroneously trying to delete the `gpbakup` default directory.

13067

Resolves a memory leak that was introduced with the fix for issue [31740](#).

13040

Clarifies a misleading error message that was displayed when resource group-based resource managment was active and Greenplum Database detected an out of memory condition. Greenplum now outputs different error messages based on the current states of Vmem, system, query, and resource group memory allocation.

Query Optimizer

12796

Resolves an issue where the Query Optimizer returned incorrect query results when the query plan included a materialize over a bitmap scan by removing the unnecessary projection of recheck/scalar filter columns.

Cluster Management

32012, 31894

Resolves an issue where `gpcheckcat` returned the error `invalid input syntax for integer` during the `orphaned_toast_tables` test because the command did not correctly handle a temporary toast table.

12957

Resolves an issue where invoking `gpconfig` or `gpinitssystem -p` to set the value of a server configuration parameter(s) comments out any parameter setting in the `postgresql.conf` file whose name starts with the same text string.

32042

Resolves an issue introduced in Greenplum Database 6.19.0 where `gpinitisystem` was failing during the add mirrors portion of initializing, due to entries missing from the `pg_hba.conf` file.

Data Flow

31936, 31913

In certain cases, an `INSERT` operation performed on a `gpfdist` external writable table both did not write the complete data set and reported no error. This issue is resolved; `gpfdist` now correctly reports and completes error processing when it encounters a retry failure due to poor network conditions.

Release 6.19.1

Release Date: 2022-01-21

VMware Tanzu Greenplum 6.19.1 is a maintenance release that resolves several issues.

Changed Features

Greenplum Database 6.19.1 includes these changes:

- Greenplum Database 6.19.1 introduces the server configuration parameter `gp_log_resqueue_priority_sleep_time`. You can use this debug parameter when resource queue-based resource management is active to enable statement sleep duration logging for post-query concurrency analysis.
- When `wal_level=minimal`, Greenplum Database now suppresses insert and truncate WAL records for mirrorless clusters to decrease disk space usage and to improve performance of AO/AOCO operations.
- The `acl` and `owner` tests are no longer run by default when you invoke the `gpcheckcat` utility. You can choose to run one or both of these test suites by specifying the `-R` option to the command.
- The `gpexpand.status_detail` table includes a changed column (`root_partition_name` is now named `root_partition_oid`) and a new column (`rel_storage`).

Resolved Issues

VMware Tanzu Greenplum 6.19.1 resolves these issues:

Server

31957, 12930

Resolves a runtime performance issue that was observed when a query that included a `NOT IN / IN` construct was more performant when run on Greenplum 5.x compared to Greenplum 6.x.

31850, 12703

Resolves an issue where Greenplum Database might PANIC if a primary segment goes down during a transaction that operates on a cursor.

31019

Resolves an issue where the `gpexpand.status_detail` table did not allow for tracking partitions during expansion by expanding each leaf partition separately, in parallel.

12975

Resolves an issue where the Query Dispatcher failed when it encountered an error processing `nextval()` and subsequently cancelled all unfinished Query Executors.

12900

Resolves an issue where Greenplum Database incorrectly restored a null-valued server configuration parameter.

12851

Resolves an issue where Greenplum Database logged an `INFO`-level message with the text

provided user name (<username1>) and authenticated user name (<username2>) do not match because it performed an unnecessary authentication check.

12647

Synchronizes the Greenplum Database `amgetbitmap` definition with upstream PostgreSQL.

9649

Resolves an issue where an intermittent `LWLock` panic error occurred when canceling a query that is waiting on a resource queue.

9904

Resolves an issue where PANIC errors were occurring due to the server erroneously collecting execution statistics when the query failed.

Query Optimizer

31884

Resolves an issue where the Query Optimizer generated a plan for a query that included a subquery `ALL` construct that could generate incorrect results or crash during execution.

31986

Resolves an issue where a query crashed during optimization when the Query Optimizer relied on statistics that were not yet derived; Greenplum Database now falls back to the Postgres Planner.

31953

Resolves an issue where a query returned the error `could not determine which collation to use for string comparison` when the Query Optimizer could not determine the collation string to use for a string comparison when the column was generated by an expression.

31956

Resolves an issue where users could not cancel `analyzedb` because process interrupts were not being handled correctly.

180241036

In some cases, the Query Optimizer generated an incorrect cardinality estimate when a predicate contained an `ALL` operator. This issue is resolved.

Cluster Management

31311

Resolves an issue where `gpcheckcat` ran slowly due to long-running `acl` and `owner` tests by removing these test suites from the default set of tests that are run.

Release 6.19.0

Release Date: 2021-11-24

VMware Tanzu Greenplum 6.19.0 is a minor release that includes feature changes and resolves several issues.

Features

Greenplum Database 6.19.0 includes these new and changed features:

- Greenplum 6.19.0 includes the utilities `gpmemwatcher` and `gpmemreport` for tracking and analyzing memory usage.
- The Greenplum Platform Extension Framework (PXF) software is removed from the Greenplum Database Server distribution. If you are running PXF from your Greenplum installation (`$GPHOME/pxf`), you must download and install a PXF `rpm` or `deb` package to continue using the service in your Greenplum Database 6.19.0+ cluster. See [Upgrading](#)

Greenplum in these release notes and [Upgrading PXF When you Upgrade Greenplum 6](#) for upgrade information.

- Greenplum 6.19.0 introduces three new connection server configuration parameters: `gp_dispatch_keepalives_count`, `gp_dispatch_keepalives_idle`, and `gp_dispatch_keepalives_interval`. You can use these parameters to tune TCP keepalives between a Query Dispatcher and its Query Executors.
- Greenplum 6.19.0 includes commits from PostgreSQL releases 9.4.24 to 9.4.26.
- The `s3 external table protocol` now supports a `config_server` option. You can use this option in the `CREATE EXTERNAL TABLE LOCATION` clause to specify the `http/https` server URL from which Greenplum Database obtains the `s3` protocol configuration file.
- `gpload` adds a `NEWLINE` property to the load control file. You can use this property to specify the type of line break present in text and CSV files that you load with the tool.
- Greenplum 6.19.0 introduces the `enable_implicit_timeformat_YYYYMMDDHH24MISS` server configuration parameter. You can set this parameter to `on` to instruct Greenplum Database 6.19+ to enable the deprecated implicit conversion of a string with the timestamp format `YYYYMMDDHH24MISS` into a valid date/time type.
- The Query Optimizer (GPORCA) improves optimization time performance by not generating nested loop join alternatives when a hash join is possible. You can configure GPORCA to restore its prior behavior by setting the new `optimizer_force_comprehensive_join_implementation` server configuration parameter to `true`.

Resolved Issues

VMware Tanzu Greenplum 6.19.0 resolves these issues:

Cluster Management

31849

Resolved an issue where the `memreport` utility was failing with the error `Unable to find postmaster process` due to incorrect parsing options.

179158687

Resolved a `gpinitssystem` failure that could occur if `.bashrc` was configured to display banner text. A marker has been added to the output so that `gpinitssystem` can ignore banner text when interpreting output messages.

180235316

Resolved an issue where the log file did not show that Greenplum was started in restricted mode if master only mode was used (`gpstart -m -R`).

180291768, 179715424

Resolved a packcore/gdb test failure that occurred when environment variables were set on RHEL8 systems.

Data Flow

31768

Resolved an issue where `gpload` was reporting the error `No such file or directory",,,,,,"CREATE EXTENSION IF NOT EXISTS dataflow;` when connecting to a Greenplum Database 5.x. This fix checks the Greenplum version to determine whether it should create a new extension.

Greenplum Installation

572

Resolved an issue with the `rpm` installers, so installing Greenplum does not overwrite the symlink if the install file is for a different major version.

Query Planner

31759

Resolves in issue where an `EXPLAIN ANALYZE` query never completed by improving optimization time performance. GPORCA now disables the generation of nested loop join alternatives when a hash join is available.

31712

Fixed a bug where a window aggregate query crashed during execution by improving `MemoryContextContains()`.

31391

Improved the default optimization cost model for GPORCA since the `exhaustive2` algorithm was causing performance regression.

180418263

Removes a stale assertion that caused GPORCA to generate different plans when running Greenplum Database with and without asserts.

180467007

Resolves an issue where GPORCA generated an incorrect plan for a CTAS operation because it created a hash distribution spec with the wrong operator families.

Server

Postgres CVE fixes

This release backports the following Postgres CVE fixes:

- [CVE-2021-23214](#) Server processes unencrypted bytes from man-in-the-middle.
- [CVE-2021-23222](#) libpq processes unencrypted bytes from man-in-the-middle.

31952

Resolved an issue where `gpload` reported the error `date/time field value out of range: <date>` when loading data originating in Greenplum 5 by introducing the new server configuration parameter `enable_implicit_timeformat_YYYYMMDDHH24MISS`.

31940

When `global_deadlock_detector` was set to `on`, parallel update jobs could sometimes fail and cause a segment crash (SIGSEGV). When `global_deadlock_detector` is enabled, the Query Executor can become blocked by another transaction's UPDATE operation. However, when the Query Executor later became unblocked it would attempt to re-initialize all sub-plans even if they were not needed for the plan being re-evaluated. Greenplum now considers subplan motions when re-initializing, and correctly throws an error instead of causing a PANIC condition.

31887

Resolves a resource queue issue where a session with multiple active portals did not decrement the active statement count following a deadlock report or statement cancellation.

31808

When running a `COPY` command using `SELECT`, `WHERE` and `ON SEGMENT`, Greenplum was not saving the segment data correctly. This issue is now resolved.

31654

Resolved an issue where not all spill files were using the GUC `temp_tablespace`. Now all spill

files will use `temp_tablespaces` if set.

11307

Fixes Query Catalog Table errors when using `targetlists` with `generate_series` functions, and Index Only Scan plans.

12228

Resolves generation of faulty plans that could result in segfault on indexed tables. The issue occurred when path nodes with bottleneck locus types (Entry and SingleQE), and equal `numsegments`, were moved.

12871

Resolves a PL/pgSQL function infinite recursion issue by always writing a snapshot file to the default tablespace, even when `temp_tablespaces` is set.

12860 - pg_upgrade

Disables the `pg_upgrade` check for line datatypes.

12656

Resolves an issue where Greenplum Database may incorrectly drop `ORDER BY` and `DISTINCT ON` clauses in a subquery when it pulls up sublinks.

<! –

12212 - gpexpand

Resolves an issue where Greenplum Database copied the `postgresql.auto.conf` file that resided on the master host to the new host(s) during an expand operation. Because the segment hosts may have different server configuration parameter settings, Greenplum now copies a `postgresql.auto.conf` file that resides on an existing segment host to the new host(s). – >

11308

Fixed a bug that caused data corruption during scan on bitmap index when there was an `INSERT` operation running in the backend.

10955

Improved the logging and adjusted log level from INFO to DEBUG for the message `We thought we were done (...) but libpq says we are still busy.`

179498672

When using mirrorless clusters, queries did not fail during virtual machine restart. This issue has been fixed by adding new GUCs to tune TCP keepalives for connections between the Query Dispatcher and Query Executors: `gp_dispatch_keepalives_count`, `gp_dispatch_keepalives_idle`, and `gp_dispatch_keepalives_interval`.

Release 6.18

Release 6.18.1

Release Date: 2021-10-29

VMware Tanzu Greenplum 6.18.1 is a maintenance release that resolves several issues.

Resolved Issues

VMware Tanzu Greenplum 6.18.1 resolves these issues:

Server

31756

In some cases, an `INSERT` query that was run on a table containing a sequence column could not be cancelled. This issue is resolved; Greenplum Database now adds an interrupt check when it processes the next value of a sequence.

31740

Resolved an issue where incremental `gprecoverseg` failed to bring a mirror segment back online. This was due to the checkpoint process on a newly recovered mirror failing because the recovery process was searching for a file that had been rightfully deleted.

12670

Introduces a `contentId(%c)` parameter to the WAL `archive_command` and `restore_command`; this parameter identifies a WAL stream from a given segment.

12024

Removes the redundant calls to `Gpmon_Incr_Rows_Out()` that made the `rowsout` field of `gpperfmon qexec` packets incorrect for `Sort` nodes.

11371

Resolves an AOCO table inconsistency that occurred when an `ALTER TABLE ... ADD COLUMN` operation was rolled back.

179726460

The `pg_xlogdump` utility was not providing sufficient information to assist in diagnosing bitmap index issues. This has been resolved. `pg_xlogdump` now includes bitmap-related information.

179719406

The `pg_log` utility was not providing sufficient information to assist in diagnosing bitmap index issues. This has been resolved. The bitmap index name is now included in Greenplum Database logs.

Query Optimizer

31784

If `ANALYZE` was performed against a leaf partition as part of a transaction, statistics for the leaf were never merged. `ANALYZE` would first update the leaf statistics, but when checking to determine if all leaves have been analyzed, it would use a cache that did not include the updated number of rows. This would then trigger a sampling of the root table, which can be expensive. The problem was resolved by advancing the command counter to make the page and tuple updates visible when merging the leaf statistics.

31774

Resolves an issue where the Query Optimizer generated an incorrect plan and returned wrong results on a `select count(*)` query when it incorrectly handled a nested set-returning function.

31767

In some cases, the Query Optimizer ran out of memory when planning a query because it did not correctly propagate the OOM error that would ultimately cancel the query. This issue is resolved in the Query Optimizer runaway cleaner exception handler.

Release 6.18.0

Release Date: 2021-10-8

VMware Tanzu Greenplum 6.18.0 is a minor release that includes feature changes and resolves several issues.

Features

Greenplum Database 6.18.0 includes these new and changed features:

- The `gpstate -e` and `gpstate -s` commands now provide more detailed output about the status of primary-mirror segment WAL synchronization. Moreover, as part of these output changes:
 - The `gpstate -s` output fields `Change tracking data size`, `Estimated total data to`

`synchronize`, and `Data synchronized` output fields are now gone.

- The `Mirror status` field in `gpstate -s` output for primary segments now has just two valid values: Synchronized or Not in Sync.
- Greenplum 6.18.0 introduces a new Query Optimizer server configuration parameter, `optimizer_xform_bind_threshold`. You can use this parameter to reduce the optimization time and overall memory usage of queries that include deeply nested expressions by specifying the maximum number of bindings per transform that GPORCA produces per group expression.
- The new `gp_autostats_allow_nonowner` server configuration parameter enables you to configure Greenplum Database to trigger automatic statistics collection on a table when the table is updated by a non-owner. This parameter is off by default.
- Greenplum 6.18.0 introduces the new contrib module `gp_legacy_string_agg`. This module implements the single-argument `string_agg(text)` function that is available in Greenplum 5; you may choose to use the module to aid migration to Greenplum 6.
- The license file for the Windows Client and Loader Tools Package was updated to the latest version.
- Greenplum 6.18.0 removes the `~/.gphostcache` file; the management utilities now use an alternate mechanism to map hostnames to interfaces.
- To enhance the supportability of the product and to aid debugging efforts, Greenplum Database now reports both the reserved and maximum virtual memory allocation when it encounters an out of memory (OOM) condition.

Resolved Issues

VMware Tanzu Greenplum 6.18.0 resolves these issues:

Server

Postgres CVE fixes

This release backports the following Postgres CVE fixes:

- [CVE-2020-25696](#) `psql' s \gset` allows overwriting specially treated variables.
- [CVE-2020-25695](#)/ Multiple features escape “security restricted operation” sandbox
- [CVE-2021-32027](#)/Buffer overrun from integer overflow in array subscripting calculations

31736, 31727

When the `log_lock_waits` GUC was enabled it resulted in spurious deadlock reports and orphaned wait queue states which, in turn, could lead to memory corruption of certain internal tables. This issue is resolved by disabling the `log_lock_waits` GUC. The `log_lock_waits` GUC is not supported by Greenplum Database.

31736 - Resource Queues

Due to improper error handling, Greenplum Database raised a duplicate portal identifier warning that was in some cases immediately followed by an out of shared memory error. This issue is resolved; Greenplum Database now raises distinct errors for duplicate portal identifier and out of shared memory.

31734

Greenplum was generating the error `ERROR: interconnect error: A HTAB entry for motion node 77 already exists` after creating the extension for the `ltree` module. This issue has been resolved.

31725 - Execution

In some cases, Greenplum Database generated a PANIC when the user cancelled a query on an AO table due to a double free of a visimap object. This issue is resolved.

31708 - Catalog and Metadata

Resolves an issue where a non-superuser who ran `VACUUM FULL` on a table that they had no permission to access could block further access to the table by currently running transactions. Greenplum Database now performs the permission check before it acquires a lock on the table.

31704 - Planner

In some cases, Greenplum Database returned an incorrect plan when an `UPDATE` statement included a subquery. This issue is resolved.

31679 - Functions and Languages

Resolves an issue where a function invocation failed with the error `cannot create a unique ID for path type: 116` by disallowing the unique row id path when Greenplum Database encounters an index-only scan.

31654 - Storage

Resolves an issue where Greenplum Database did not honor the `temp_tablespace` setting when it generated temporary files during a sort operation on a large data set. Greenplum now places these temporary files in a tablespace specified in `temp_tablespace`.

31617 - Resource Groups

A database instance was failing to start up, with the message `Command pg_ctl reports Master gdm instance active` because a mirror segment couldn't be recovered. This was due to the incorrect type of lock being used when creating or altering a resource group. This issue is resolved.

31615 - Analyze

Resolves an issue where Greenplum Database did not collect statistics on a table when the table was updated by a non-owner. Greenplum Database 6.18 introduces the new server configuration parameter `gp_autostats_allow_nonowner` (default is off) to enable automatic statistics collection when a non-owner updates a table.

31517

Fixed a bug with function `fixup_unknown_vars_in_setop` that would cause Greenplum Database to `PANIC`.

31385 - Planner

Resolves an issue where Greenplum Database returned wrong results for a query because it chose an incorrect motion type during plan tree iteration.

12482

Reinstates the Greenplum Database-specific `--wrapper` and `--wrapper-args` options to the `pg_ctl` command that were available in Greenplum Database 5.

12420

Fixes an environmental variable generation issue caused when symlinks were pointing to alternative locations than the ones expected.

12419

Resolves an issue where Greenplum Database, during node recovery, generated an error when the field `standby_mode=on` was set in the `recovery.conf` file. The error was similar to:

```
"FATAL","22023","recovery command file ""recovery.conf"" request for standby mode
not specified",,,,,,0,,,"xlog.c",5465
```

Greenplum Database now supports server recovery in a non-continuous mode using `standby_mode=on`.

12409

`pg_relation_filenode()` function did not provide proper output for Append Optimized (AO) auxiliary tables. This issue has been resolved.

12408

Resolves an issue where Greenplum Database threw an assertion failure when the size of an AO table exceeded 1GB.

12402

Resolves an issue where Greenplum Database failed to complete a query when the target relation of an `UPDATE` or `DELETE` operation was a partition table and Greenplum generated a unique row id plan.

12299 - gpexpand

Resolves an issue where WAL-replication was using excessive external bandwidth due to misuse of the hostname and address in `gp_segment_configuration`. Greenplum Database now uses the primary's address for WAL-replication in `gpexpand`.

11371

Greenplum Database would initialize `pg_aocsseg` table entries with frozen tuples to ensure these entries were implicitly visible even after a rollback. This strategy created issues with the roll back of Append Optimized Columnar (AOC) tables. This issue has now been resolved.

685, 9208, 9429

In some cases, the value of a server configuration parameter could be inconsistent among the query dispatcher (QD) and/or query executors (QEs) when the parameter value was updated and then reset in the same session. This issue is resolved.

Query Optimizer

31733

Queries were crashing due to GPORCA prematurely terminating the motion node before interconnect was torn down. This issue is now resolved.

31640

Running queries with GPORCA enabled generated the error `ERROR: could not open existing temporary file "base/pgsql_tmp/pgsql_tmp_SIRW_145011_97_0": No such file or directory`, caused by temporary file name changes during cross-slice communication. This issue has been resolved.

179345712

Resolved an issue with the `minirepro` utility where it generated incorrect input when inserting columns containing arrays.

179244161

Resolved an issue where Greenplum processes crashed when trying to write an error message to the log due to a null pointer dereference.

167242211

Resolved an issue that caused wrong results when running queries with GPORCA when having the `IS DISTINCT FROM FALSE` predicate inside a `NOT EXIST` subquery.

Cluster Management

31746

Resolves an issue where Greenplum Database threw cosmetic errors during `gpstate` execution when a database of the same name as the `$USER` running the command did not exist.

31581

`gpconfig` would fail with error similar to `ValueError: filedescriptor out of range in select()` due to liveness checks performed on all hostnames associated with each database id. This issue has been resolved and liveness checks are now performed only on unique hostnames.

31558 - gpinitssystem

If a `gpinisystem` operation failed before creating the necessary segment backout scripts, manual steps were required to clean up the directories after the failure. To resolve this problem `gpinisystem` now creates a single backout script earlier in the process; the script can be used to cleanup all segment directories even if a failure occurs later in the `gpinisystem` operation.

179336062

The Greenplum utilities `gprecoverseg`, `gpinitstandby`, `gpstart`, and `gpstop` fail when there is a message banner in `.bashrc`. This issue has been resolved, and now banner messages are not parsed.

178936675 - gpstate

Beginning in Greenplum 6.0, the `gpstate` utility no longer provided mirror synchronization status. This problem was resolved by adding the `Mirror status` field in `gpstate -s` output for primary segments.

178831426 - gpcheckperf

When executing `gpcheckperf` via `gpssh`, the `gpcheckperf` utility could issue a `pkill -f` command that killed the `gpssh` process and disconnected the established SSH connections. This problem was resolved by removing the use of `pkill -f` in `gpcheckperf`.

178761563

Removes unrelated output message regarding `netperf` test, that was shown when running `gpcheckperf -r N`.

178637128

Fixes the issue of the missing `--help` option for `gpcheckcat`.

Data Loading

N/A

Reverts a previously-committed `gpload` improvement that removed a left-join merge because it introduced a performance regression in certain situations.

31613, [12454](#)

Resolves an issue where a `COPY` command failed to read a file that included special characters at the end of a line because Greenplum Database did not recognize the EOL character.

Release 6.17

Release 6.17.7

Release Date: 2021-10-2

VMware Tanzu Greenplum 6.17.7 is a maintenance release that resolves a single issue.

Resolved Issue

Server

31818

The fix for issue [11308](#), added in Greenplum 6.16, introduced a regression that could cause incorrect results for queries having a bitmap index condition. This problem was resolved in 6.17.7 by reverting the original fix.

Release 6.17.6

Release Date: 2021-9-25

VMware Tanzu Greenplum 6.17.6 is a maintenance release that resolves a single issue.

Resolved Issue

Server

31807

Incorrect bitmap index page data was written to WAL logs, resulting in bitmap index corruption after failover to mirror segments or after crash recovery on primaries. This issue has been resolved.

Release 6.17.5

Release Date: 2021-9-22

VMware Tanzu Greenplum 6.17.5 is a maintenance release that resolves a single issue.

Resolved Issue

Postgres Query Planner

12583

A previous fix to resolve duplicate sequence values (178253995) resulted in a performance regression. An incomplete hash key in the fix caused most hash table lookups to fail, which increased the time required to insert data having columns with sequence values. The problem was resolved by ensuring that the hash key contains complete information.

Release 6.17.4

Release Date: 2021-9-21

VMware Tanzu Greenplum 6.17.4 is a maintenance release that resolves several issues.

Resolved Issues

VMware Tanzu Greenplum 6.17.4 resolves these issues:

Query Optimizer

31715

A memory allocation function failed to handle a null pointer exception, which could lead to a system panic when creating the memory pools on Greenplum segments. This issue was resolved, by raising an exception if the memory allocation fails.

31732

A query plan with a nested loop join and a dynamic table/index scan on the inner side of the join could cause an out of memory exception during a high concurrency workload. This was caused by an inefficient use of executor memory in the dynamic table/index scan operators. This issue has been resolved.

Server

31776

Segment failover caused bitmap index corruption and returned the error `Invalid page in block 0 of relation`. This was caused by the metapage not being present in the shared buffers. This issue has been resolved.

Release 6.17.3

Release Date: 2021-8-30

VMware Tanzu Greenplum 6.17.3 is a maintenance release that resolves several issues.

Resolved Issues

VMware Tanzu Greenplum 6.17.3 resolves these issues:

Query Optimizer

31714

In some cases, when processing queries that contained inner joins, the optimizer failed to process statistics, which resulted in a PANIC. This has been resolved.

Server

31726, 31696

A lock table corruption issue caused the Greenplum Database master segment to PANIC if a query waiting for a resource queue lock was cancelled, or if the query errored with a deadlock report. This issue is resolved.

Release 6.17.2

Release Date: 2021-8-6

VMware Tanzu Greenplum 6.17.2 is a maintenance release that resolves several issues.

Resolved Issues

VMware Tanzu Greenplum 6.17.2 resolves these issues:

Cluster Management

31558

This fix creates a single backout script when `gpinitssystem` runs so it is possible to clean up all segment directories in case of an error.

178761563

The `gpcheckperf` output displayed a `NOTICE` about deprecated flags for `gpnetbench`, however these flags are still used in `netperf`. This fix removes the `NOTICE` message.

178637128

The command `gpcheckcat` now has a `--help` option.

31581

For large clusters `gpconfig` returned the error `filedescriptor out of range in select()` due to the liveness check being performed on all hostnames associated with each Database ID. This fix addresses this issue by performing liveness check only on unique hostnames.

Extensions

31610

This version introduces a new type extension `pljavat` which only installs a language handler for the trusted language `pljava` and not the untrusted language `pljavau`.

Query Optimizer

178747560

For queries that insert from a replicated table into a distributed table, the query optimizer could generate a plan that produced incorrect results. Specifically, for operations involving a `SEQUENCE` function on the replicated table, the result was not guaranteed to be identical across different segments. This issue was resolved by identifying these scenarios and redistributing tuples from a single segment, rather than exploiting the advantages of replicated table.

31609

The query optimizer generated a better plan with `optimizer_join_order` set to “greedy” in comparison to the default value of “exhaustive.” This occurred because the default join order algorithm was partial to finding a plan that exploited dynamic partition elimination (DPE) and sometimes ignoring cases where both static and dynamic partition elimination would improve plan performance. This was done to prevent increasing the optimization time significantly at the expense of a sub-optimal plan. To avoid generating sub-optimal plans, the query optimizer now generates both partition elimination options but only for the greedy algorithm, regardless of the join order chosen. This helps to generate some lower-cost alternatives while incurring only a moderate increase in optimization time (15%).

31556

Creating a temp table with `DISTRIBUTED RANDOMLY` from a `DISTRIBUTED REPLICATED` table put all records into one instance when the query optimizer was enabled. This issue was resolved by adding the necessary logic to insure that, when inserting from a replicated table into a randomly-distributed table, the query optimizer randomizes the tuples to data skew.

31515

GPORCA could generate wrong results if a query used both a `WITH` clause and a join condition across different output columns of the same derived tables. The problem occurred because the distribution policy created for the `WITH` clause subquery was incorrectly propagated. GPORCA has resolved this problem by pushing properties into the `WITH` clause only when all columns come from the same derived table.

31448

Incorrectly estimating cardinality for casted columns resulted in a bad join order, which could lead to a query that did not finish. This issue was resolved by updating the cardinality estimation model when the input histogram is not well formed, as is the case when columns are casted.

Server

31564

Resolved an issue where a database server process was not properly holding the `partitionLock` and `ResQueueLock` after releasing a resource queue lock following a deadlock error, which resulted in a segmentation fault.

gpload

31466

Resolved an issue where `gpload` would fail with column names that used uppercase or mixed-case characters. `gpload` now automatically adds double quotes to column names that are not already quoted in the YAML control file.

Release 6.17.1

Release Date: 2021-7-23

VMware Tanzu Greenplum 6.17.1 is a maintenance release that resolves several issues and changes one feature.

Changed Feature

Disabled unsafe TLS 1.0 and TLS 1.1 protocols for `gpfdist`.

Resolved Issues

VMware Tanzu Greenplum 6.17.1 resolves these issues:

Postgres Planner

31630

Fixed a problem where the Postgres Planner failed to consider aggregates on the entry flow. This could cause queries to fail with: `ERROR: MIN/MAX subplan has unexpected flowtype`.

Query Optimizer

31522

During a left outer join query, with an index on the join column, the Query Optimizer explored a plan search space that hit an exception, was unable to generate a plan, and reverted to the Postgres Planner. This issue has been fixed by changing the requested collocation property, and eliminating the invalid search space.

174732670

The query optimizer added an unnecessary Explicit Redistribute Motion when generating a plan for queries using `DELETE` on a randomly distributed table. This issue has been resolved.

Server

12197

Resolves a data corruption issue that could occur with concurrent DML queries on AO/AOCO tables when Greenplum Database was not aware of committed transactions that started after snapshot initiation.

Release 6.17.0

Release Date: 2021-7-9

VMware Tanzu Greenplum 6.17.0 is a minor release that includes feature changes and resolves several issues.

Greenplum Database 6.17.0 includes these new and changed features:

Features

- The PXF version 6.1.0 distribution is available with this release; you can download it from the *Release Download* directory named *Greenplum Platform Extension Framework* on [VMware Tanzu Network](#). Refer to the [PXF documentation](#) for information about this release and for installation and upgrade instructions.
- The `gprecoverseg`, `gpaddmirrors`, and `gpmovemirrors` utilities now include a `-b` option to specify the maximum number of segments per host to operate on in parallel.
- The `gpecheckcat` utility now permits users to skip one or more tests, with the new `-s` option. In addition, the `-R` option now accepts a comma-separated list of multiple tests to run.
- The Progress DataDirect JDBC Driver v6.0.0+181 is included in this release. See the [Readme file](#) for a list of new features available in v6.0.0

Resolved Issues

VMware Tanzu Greenplum 6.17.0 resolves these issues:

Server

178150185

Resolved an issue where the message, `An exception was encountered during the execution of a statement` was unable to be suppressed. Users can now control the verbosity of the exception message with the `log_min_messages` GUC.

31335

Resolved an out of memory condition that could occur because the server held certain data contexts longer than necessary.

31185

When altering a role from superuser to non-superuser, the role resource group was not changing from `admin_group` to `default_group`. This fix addresses this issue.

31320

Resolved an issue where issuing a `UPDATE/DELETE` statement while a `VACUUM` operation was running returned the error `tuple concurrently updated`, due to an out of date snapshot.

31435

Fixed the error `unrecognized parameter "appendoptimized"` that was reported when using the `appendoptimized` clause for a table partition definition.

31584

Resolved a bug that caused the database to crash when running queries against tables that had not been redistributed after an expansion.

31588

Resolved an issue where a `CTAS` statement referencing a table created with the `DISTRIBUTED REPLICATED` clause was generating incorrect results with the Legacy Planner.

Query Optimizer

31481

For partitioned tables with indexes, ORCA would cause a `PANIC` while trying to create an index plan, when root and leaf partitions did not have the same underlying dropped column structure. This issue has been resolved.

31463

Running queries with the GPORCA query optimizer that used an `INNER JOIN` with an `EXCEPT` clause was causing a fallback to Legacy Planner and reporting the error: `No plan has been computed for required properties`. This issue has been resolved.

10967

Resolved an issue where running queries with a `LEFT OUTER JOIN` were producing incorrect results as it was being replaced with an `INNER JOIN` in the subquery plan.

31440

Resolved an issue where running a query using `UNION ALL` and an external table was returning incorrect results with GPORCA query optimizer, due to not all information from the external table being gathered.

177874343

The ORCA Query Optimizer was unnecessarily opting out of certain optimizations when it encountered a `NO SQL` function. It no longer does that.

178477120

Introduced a fix to verify that materialize does not project in ORCA Query Optimizer.

11880

Resolved an issue with array overflow for function argument types which was causing memory

corruption and a database crash with ORCA Query Optimizer.

31527

Resolved a bug in the implementation of Left Outer Joins that was causing a database crash when using ORCA Query Optimizer.

Cluster Management

178173416

Resolved an issue where `gprecoverseg -r` when it called `gprescoverseg` internally a second time – did not correctly pass on the `-B` and `-b` options.

31417

Resolved an issue where `gprecoverseg` was updating the `pg_hba.conf` file on all primaries regardless of whether those primaries needed to be updated.

31350

Resolved an issue where `gpmovemirrors -B` was calling `gprecoverseg` with an excessively large number of parallel processes.

31338, 31351

Resolved an issue where old mirror directories were not being removed from old tablespace directories after a mirror was moved using `gpmovemirrors`.

31419

Resolved an issue where `gprecoverseg` was printing out empty `pg_rewind` progress lines for mirrors.

31519

`gprecoverseg` no longer adds `pg_hba.conf` entries if they are already present in the file.

31579

For all GUCs with a vartype of `string`, you may no longer enclose the value you pass to `gpconfig -c` in single quotes.

178254153

Resolved an issue where `gprecoverseg -p` was reporting an error despite the operation being successful.

177862886

Resolved an issue where `gprecoverseg -p` would error out when master could not connect to an individual segment host.

Postgres Query Planner

178238691

Resolved an issue where an error occurred when the planner was executing a query that performed a `UNION ALL` between a replicated table and a subquery with an explicit sequence `nextval`.

178253995

Resolved an issue where the sequence executor node was generating duplicate sequence values.

Release 6.16

Release 6.16.3

Release Date: 2021-07-02

VMware Tanzu Greenplum 6.16.3 is a maintenance release that resolves several issues.

Resolved Issues

VMware Tanzu Greenplum 6.16.3 resolves these issues:

Server

31549, 31577

Resolved an issue that made Greenplum unable to cast unknown-type literals to `cstring` in certain circumstances. This problem could surface in several ways including query panics, out of memory conditions, and the following compression error: `"ERROR", "XX000", "compressed data is corrupt (pg_lzcompress.c:737)"`.

Analyze

31589

When running `ANALYZE` on a leaf table, Greenplum would compute statistics for all columns when merging statistics for the parent table, even if one or more columns had been configured with `STATISTICS` set to 0 (to disable statistics collection for that column). Greenplum no longer computes statistics for columns that have `STATISTICS` set to 0 when merging statistics for the parent table.

Release 6.16.2

Release Date: 2021-06-04

VMware Tanzu Greenplum 6.16.2 is a maintenance release that resolves several issues.

Resolved Issues

VMware Tanzu Greenplum 6.16.2 resolves these issues:

Cluster Management

178140424

Resolved an issue where, when `gprecoverseg -v` was invoked, `pg_rewind`'s log was generated but was not preserved in case of an incremental recovery failure.

Server

178280660

Resolved an issue with the Postgres planner partition selection when the types of the partitioning key and the search values are different.

31436

Resolved an issue in which, when running `\df+` on a function that has exec location `INITPLAN`, the `Execute on` column did not properly display `"initplan"`.

31335

Resolved an out of memory condition that could occur because the server held certain data contexts longer than necessary.

12015

Fixed an inconsistency between master and segments regarding the value of `collname` when creating a `DOMAIN`.

11999

Resolved an issue in which `CREATE MATERIALIZED VIEW` was failing with `ERROR: division by zero` when `WITH NO DATA` was being specified.

Query Executor

31439

Resolved an issue which caused the database to **PANIC** due to a double free of the memory context **TupleSort**.

Release 6.16.1

Release Date: 2021-5-21

VMware Tanzu Greenplum 6.16.1 is a maintenance release that resolves several issues.

Resolved Issues

VMware Tanzu Greenplum 6.16.1 resolves these issues:

n/a - **gprecoverseg**

Resolved an issue where using **gprecoverseg** to perform an incremental recovery removed log files from the **pg_log** directory. **gprecoverseg** now retains files under **pg_log** so that they can be used for troubleshooting after an incremental recovery.

177336745 - Cluster Management

Resolved an issue with **gpconfig** where the process hung when cancelling it due to hosts being unreachable.

31453, 177970816 - Query Optimizer

Resolved an issue in which the optimizer was failing with a segfault while querying a view, if the view had a join between tables and any of the table had a column that was dropped after view creation.

31415 - Server

Resolved an issue in which **REFRESH MATERIALIZED QUERY** was failing if the **WHERE** clause included an embedded query.

31405 - Server

Resolved an issue in which certain queries resulted in a master panic because of the way temporary files were being tracked.

31383 - Server

Resolved an issue that was causing slow query performance for view creation when using the **NOT in** clause.

31380 - Cluster Management

The new functionality for **gprecoverseg** to ignore segments on unreachable hosts had introduced an issue for the **gprecoverseg -p newhost** option as it skipped the case of a new host replacing an unreachable host. This issue is now resolved.

31368 - Cluster Management

Resolved an issue with **gpmovemirror** which caused the wrong error message to be printed when there was an issue with the provided configuration file.

31361 - Query Executor

Resolved an issue in which multiple segments failed with **PANIC** errors due to how newly allocated memory was being handled.

31337 - Query Optimizer

Resolved an issue in which the optimizer was crashing – instead of simply throwing an error – when it was running out of memory.

31297 - Server

Resolved an issue in which **VACUUM FULL ANALYZE** was failing to clear some tables of bloat.

31279 - Server

Resolved an issue with incremental recovery when a failed segment that was acting as primary had to be recovered. The issue was caused by WAL files required by the recovery being removed.

31110 - Server

Resolved an issue in which a View with an unknown field could not be restored because columns were not being correctly cast from type `cstring` to type `date`.

30762 - Server

Resolved an issue with `gpload` in which a global transaction was not aborted when the session was reset.

29998 - Query Optimizer

Resolved an issue in which the optimizer was returning incorrect results when the query involved a CTE with an `EXCEPT` clause. The issue occurred because the query optimizer did not add scalar casts for any input columns whose types did not match the output types of the `SetOp`.

Release 6.16.0

Release Date: 2021-4-22

VMware Tanzu Greenplum 6.16.0 is a minor release that includes feature changes and resolves several issues.

Features

Greenplum Database 6.16.0 includes these new and changed features:

- Greenplum Resource Groups include now a new mode for assigning CPU resources by percentage, Ceiling enforcement mode, apart from the existing Elastic mode.
- The PXF version 6.0.0 distribution is available with this release; you can download it from the *Release Download* directory named *Greenplum Platform Extension Framework* on [VMware Tanzu Network](#). Refer to the [PXF documentation](#) for information about this release and for installation and upgrade instructions.
- Greenplum Streaming Server (GPSS) version 1.5.3 is included, which includes changes and bug fixes. Refer to the [GPSS Documentation](#) for more information about this release and for upgrade instructions.
- Greenplum Database 6.16.0 includes MADlib version 1.18.0, which introduces new Deep Learning features, improvements, and bug fixes. See the [MADlib 1.18.0 Release Notes](#) for a complete list of changes.
- The `gp_sparse_vector` module now installs its functions and objects into a schema named `sparse_vector`. See Resolved Issue 31360.

Note: If you are using `gp_sparse_vector` in your current Greenplum Database distribution, review [Upgrading the gp_sparse_vector Module](#) for upgrade implications and instructions.

- The default value of the `optimizer_join_order` server configuration parameter is changed from `exhaustive2` to `exhaustive`, which was the default used in Greenplum versions prior to version 6.14.0. The Greenplum Database Query Optimizer (GPORCA) uses this configuration parameter to identify the join enumeration algorithm for a query. See Resolved Issue 31391.

Resolved Issues

VMware Tanzu Greenplum 6.16.0 resolves these issues:

31391 - Query Optimizer

Resolves an issue where a query using the GPORCA query optimizer took longer to complete on Greenplum Database version 6.15.0 with the `optimizer_join_order` server configuration parameter default value of `exhaustive2`. The default value of this configuration parameter is

changed (back to) `exhaustive`.

31360 - gp_sparse_vector

Resolves an issue where the `gp_sparse_vector array_agg()` function overrode the system `pg_catalog.array_agg()` function and returned a different type of array. The `gp_sparse_vector` module now installs its functions and objects into a separate schema named `sparse_vector`.

31333 - Optimizer

GPORCA would generate invalid plans for certain queries with scalar subquery in the projection list, and a predicate that could use an underlying index. This could cause Greenplum Database to `PANIC` when running certain functions with the Optimizer enabled. This issue has now been resolved.

31308 - Server

Fixed an issue of queries hanging when logging is configured to write `NOTICE` level messages.

31296 - Server

Fixed an issue with `gpcheckcat` reporting an error when a `VIEW` is defined without a target and does not have an entry in `pg_attribute`.

31272 - Data Flow

In dual stack IPv4 and IPv6 hosts, `gpfdist` would bind to an IPv4 port but fail to bind to an IPv6 port, if there was another process listening on the same IPv6 port. This issue has been resolved.

31259 - Query Optimizer

When querying partitioned tables that had been defined with open boundaries, the Query Optimizer was performing unnecessary scans. This issue has been resolved.

31247 - Cluster Management

`gpstate` would log `ERROR/FATAL` messages relating to `gpexapnd.status` when no expansion was in progress, and when `gpstate -s` output showed a healthy cluster state. This issue has been resolved.

31346 - Query Optimizer

Resolved an issue with incorrect group pathkey that was causing the Greenplum database to go into recovery mode when using `GROUP BY GROUPING SETS`.

11655 - Query Optimizer

Fixed the error `Lookup of object 0.0.0.0 in cache failed` when querying a partitioned table.

11308 - Server

Fixes an issue where a bitmap index scan running concurrently with an index `INSERT` on a full bitmap page, occasionally failed to read the correct `tid`.

Release 6.15

Release 6.15.0

Release Date: 2021-3-11

VMware Tanzu Greenplum 6.15.0 is a minor release that includes changed features and resolves several issues.

Features

Greenplum Database 6.15.0 includes these new and changed features:

- `gprecoverseg` now rebalances segments whose hosts are reachable even if there are other segments whose hosts are not; for segments on unreachable hosts, `gprecoverseg` now emits a warning message.

- Greenplum Streaming Server (GPSS) version 1.5.2 is included, which introduces bug fixes. Refer to the [GPSS Release Notes](#) for more information on release content and to access the GPSS documentation.

Note: If you have previously used GPSS in your Greenplum 6.x installation, you are required to perform upgrade actions as described in [Upgrading the Streaming Server](#).

- The `analyzedb` utility has a new `--skip_orca_root_stats` option. When this option is specified, `analyzedb` will not update root partition statistics. This option should be used only if GPORCA is disabled.

Resolved Issues

VMware Tanzu Greenplum 6.15.0 resolves these issues:

31267 - Server

Fixed error `resource group wait queue is corrupted (resgroup.c:3502)` that caused a `PANIC` on Greenplum Master.

31262 - Server

Resolved an issue with inconsistencies in returned results when using the `grouping` function.

31260/30895 - External Tables

Fixed issue with Web External Tables when `escape='OFF'`.

31249 - Query Optimizer

Certain queries that selected random rows in a partitioned table, using functions like `random()` or `timeofday()`, would cause host `PANIC`. This issue has been resolved.

31244 - analyzedb

Added `--skip_orca_root_stats` option, which prevents `analyzedb` from updating root partition statistics.

31228 - Data Flow

`dblink` includes function `dblink_connect_no_auth` that skips authentication checks.

31223 - Query Optimizer

Fixed optimizer issue with cardinality estimation for point queries on `CDOUBLE` types, such as `timestamp`.

31220 - Data Flow

Resolved an issue in which `gpfdist` reads from external tables were resulting in “No route to host” errors.

31210 - Interconnect

Resolves a high memory usage issue with proxy background worker processes when `gp_interconnect_type = proxy`, and the pause/resume flow control process causes a busy receiver to cache or duplicate packets while waiting for the backend to consume them. Greenplum Database now uses a more active flow control mechanism to control packet buffering and transmission.

31191 - Server

Fixed planner issue of queries crashing with `FailedAssertion` error due to planner issue.

31055 - Server

Prohibits the execution of queries with set returning functions in `WHERE` clause, which caused segment panic. Greenplum now generates an error similar to: `set-returning functions are not allowed in WHERE clause`.

176693327 - Cluster Management

`gpinitssystem` now treats equivalent locales as equivalent (for example, `en_US.UTF-8` is now treated the same as `en_US.utf8`).

176521407 - Cluster Management

Because `gprecoverseg` now reports progress on both incremental and full segment recovery,

there is no longer any need to call `gpstate -m` to determine recovery progress.

Release 6.14

Release 6.14.1

Release Date: 2021-2-22

VMware Tanzu Greenplum 6.14.1 is a maintenance release that resolves several issues and includes related changes

Changed Features

Greenplum Database 6.14.1 includes this change:

- PostGIS version 2.5.4+pivotal.4 is included, which resolves the segfault described in PostGIS ticket [#4691](#).

Resolved Issues

VMware Tanzu Greenplum 6.14.1 resolves these issues:

31258 - Server

Resolves an issue where the `array` typecasts of operands in view definitions with operators were erroneously transformed into `anyarray` typecasts. This caused errors in the backup and restore of the view definitions.

31249 - Query Optimizer

Resolves an issue where Greenplum Database generated a PANIC during query execution when the Query Optimizer attempted to access the argument of a function (such as `random()` or `timeofday()`), but the query did not invoke the function with an argument.

31242 - Server

Optimized locking to resolve an issue with certain `SELECT` queries on the `pg_partitions` system view, which were waiting on locks taken by other operations.

31232 - Server

Resolves an issue where, after an upgrade from version 5.28 to 6.12, a query execution involving external tables resulted in a query PANIC and segment failover. This issue has been resolved by optimizing the query subplans.

31211 - gpfdist

When an external table was configured with a transform, `gpfdist` would sporadically return the error `404 Multiple reader to a pipe is forbidden`. This issue is resolved.

176684985 - Query Optimizer

This release improves Greenplum Database's performance for joins with multiple join predicates.

Release 6.14.0

Release Date: 2021-2-5

VMware Tanzu Greenplum 6.14.0 is a minor release that includes changed features and resolves several issues.

Features

Greenplum Database 6.14.0 includes these new and changed features:

- CentOS/RHEL 8 and SUSE Linux Enterprise Server x86_64 12 (SLES 12) Clients packages

are available with this Greenplum Database release; you can download them from the *Release Download* directory named *Greenplum Clients* on [VMware Tanzu Network](#).

- The PXF version 5.16.1 distribution is available with this release; you can download it from the *Release Download* directory named *Greenplum Platform Extension Framework* on [VMware Tanzu Network](#).
- The default value of the `optimizer_join_order` server configuration parameter is changed from `exhaustive` to `exhaustive2`. The Greenplum Database Query Optimizer (GPORCA) uses this configuration parameter to identify the join enumeration algorithm for a query. With this new default, GPORCA operates with an emphasis on generating join orders that are suitable for dynamic partition elimination. This often results in faster optimization times and/or better execution plans, especially when GPORCA evaluates large joins. The [Faster Optimization of Join Queries in ORCA](#) blog provides additional information about this feature.
- The default cost model for the `optimizer_cost_model` server configuration parameter, `calibrated`, has been enhanced; GPORCA is now more likely to choose a faster bitmap index with nested loop joins rather than hash joins.
- GPORCA boosts query execution performance by improving its partition selection algorithm to more often eliminate the default partition.
- GPORCA now generates a plan alternative for a right outer join transform from a left outer join when equivalent. GPORCA's cost model determines if/when to pick this alternative; using such a plan can greatly improve query execution performance by introducing partition selectors that reduce the number of partitions scanned.
- The output of the `gprecoverseg -a -s` command has been updated to show more verbose progress information. Users can now monitor the progress of the recovering segments in incremental mode.
- The `gpcheckperf` command has been updated to support Internet Protocol version 6 (IPv6).

Resolved Issues

VMware Tanzu Greenplum 6.14.0 resolves these issues:

31195 - Server: Execution

Resolves an issue where Greenplum Database generated a PANIC when the `pg_get_viewdef_name_ext()` function was invoked with a non-view relation.

31094 - Server: Execution

Resolves an issue where a query terminated abnormally with the error `Context should be init first` when `gp_workfile_compression=on` because Greenplum Database ignored a failing return value from a `ZSTD` initialization function.

31067 - Query Optimizer

Resolves a performance issue where GPORCA did not consistently eliminate the default partition when the filter condition in a query matched more than a single partition. GPORCA has improved its partition selection algorithm for predicates that contain only disjunctions of equal comparisons where one side is the partition key by categorizing these comparisons as equal filters.

31062 - Cluster Management

Resolves a documentation and `--help` output issue for the `gprecoverseg`, `gpaddmirrors`, `gpmovemirrors`, `gpinitstandby` utilities, where the `--hba-hostnames` command line flag details were missing.

31044 - Query Optimizer

Fixes a plan optimizer issue where the query would fail due to the planning time being dominated by the sort process of irrelevant indexes.

30974 - Server: Execution

Greenplum Database generated a PANIC when a query run in a utility mode connection invoked the `gp_toolkit.gp_param_setting()` function. This issue is resolved; Greenplum now ignores a function's `EXECUTE ON` options when in utility mode, and executes the function only on the local node.

30950 - Query Optimizer

Resolves an issue where GPORCA did not use dynamic partition elimination and spent a long time planning a query that included a mix of unions, outer joins, and subqueries. GPORCA now caches certain object pointers to avoid repeated metadata lookups, substantially decreasing planning time for such queries when `optimizer_join_order` is set to `query` or `exhaustive2`.

30947 - Query Optimizer

Resolves an issue where Greenplum Database returned the error `no hash_seq_search scan for hash table "Dynamic Table Scan Pid Index"` because GPORCA generated a query plan that incorrectly rescanned a partition selector during dynamic partition elimination. GPORCA now generates a plan that does not demand such a rescan.

11211 - Server

During the parallel recovery and rebalance of segment nodes after a failure, if an error occurred during segment resynchronization, the main recovery process would halt and wait indefinitely. This issue has been fixed.

11058 - Query Optimizer

Resolves an optimizer issue where CTE queries with a `RETURNING` clause would fail with the error `INSERT/UPDATE/DELETE must be executed by a writer segworker group`.

174873438 - Planner

Resolves an issue where an index scan generated for a query involving a system table and a replicated table could return incorrect results. Greenplum no longer generates the index scan in this situation.

Release 6.13

Release 6.13.0

Release Date: 2020-12-18

VMware Tanzu Greenplum 6.13.0 is a minor release that includes changed features and resolves several issues.

Features

Greenplum Database 6.13.0 includes these new and changed features:

- This release introduces the new VMware Tanzu Greenplum Connector for Apache NiFi 1.0.0. The Connector provides a fast and simple, UI-based way to build data ingestion pipelines for Greenplum Database, code-free. The Connector is available as a separate download from [VMware Tanzu Network](#). Refer to the [VMware Tanzu Greenplum Connector for Apache NiFi](#) documentation for installation, configuration, and usage information for the Connector.
 - Greenplum Streaming Server (GPSS) version 1.5.0 is included, which introduces many new and changed features and bug fixes. Refer to the [GPSS Release Notes](#) for more information on release content and to access the GPSS documentation.
- Note:** If you have previously used GPSS in your Greenplum 6.x installation, you are required to perform upgrade actions as described in [Upgrading the Streaming Server](#).
- The distribution includes the `advanced_password_check contrib` module; you can use this

module to specify password string quality policies for Greenplum Database. Refer to the [advanced_password_check](#) module documentation for more information.

- The Greenplum Database Query Optimizer exposes a new server configuration parameter to enable index-only scans. These scans answer queries from an index alone without requiring any heap access. This configuration parameter is named `optimizer_enable_indexonlyscan`, and is enabled by default.

Resolved Issues

VMware Tanzu Greenplum 6.13.0 resolves these issues:

30994 - Cluster Management

Resolved an issue where `gpstart` could fail with a non-descript error when a segment host was unreachable during Greenplum Database initialization. `gpstart` now continues the startup process even if some cluster hosts are unreachable.

31028 - Cluster Management

When using `gpconfig -s client_min_messages` to set the client messaging level (for example “notice” or “warning”), the output showed “error” instead of the level configured by the user. This issue has been resolved.

10720 - Planner

Resolved a problem that could cause the Postgres Planner to crash or return incorrect results if a query used a grouping expression (rather than a column name) along with other ungrouped targets that referenced the group key.

10961 - Locking

Improved the locking behavior to avoid deadlocks that can occur when creating multiple indexes on an Append-Only table.

30951 - Query Optimizer

Resolves an issue where a query performed on a `serial`-type column of a replicated Greenplum table (created `DISTRIBUTED REPLICATED`) failed to return a consistent value on all segments.

30976 - Server: Execution

In some cases, Greenplum Database returned incorrect results when it ran certain system functions in an EntryDb (a special query executor (QE) that runs on the master instance). This issue is resolved; Greenplum now returns the error “`This query is not currently supported by GPDB.`” when it encounters a function invocation that it does not support.

31011 - Server: Execution

Resolved a problem that could cause a segfault when spilling hash tables to disk. In Greenplum 6 this problem was reported with a materialized view query that produced a HashAggregate plan.

31073 - Segment Mirroring

Resolves an issue where the kernel Recv-Q buffer filled up on a Greenplum mirror segment instance when the mirror sent statistics to the statistics collector, but the collector was not running because the mirror was not in hot standby mode.

31082 - Server: Execution

Resolved an issue where the planner generated an incorrect plan for some queries that included a merge join and dynamic partition elimination. The storage needed for the merge join key was incorrectly allocated on the inner side of the plan tree. This led to a SIGSEGV when executing the sort node of the inner side of the merge join. The problem was resolved by ensuring that only the nodes that need to use the join key are provisioned with the right amount of storage, leaving the rest of the plan tree intact.

31090 - Storage: Segment Mirroring

`pg_rewind` was updated to reduce the number of `lstat` operations it performs, in order to

improve the performance of incremental recovery with a large number of data files.

173157638 - Cluster Management

When the user specified a valid port range using the `gpaddmirrors -p` option, `gpaddmirrors` would generate an error similar to `error: Value of port offset supplied via -p option produces ports outside of the valid range. Mirror port base range must be between 6432 and 61000`. This issue has been resolved.

Release 6.12

Release 6.12.1

Release Date: 2020-11-20

VMware Tanzu Greenplum 6.12.1 is a maintenance release that resolves several issues.

Resolved Issues

VMware Tanzu Greenplum 6.12.1 resolves these issues:

9207 - Server Standby

Fixed a memory overflow condition that could cause a standby node to shut down with the error, `"FATAL", "XX000", "the limit of 500 distributed transactions has been reached (cdbdtxrecovery.c:571)"`.

11003 - Postgres Planner

Resolved an issue where a query that selected a constant and that specified one or more empty `GROUPING SETS` returned incorrect results.

30923 - Server Execution, Planner

Resolved a problem where a query could return incorrect results if segments held a NULL value in an empty set.

30946 - Query Optimizer

A query on a table with a `btree` index ran longer than expected because the Query Optimizer did not perform partition elimination when the query included an index join with both a local and a join predicate. This issue is resolved; the Query Optimizer improves dynamic and static partition elimination when indexes are present.

30993 - Optimizer

Fixed an issue where certain IN queries performed slowly because full table scans were used instead of indexes.

30999 - Cluster Management

Fixes an issue where moving a mirror segment to an alternate host, using `gprecoverseg -F`, was failing.

31007 - Cluster Management

Fixes an issue where no error was logged or reported when the incremental recovery of a segment using `gprecoverseg` failed. The logs now include a message similar to: `[WARNING] :- Incremental recovery failed for my-segment-name. You must use gprecoverseg -F to recover the segment.`

31014 - analyzedb

Fixed a problem where `analyzedb` could fail if a table was dropped and recreated during the `analyzedb` operation.

31018 - gpexpand

The redistribute phase of a cluster expansion returned the error `... failed to expand: error ERROR: ... is not a table` when it tried to expand a materialized view. This issue is resolved; Greenplum Database now supports expanding materialized views.

31026 - Metrics Collector

Resolved an issue where Greenplum Command Center version 6.3.0 and 6.3.1 could not show a visual query plan in the query monitor in certain cases.

31057 - Optimizer

When simplifying constraints during preprocessing, GPORCA did not consider the case where a constraint compared a column to an empty array (for example, `EXPLAIN SELECT 1 FROM mytable WHERE mytable.mycolumn=ANY('{}');`). These types of queries would cause GPORCA to crash. This problem was resolved by ensuring that GPORCA now skips merging a constraint with an empty array.

174906043 - Metrics Collector

Resolved an issue where the Greenplum Command Center could not show metrics for `CREATE TABLE AS SELECT ... FROM` and `COPY (SELECT ... FROM ...) TO ...` statements.

175050196 - autovacuum

Resolved a fatal error that could occur when the autovacuum daemon performed a `VACUUM` operation on the `template0` database.

175372920 - Resource Groups

Resolved an issue that could cause queries to fail if an earlier `DROP RESOURCE GROUP` command failed to drop the resource group.

175471857 - Query Dispatcher

Resolved a problem that could cause a transaction to incorrectly use single-phase commit instead of two-phase commit.

275569338 - Query Dispatcher

Resolved a problem that could cause the error, `ERROR: unrecognized node type: 2139062143 (copyfuncs.c:6059)`, when the query dispatcher needed to refresh a materialized view.

Release 6.12.0

Release Date: 2020-10-30

VMware Tanzu Greenplum 6.12.0 is a minor release that includes changed features and resolves several issues.

Features

Greenplum Database 6.12.0 includes these new and changed features:

- Greenplum now supports using segment hostnames when defining proxy ports with the `gp_interconnect_proxy_addresses` parameter (previously, IP addresses were required). Note that if a segment instance hostname is bound to a different IP address at runtime, you must execute `gpstop -U` to re-load the `gp_interconnect_proxy_addresses` value. See [Configuring Proxies for the Greenplum Interconnect](#).
- Because Greenplum Database does not enforce referential integrity syntax (foreign key constraints), the `TRUNCATE` command was updated so that it truncates a table referenced in a foreign key constraint, even if the `CASCADE` option is omitted.
- The Greenplum Database 6.12.0 distribution includes the Greenplum Magic Tool (`gpmt`), a diagnostics and data collection tool.
- The Greenplum Database 6.12.0 distribution includes the `postgres_fdw` PostgreSQL `contrib` module. Refer to the `postgres_fdw` module documentation for more information.

Resolved Issues

VMware Tanzu Greenplum 6.12.0 resolves these issues:

174311661 - Query Execution

When executing a long query that contained multi-byte characters, Greenplum could incorrectly truncate the query string (removing multi-byte characters) and, if `log_min_duration_statement` was set to 0, could subsequently write an invalid symbol to segment logs. This behavior could cause errors in `gp_toolkit` and Command Center. This problem has been resolved.

173190958 - Transactions

In some cases, a Greenplum Database master reset generated one or more orphaned prepared transactions. This issue is resolved; Greenplum now periodically checks for, and aborts, these transactions.

171249005 - Transactions

Resolves an issue where Greenplum Database generated a PANIC when it exhausted retry attempts to abort prepared transactions.

30992 - Transactions

In some cases, Greenplum Database generated a PANIC after reboot due to a race condition between a checkpoint and xlog `COMMIT PREPARE` recording. When Greenplum encountered an orphaned prepared transaction that was committed after the xlog was recorded, it returned the error message: `cannot abort transaction transaction_number, it was already committed`. This issue is resolved.

30970 - Query Optimizer

In some cases, Greenplum Database crashed when the Query Optimizer attempted to generate an index scan from a predicate that contained a subquery. This issue is resolved; the Query Optimizer now disallows such plans.

30962 - Query Optimizer

The second `SELECT` on an external table within a transaction returned zero records because the Query Optimizer did not generate a unique scan number to differentiate the two queries to the external table. This issue is resolved.

30960 - Query Optimizer

Resolves an issue where the Query Optimizer entered an infinite loop when it merged statistics buckets for `double` values in `UNION` and `UNION ALL` queries due to an incorrect comparison of bucket boundary values with a small Epsilon.

30980 - diskquota Module

Resolved an issue that caused master and mirror segments to display the warning, `Share memory is not enough for active tables`, when `TRUNCATE` and `CREATE TABLE` statements were executed.

30942 - Postgres Planner

In some cases, the Postgres Planner crashed or produced incorrect results when the `HAVING` clause of a query included a subquery, and one or more columns referenced in the subquery were not also specified in the `GROUP BY` column set. This issue is resolved.

10813 - Postgres Planner

Resolved an issue that could cause the Query Dispatcher to crash when creating a query plan for a subquery that has `GROUPING SETS`.

10794 - Resource Groups

Resolves an issue where the result of a query on `pg_resgroup_get_status(NULL:oid)` could not be saved to a table.

10376 - Query Execution

Resolved an issue where executing `CREATE UNIQUE INDEX` on a table partition would implicitly change the partition's distribution key.

425 - gpbackup

When inserting into a table that is distributed by a `bpchar` and using the legacy `bpchar` hash operator, rows always used jump consistent hashing instead of legacy (modulo) hashing. This mismatch would cause `gprestore` operations to fail for when restoring Greenplum 4.x/5.x data into Greenplum 6.x. The problem occurred because a required hashing function ID was

missing from a check function that determined if an attribute used legacy hashing. Greenplum 6.12 resolves this issue by adding the required hashing function ID in the check function.

Release 6.11

Release 6.11.2

Release Date: 2020-10-2

Pivotal Greenplum 6.11.2 is a maintenance release that includes changes and resolves several issues.

Changed Features

Greenplum Database 6.11.2 includes these changes:

- Pivotal GPText version 3.4.5 is included, which includes bug fixes. See the [GPText 3.4.5 Release Notes](#) for more information.
- Pivotal Greenplum-Spark connector version 2.0.0 is included, which includes feature changes and bug fixes. See the [Greenplum-Spark Connector 2.0.0 Release Notes](#) for more information.

Resolved Issues

Pivotal Greenplum 6.11.2 resolves these issues:

30549 - Management and Monitoring

Greenplum excluded externally-routable loopback addresses from replication entries, which caused utilities such as `gpinitstandby` and `gpaddmirrors` to fail. This problem has been resolved.

30795 - GPORCA

Fixed a problem where GPORCA did not utilize an index scan for certain subqueries, which could lead to poor performance for affected queries.

30878 - GPORCA

If a `CREATE TABLE .. AS` statement was used to create a table with non-legacy (jump consistent) hash algorithm distribution from a source table that used the legacy (modulo) hash algorithm, GPORCA would distribute the data according to the value of `gp_use_legacy_hashops`; however, it would set the table's distribution policy hash algorithm to the value of the original table. This could cause queries to give incorrect results if the distribution policy did not match the data distribution. This problem has been resolved.

30903 / 30966 - Metrics Collector

Workfile entries were sometimes freed prematurely, which could lead to the `postmaster` process being reset on segments and failures in query execution, or segment PANIC. This problem has been resolved.

30928 - GPORCA

If `gp_use_legacy_hashops` was enabled, GPORCA could crash when generating the query plan for certain queries that included an aggregate. This problem has been resolved.

174812955 - Query Execution

When executing a long query that contained multi-byte characters, Greenplum could incorrectly truncate the query string (removing multi-byte characters) and, if `log_min_duration_statement` was set to 0, could subsequently write an invalid symbol to segment logs. This behavior could cause errors in `gp_toolkit` and Command Center. This problem has been resolved.

Release 6.11.1

Release Date: 2020-09-17

Pivotal Greenplum 6.11.1 is a maintenance release that includes changes and resolves several issues.

Changed Features

Greenplum Database 6.11.1 includes this change:

- Greenplum Platform Extension Framework (PXF) version 5.15.1 is included, which includes changes and bug fixes. Refer to the [PXF Release Notes](#) for more information on release content and to access the PXF documentation.

Resolved Issues

Pivotal Greenplum 6.11.1 resolves these issues:

30751, 173714727 - Query Optimizer

Resolves an issue where a correlated subquery that contained at least one left or right outer join caused the Greenplum Database master to crash when the server configuration parameter `optimizer_join_order` was set to `exhaustive2`.

30880 - gpload

Fixed a problem where `gpload` operations would fail if a table column name included capital letters or special characters.

30901 - GPORCA

For queries that included an outer ref in a subquery, such as `select * from foo where foo.a = (select foo.b from bar)`, GPORCA always used the results of the subquery after unnesting the outer reference. This could cause a crash or incorrect results if the subquery returned no rows, or if the subquery contained a projection with multiple values below the outer reference. To address this problem, all such queries now fall back to using the Postgres planner instead of GPORCA. Note that this behavior occurs for cases where GPORCA would have returned correct results, as well as for cases that could cause crashes or return incorrect results.

30913, 170824967 - gpfdists

A command that accessed an external table using the `gpfdists` protocol failed if the external table did not use an IP address when specifying a host system in the `LOCATION` clause of the external table definition. This issue is resolved in Greenplum 6.11.1.

174609237 - gpstart

`gpstart` was updated so that it does not attempt to start a standby master segment when that segment is unreachable, preventing an associated stack trace during startup.

Release 6.11.0

Release Date: 2020-09-11

Pivotal Greenplum 6.11.0 is a minor release that includes changed features and resolves several issues.

Features

Greenplum Database 6.11.0 includes these new and changed features:

- GPORCA partition elimination has been enhanced to support a subset of lossy assignment casts that are order-preserving (increasing) functions, including `timestamp::date` and `float::int`. For example, GPORCA supports partition elimination when a partition column is defined with the `timestamp` datatype and the query contains a predicate such as `WHERE`

`ts::date == '2020-05-10'` that performs a cast on the partitioned column (`ts`) to compare column data (a `timestamp`) to a `date`.

- PXF version 5.15.0 is included, which includes new and changed features and bug fixes. Refer to the [PXF Release Notes](#) for more information on release content and supported platforms, and to access the PXF documentation.
- Greenplum Command Center 6.3.0 and 4.11.0 are included, which include new workload management and other features, as well as bug fixes. See the Command Center [Release Notes](#) for more information.
- The query dispatcher now supports the PostgreSQL `LISTEN`, `UNLISTEN`, and `NOTIFY` commands.
- The DataDirect ODBC Drivers for Pivotal Greenplum were updated to version 07.16.0389 (B0562, U0408). This version introduces support for the following datatypes:

Greenplum Datatype	ODBC Datatype
citext	SQL_LONGVARCHAR
float	SQL_REAL
tinyint	SQL_SMALLINT
wchar	SQL_CHAR
wvarchar	SQL_VARCHAR

Resolved Issues

Pivotal Greenplum 6.11.0 resolves these issues:

30899 - Resource Groups

In some cases when running queries are managed by resource groups, Greenplum Database generated a PANIC when managing runaway queries (queries that use an excessive amount of memory) because of locking issues. This issue is resolved.

30877 - VACUUM

In some cases, running `VACUUM` returns `ERROR: found xmin <xid> from before relfrozenxid <frozen_xid>`. The error was caused when a previously run `VACUUM FULL` was interrupted and aborted on a query executor (QE) and corrupted catalog frozen XID information. This issue is resolved.

30870 - Segment Mirroring

In some cases, performing an incremental recovery of a Greenplum Database segment instance failed with the message `requested WAL segment has already been removed` because the recovery checkpoint was not created properly. This issue is resolved.

30858 - analyzedb

`analyzedb` failed if `analyzedb` attempted to update statistics for a set of tables and one of the tables was dropped and then recreated while `analyzedb` was running. `analyzedb` has been enhanced better handle the specified situation.

30845 - Query Execution

Under heavy load when running multiple queries, some queries randomly failed with the error `Error on receive from seg<ID>`. The error was caused when Greenplum Database encountered a divide by 0 error while managing the backend processes that are used to run queries on the segment instances. This issue is resolved.

30761 - Postgres Planner

In some cases, Greenplum Database generated a PANIC when a `DROP VIEW` command was cancelled from the Greenplum Command Center. The PANIC was generated when

Greenplum Database did not correctly handle the visibility of the relation.

30721 - gpcheckcat

Resolved a problem where `gpcheckcat` would fail with `Missing or extraneous entries check` errors if the `gp_sparse_vector` extension was installed.

30637 - Query Optimizer

For some queries against partitioned tables, GPORCA did not perform partition elimination when a predicate that includes the partition column also performs an explicit cast. For example, GPORCA would not perform partition elimination when a partition column is defined with the `timestamp` datatype and the query contains a predicate such as `WHERE ts::date == '2020-05-10'` that performs a cast on the partitioned column (`ts`) to compare column data (a `timestamp`) to a `date`. GPORCA partition elimination has been improved to support the specified type of query. See [Features](#).

10491 - Postgres Planner

For some queries that contain nested subqueries that do not specify a relation and also contain a nested `GROUP BY` clauses, Greenplum Database generated a PANIC. The PANIC was generated when Greenplum Database did not correctly manage the subquery correctly. This is an example of the specified type or query.

```
SELECT * FROM (SELECT * FROM (SELECT c1, SUM(c2) c2 FROM mytbl GROUP BY c1 ) t2 )
t3
GROUP BY c2, ROLLUP((c1))
ORDER BY 1, 2;
```

This issue is resolved.

10561 - Server

Greenplum Database does not support altering the datatype of a column defined as a distribution key or with a constraint. When attempting to change the datatype, the error message did not clearly indicate the cause. The error message has been altered to provide more information.

174505130 - Resource Groups

In some cases for a query managed by resource group, the resource group cancelled the query with the message `Canceled query because of high VMEM usage` because the resource group calculated the incorrect memory used by the query. This issue is resolved.

174353156 - Interconnect

In some cases when Greenplum Database uses proxies for interconnect communication (the server configuration parameter `gp_interconnect_type` is set to `proxy`), a Greenplum background worker process became an orphaned process after the postmaster process was terminated. This issue is resolved.

174205590 - Interconnect

When Greenplum Database uses proxies for interconnect communication (the server configuration parameter `gp_interconnect_type` is set to `proxy`), a query might have hung if the query contains multiple concurrent subplans running on the segment instances. The query hung when the Greenplum interconnect did not properly handle the communication among the concurrent subplans. This issue is resolved.

174483149 - Cluster Management - gpinitssystem

`gpinitssystem` now exports the `MASTER_DATA_DIRECTORY` environment variable before calling `gpconfig`, to avoid throwing warning messages when configuring system parameters on Greenplum Database appliances (DCA).

Release 6.10

Release 6.10.1

Release Date: 2020-08-13

Pivotal Greenplum 6.10.1 is a maintenance release that resolves known issues.

Resolved Issues

Pivotal Greenplum 6.10.1 resolves these issues:

n/a

Code changes and testing for the Greenplum [interconnect proxy feature](#) were introduced in version 6.10.0, but the feature was not enabled in the final release build. Version 6.10.1 resolves this problem and enables the feature.

10009 External table DELIMITER OFF BUG

Fixed a problem where additional data could be included after the last column of an external table if the `DELIMITER 'OFF'` formatting option was used when creating the table.

Release 6.10.0

Release Date: 2020-08-07

Pivotal Greenplum 6.10.0 is a minor release that includes changed features and resolves several issues.

Features

Greenplum Database 6.10.0 includes these new and changed features:

- Greenplum Database 6.10 introduces the server configuration parameter `max_slot_wal_keep_size` that sets the maximum size in megabytes of replication WAL log files on disk per segment instance. The default is -1, Greenplum can retain an unlimited amount of WAL files on disk.
- Greenplum Database 6.10 introduces the server configuration parameter `gp_add_column_inherits_table_setting` for append-optimized, column-oriented tables. When adding a column to a table with the `ALTER TABLE` command, the parameter controls whether the table's data compression parameters for a column (`compress_type`, `compress_level`, and `blocksize`) can be inherited from `WITH` clause values when the table was created. The default is `off`, the table's data compression settings are not considered when adding a column to the table. If the value is `on`, the table's `WITH` clause values are considered.
- When reading data, the `gpload` utility now supports the control file parameter `FILL_MISSING_FIELDS` that can add `NULL` values to a data row if the row has trailing field values that are missing. To enable this feature, set the parameter to `true`.
- Greenplum Database supports using proxies for Greenplum Database interconnect communication to reduce the use of connections and ports during query processing. The interconnect proxies consumes fewer connections and ports than `TCP` mode, and has better performance than `UDPIFC` mode in a high-latency network.

To enable interconnect proxies for the Greenplum system, set these system configuration parameters.

- List the proxy ports with the new parameter `gp_interconnect_proxy_addresses`. You must specify a proxy port for the master, standby master, and all segment instances.
- Set the parameter `gp_interconnect_type` to `proxy`. The `proxy` value is new in Greenplum Database 6.10.

Note: Code changes and testing for the Greenplum interconnect proxy feature were introduced in version 6.10.0, but the feature was not enabled in the final release build. Use version 6.10.1 to enable the feature.

- The PgBouncer connection pooler was updated from version 1.8.1 to version 1.13. To support this change on RHEL/CentOS 6 platforms, the Greenplum Database package now requires `libevent2` instead of `libevent`. RHEL/CentOS 7 requirements are unchanged. See the [PgBouncer 1.13.x Release Notes](#) for a summary of changes.
- The `gpcheckcat` catalog verification utility adds a new test, `aoseg_table`, that you can use to check that the vertical partition information on append-optimized, column storage tables is consistent with `pg_attribute`.
- Greenplum Database 6.10 introduces a new server configuration parameter, `gp_fts_replication_attempt_count`, that you can use to configure the maximum number of times that the Greenplum fault tolerance service (FTS) attempts to establish a primary-mirror replication connection.
- PXF version 5.14.0 is included, which includes new and changed features and bug fixes. Refer to the [PXF Release Notes](#) for more information on release content and supported platforms, and to access the PXF documentation.
- Greenplum Streaming Server (GPSS) version 1.4.1 is included, which includes changes and bug fixes. Refer to the [GPSS Release Notes](#) for more information on release content and to access the GPSS documentation.

Note: If you have previously used GPSS in your Greenplum 6.x installation, you are required to perform upgrade actions as described in [Upgrading the Streaming Server](#).

Resolved Issues

Pivotal Greenplum 6.10.0 resolves these issues:

30554 - ANALYZE, gpstore

In some cases, when performing concurrent `ANALYZE` operations on large partition tables generated the error `Canceling query because of high VMEM usage`. This issue occurred during some restore operations with `gpstore`. This issue is resolved.

30583 - Transaction Management

In some cases, a segment mirror went offline when the replication WAL log files on the mirror system caused disk full issues. Greenplum Database introduces the server configuration parameter `max_slot_wal_keep_size` to limit the amount of WAL logs stored on disk. See [Features](#).

30792 - Logging

Resolves a disk space issue encountered when a query that generated a large number of spill files also generated an excessive number of `HashJoin: Too many batches computed` log messages by decreasing the severity level of the message.

173680224 - gpcoverseg

In some cases, `gpcoverseg` hangs when performing an incremental recovery while trying to perform a clean shutdown of the segment instance due to a locking issue. This issue is resolved.

30781, [9427](#) - Postgres Planner

For some queries that perform joins between partitioned tables, Greenplum Database returned `ERROR: unrecognized path type 106`. This issue is resolved.

[10419](#) - Postgres Planner

In some cases when generating query plans, the Postgres Planner did not handle volatile functions correctly and allowed multiple executions of the function during query execution.

This could cause incorrect results. This issue is resolved.

30692 - System Catalog Functions

`pg_get_viewdef()` returned an incorrect view definition when the view was created with the Greenplum-specific `CASE WHEN (arg1) IS NOT DISTINCT FROM (arg2)` clause. This issue is resolved.

30558 - Query Optimizer

Resolves an issue where execution time and spill file size increased for a query on a larger width table because Greenplum Database overestimated row cardinality when the query specified multiple predicates that included distribution keys.

30512 - MPP: Dispatch

Resolves an issue where Greenplum Database hung while continuously retrying a primary-mirror replication connection. Greenplum 6.10 introduces a new server configuration parameter, `gp_fts_replication_attempt_count`, with which you can configure the maximum number of retry attempts.

10141 - ALTER TABLE ... INHERIT

Greenplum Database restricted you from creating both a replicated table that inherits from another table, and a table that inherits from a replicated table, but Greenplum did allow you to use the `ALTER TABLE ... INHERIT` command to assign inheritance to/from a replicated table after it was created. Update commands on such a table returned the misleading error `ModifyTable mixes distributed and entry-only tables`. This issue is resolved; Greenplum 6.10 enforces replicated table inheritance restrictions uniformly, including on `ALTER TABLE ... INHERIT` statements.

10057 - Server: Transactions

Greenplum Database returned the error `Too many distributed transactions for snapshot` when processing many distributed transactions and the `max_prepared_transactions` server configuration parameter was set to a low value. This issue is resolved; Greenplum now uses a more robust method to determine the maximum number of distributed transactions.

10030 - Server: Query Execution

Greenplum Database incorrectly used the value of the `gp_enable_global_deadlock_detector` server configuration parameter on query executors to determine the lock mode. This issue is resolved, the parameter is now master only.

9896 - gpexpand

`gpexpand` failed on a partitioned Greenplum Database table that included an external table leaf child partition. This issue is resolved; Greenplum Database now skips external table partitions during expansion.

9207 - Server: Transactions

In certain situations, the Greenplum Database standby master host shutdown down and exited abnormally with the FATAL error `the limit of *N* distributed transactions has been reached` when the global transaction limit was exceeded. This issue is resolved; Greenplum now uses a more robust method to determine the maximum number of distributed transactions.

173219210 - Resource Groups

The Greenplum Database `gp_toolkit.gp_resgroup_status_per_host` view incorrectly reported CPU usage as the sum of resource group CPU usage on all segments on the same host. This issue is resolved; Greenplum Database now correctly reports the average CPU usage of resource groups on all segments on the host.

171849582 - Tablespace

Greenplum Database generated a PANIC when it did not check for the existence of a tablespace directory before attempting to delete the directory. This issue is resolved.

Release 6.9

Release 6.9.1

Release Date: 2020-07-24

Pivotal Greenplum 6.9.1 is a maintenance release that resolves several issues.

Note: Greenplum 6.9.1 also includes the Greenplum Database R Client (GreenplumR) version 1.1.0. This version of GreenplumR adds the `input.signature` argument to `db.gpapply()` and `db.gptapply()`, to match function argument names to table column names when the function input argument is not a single data frame. See [Greenplum Database R Client](#).

Resolved Issues

Pivotal Greenplum 6.9.1 resolves these issues:

n/a

The DataDirect ODBC Drivers were updated to version 7.16.359 to incorporate hot fix changes and certify compatibility with SUSE Linux Enterprise Server 15 clients. See the [DataDirect Release Notes](#) for additional information.

10230, 31582 - Server: Execution

Greenplum Database generated a segmentation fault during execution of a hash aggregate query when it incorrectly initialized a tuple memory context for a partitioned table that contained a btree index. This issue is resolved.

30750

The `ANALYZE` code did not exclude external tables (which cannot be analyzed) if an external table was part of a table partition hierarchy. This would result in the failure `ERROR: unsupported table type` when performing partitioned table operations that use `ANALYZE`, such as `ALTER TABLE ... EXCHANGE PARTITION`. The problem was resolved by updating the `ANALYZE` code to correctly exclude these external tables.

Release 6.9.0

Release Date: 2020-06-26

Pivotal Greenplum 6.9.0 is a minor release that includes changed features and resolves several issues.

Features

Greenplum Database 6.9.0 includes these new and changed features:

- Greenplum Streaming Server (GPSS) version 1.4.0 is included, which introduces many new and changed features and bug fixes. Refer to the [GPSS Release Notes](#) for more information on release content and to access the GPSS documentation.
Note: If you have previously used GPSS in your Greenplum 6.x installation, you are required to perform upgrade actions as described in [Upgrading the Streaming Server](#).
- PXF version 5.13.0 is included, the first PXF release to also provide a separate download package that enables you to install PXF in a file system location outside of the Greenplum install directory. Refer to the [PXF Release Notes](#) for more information on release content and supported platforms, and to access the PXF documentation.

Resolved Issues

Pivotal Greenplum 6.9.0 resolves these issues:

30630 - Segment Mirroring

In some cases during a failover of a segment instance, Greenplum Database returned the FATAL error `requested WAL segment WAL_seg_ID has already been removed`. Greenplum Database WAL replication incorrectly removed segment files before they were processed during failover. This issue is resolved.

10216 - ALTER TABLE, ALTER DOMAIN

In some cases, heap table data is lost when performing concurrent `ALTER TABLE` or `ALTER DOMAIN` commands where one command alters a table column and the other rewrites or redistributes the table data. For example, performing concurrent `ALTER TABLE` commands where one command changes a column data type from `int` to `text` might cause data loss. This issue might also occur when altering a table column during the data distribution phase of a Greenplum system expansion. Greenplum Database did not correctly capture the current state of the table during command execution. This issue is resolved.

10224 - ALTER TABLE

For a leaf partition of a partitioned table, `ALTER TABLE` allowed the distribution policy to be changed to `REPLICATED`. This is resolved. `ALTER TABLE` no longer allows the change.

30647 - Postgres Planner

Some queries that performed multistage aggregation returned results in the incorrect order. For example, some queries that perform a `COUNT` in the select list and also contain a `GROUP BY` clause returned results in the incorrect order. This issue is resolved.

10013 - Postgres Planner

In some cases, Greenplum Database generated a PANIC when it encountered a lateral subquery that included a `LIMIT 1` or `GROUP BY` clause. Greenplum 6.9 resolves this issue by forcing the gathering and materialization of any relation containing a `GROUP BY` or `LIMIT` clause.

10315 Postgres Planner

For some queries that perform a `FULL JOIN` using a subselect that contains a `COALESCE` function, Greenplum Database returned "ERROR: could not find hash distribution key expressions in target list". This issue is resolved.

8919 - MPP, Query Execution

Greenplum Database did not properly handle concurrent updating operations to a table when one of the operations moved a table distribution key to another segment instance. Now when a table distribution key is moved to another segment instance, a concurrent updating operation returns an error.

173243811 - Resource Groups

When resource groups are enabled and a user attempted to move a running query from one resource group to a resource group configured using the `memory_limit=0` with the `pg_resgroup_move_query()` function, Greenplum Database returned the error `ERROR: group <group_ID> doesn't have enough memory on master`. This issue is resolved.

172931886 - Transaction System

Greenplum 6.9 resolves an issue where restarting a primary could lead to a segment process hang when there were prepared, but not yet committed or aborted, transactions in progress at the time of shutdown.

Release 6.8

Release 6.8.1

Release Date: 2020-06-11

Pivotal Greenplum 6.8.1 is a maintenance release that contains a changed feature and resolves several issues.

Changed Feature

The Greenplum PostGIS extension package has been updated to `postgis-2.5.4+pivotal.2`. The release contains these changes:

- Adds support for the PostGIS TIGER geocoder extension and the PostGIS address standardizer and address rules files extensions.
- Removes PostGIS Raster function limitations.
- Uses the `CREATE EXTENSION` and `DROP EXTENSION` commands to enable and disable support for the PostGIS extension and supported, optional PostGIS extensions.

Note: The `postgis_manager.sh` script is deprecated and will be removed in a future release of Greenplum PostGIS. To enable or disable PostGIS support, use the `CREATE EXTENSION` or `DROP EXTENSION` command. See [Enabling and Removing PostGIS Support](#)

Resolved Issues

Pivotal Greenplum 6.8.1 resolves these issues:

30664 - Query Optimizer

For a complex CTAS query that has implicit casts in the project list, GPORCA may generate a plan with duplicate eliminating motions, to ensure correctness. However, if a duplicate eliminating motion is performed under the hash operation of a Hash Join, an implicit cast operation creates an additional column that causes memtuple binding issues in the executor. To address this problem, GPORCA now generates a modified plan that prunes the output of any duplicate eliminating motions before sending the output to the hash operation.

30684 - Query Optimizer

GPORCA returned incorrect results for some queries when the query's select list contains a window function and the window function contains a correlated subquery or an outer reference. Now the query falls back to the Postgres planner.

30615 - Query Optimizer

GPORCA query performance degraded when compared with Greenplum 5 for some queries that perform joins using an equality predicate and the equality predicate contains a function, for example `coalesce(tbl1.a, '999999') = coalesce(tbl2.a, '999999')`. The performance issue was caused by inaccurate cardinality estimates. GPORCA cardinality estimation has been improved for the specified type of query.

172732495, 9953 - query execution

Greenplum Database generated a PANIC when executing a query that executes multiple user-defined functions and more than one of the functions is defined with the `EXECUTE ON INITPLAN` attribute. This issue is resolved.

172098556 - psql

Resolved a problem where the `psql` client `\dm` command did not display materialized views.

172094194, 9837 - gprecoverseg

In some cases when recovering segment instances using the `gprecoverseg` utility with the `-i <recover_config_file>` option to specify details about failed segments to recover, the utility changed some segment instance `dbid` values in the Greenplum system configuration. This issue is resolved.

Release 6.8.0

Release Date: 2020-06-05

Pivotal Greenplum 6.8.0 is a minor release that includes changed features and resolves several issues.

Features

Greenplum Database 6.8.0 includes these new and changed features:

- Greenplum Streaming Server (GPSS) version 1.3.6 is included, which introduces many new and changed features and bug fixes since the last GPSS version installed in Greenplum 6.x (1.3.1). Refer to the [GPSS Release Notes](#) for more information on release content and to access the GPSS documentation.

Note: If you have previously used GPSS in your Greenplum 6.x installation, you are required to perform upgrade actions as described in [Upgrading the Streaming Server](#).

- The `gpinitssystem` input configuration file specified with the `-I` option supports an additional format to specify hosts. The `QD_PRIMARY_ARRAY`, `PRIMARY_ARRAY`, and `MIRROR_ARRAY` host parameters may now be specified using either of the following formats:

```
host~port~data_directory/seg_prefix<segment_id>~dbid~content_id
```

```
hostname~address~port~data_directory/seg_prefix<segment_id>~dbid~content_id
```

The first format, which is the pre-existing format, sets both the `hostname` and `address` columns of the `gp_segment_configuration` catalog table to the value in the `host` field. The second format sets the `hostname` and `address` columns of the `gp_segment_configuration` catalog table to the values in the respective `hostname` and `address` fields.

- PXF version 5.12.0 is included, which introduces new and changed features and bug fixes. See [PXF Version 5.12.0](#) below.
- PL/Container version 2.1.2 is included, which introduces the following new features:
 - Support for R version 3.6.3.
 - A new `--use_local_copy` option to the `plcontainer add-image` command that you can use to install the specified image only on the local host.
- Greenplum Database 6.8 adds support for [Moving a Query to a Different Resource Group](#).
- Greenplum Database 6.8 includes a new metrics collector extension that is compatible with Greenplum Command Center 6.2 and above. If you are using Command Center 6.0 or 6.1 you must download and install Command Center 6.2 after you install Greenplum Database 6.8.

PXF Version 5.12.0

PXF includes the following new and changed features:

- PXF trims right-padded white space added by Greenplum before it writes Parquet data.
- PXF bundles newer `hive`, `jackson-databind`, and supporting internal libraries.
- A PXF server running on Java 11 can now read from Hive using an external table that specifies a `Hive*` profile.
- PXF introduces the new custom option `IGNORE_MISSING_PATH` for external tables that you use to read file-based data. Setting this option may be useful when a PXF external table is a child partition of a partitioned Greenplum table. Refer to [About PXF External Table Child Partitions](#) for more information.
- PXF bundles the `jodd-core` library to satisfy a missing transitive dependency that is required when PXF reads Parquet files that contain data in timestamp format.
- PXF adds column projection support for the `Hive` and `HiveRC` profiles by changing the

implementation to use column name-based, rather than column index-based, mapping.

Note: If you have existing PXF external tables that specify a `Hive*` profile, you may be required to perform upgrade actions as described in [Upgrading PXF](#).

Resolved Issues

Pivotal Greenplum 6.8.0 resolves these issues:

329, 30602 - PXF

PXF did not correctly read a partitioned Hive table when the external table specified a `Hive*` profile and the external table and Hive table had a differing number of columns. This issue is resolved. PXF now supports column projection for the `Hive*` profiles and correctly handles this situation.

30611 - Query Optimizer

When falling back to the Postgres planner, GPORCA incorrectly logged messages that were internal messages. This made the log file difficult to read and caused bloat in the file. This issue is resolved. GPORCA message logging has been improved and the internal messages are no longer sent to the log files.

30585 - Locking

Resolved a problem that could corrupt resource queue locks, and potentially other types of locks, in shared memory. This problem could cause errors such as `lock lock_name on object object_identifier is already held`.

30557 - DDL

When performing a data reorganization with the `ALTER TABLE` command on a leaf partition of a partitioned table that did not change the distribution policy, Greenplum Database returned the error `ERROR: can't set the distribution policy`. This type of redistribution is allowed in Greenplum 5. Now Greenplum allows data reorganization on a leaf partition if the distribution policy is not changed.

30289 - Query Optimizer

When GPORCA performed dynamic partition elimination for some queries against partitioned tables that perform joins, GPORCA was not using the correct statistics. This caused a performance degradation when compared with Greenplum 5. GPORCA has improved how statistics are computed for the specified type of query.

172854840 - Interconnect

In some cases, a query that executes a stable function that contains an SQL statement might hang because the query dispatcher (QD) did not correctly manage the execution of the function and the dispatching of the query plan. This issue is resolved.

172832212 - Interconnect

In some cases, communication between a query dispatcher (QD) and a query executor (QE) on different segments was slow when the Greenplum interconnect type is set to the TCP networking protocol for Greenplum Database interconnect traffic. Now the communication between a QD and a QE is more efficient.

172615233 - Query Optimizer

For text data types, the GPORCA the cardinality estimation algorithm has been improved for equality comparisons. For example, when a query contains an IN clause that contains text elements.

172576000 - COPY

If data format errors occurred while copying data into a partitioned table with a `COPY FROM` command in single row error isolation mode, Greenplum Database might crash when a query executor (QE) did not handle the data format error correctly. This issue is resolved.

30487 - Utility Commands

On a Greenplum Database 6 system with FIPS enabled, Greenplum utility commands such as

`gpinitssystem` returned the error "ERROR:root:code for hash md5 was not found." This issue is resolved.

30484 - Utility Commands

When initializing a Greenplum Database system with `gpinitssystem`, the primary segments were erroneously named using DNS resolvable external hostnames instead of the internal interconnect interface hostnames. At the same time, the segment mirrors were correctly named. This issue is now resolved.

Release 6.7

Release 6.7.1

Release Date: 2020-04-30

Pivotal Greenplum 6.7.1 is a maintenance release that resolves several issues. In addition to these resolved issues:

- Version 6.7.1 updates PostGIS to version 2.5.4, which removes several previous limitations. See [Geospatial Analytics](#) for more information.
- The Greenplum R client is no longer considered a Beta feature.

Resolved Issues

Pivotal Greenplum 6.7.1 resolves these issues:

n/a - MADlib

In Greenplum 6.7.0 the MADlib download files that were originally provided, `madlib-1.17.0+2-gp6-rhel7-x86_64.tar.gz` and `madlib-1.17.0+2-gp6-rhel6-x86_64.tar.gz`, contained MADlib version 1.16 instead of version 1.17. This is resolved in Greenplum 6.7.1, and in Greenplum 6.7.0 with the newly-provided files `madlib-1.17.0+3-gp6-rhel7-x86_64.tar.gz` and `madlib-1.17.0+3-gp6-rhel6-x86_64.tar.gz`.

9790 - Server

A crash could occur when performing a `SELECT` query against a column-oriented table, when the table was created using the `WITH NO DATA` clause. The problem occurred because the `WITH` clause options were not correctly added to the `pg_attribute_encoding` table. This problem has been resolved.

30499 - Server: Execution

Fixed a memory leak that occurred when executing `CHECKPOINT` commands.

30559 - Query Optimizer

Queries that contain an `IN` clause with a large number of constants took a long time to generate a query plan. Most of the time was spent estimating the cardinality of the `IN` clause predicate. The cardinality estimation algorithm has been enhanced and significantly reduces the cardinality estimation time for the specified type of query.

30579 - Interconnect

In some cases during query execution, the query hung with the query dispatcher (QD) waiting for the query executor (QE) on a few segment instances to complete. This issue is resolved.

30844 - gpreload

`gpreload` returned the error `more than one row returned` when attempting to reload a table and a view with the same name exists in a different schema in the database. This issue is resolved.

172163076 - Server

A subtransaction would incorrectly use 1-phase commit instead of 2-phase commit if `\set ON_ERROR_ROLLBACK interactive` was enabled in a client's `.psqlrc` file. This problem has

been resolved.

172324858, 9891 - MPP: Locking, Signals, Processes

In some cases, Greenplum Database did not manage snapshots correctly when processing concurrent distributed transactions. This caused a concurrent transaction to access a distributed log file that was no longer available and generated the error message `Could not open file "pg_distributedlog/<file-name>": No such file or directory`. This issue is resolved.

172348849 - Postgres Planner

Some queries that contain a `UNION ALL` that combines the results from `SELECT` command that uses a replicated table with another `SELECT` command returns the error `ERROR: could not build Motion path`. This issue is resolved.

172284550 9823 - ALTER DATABASE

The `ALTER DATABASE...FROM CURRENT` command did not set a server configuration parameter for a database. This issue is resolved.

Release 6.7.0

Release Date: 2020-04-17

Pivotal Greenplum 6.7.0 is a minor release that includes changed features and resolves several issues.

Features

Greenplum Database 6.7.0 includes these new and changed features:

- Greenplum Database 6.7 introduces the new `gp_resource_group_queuing_timeout` server configuration parameter. When the resource group-based resource management scheme is active, `gp_resource_group_queuing_timeout` specifies the maximum amount of time a transaction waits for execution in a queue on a resource group before Greenplum Database cancels the transaction. By default, queued transactions in a resource group can wait indefinitely.
- Greenplum Database 6.7 includes MADlib version 1.17, which introduces new Deep Learning features, k-Means clustering, and other improvements and bug fixes. See the [Apache MADlib](#) page for additional information and Release Notes.

Note: In Greenplum 6.7.0 the MADlib download files that were originally provided, `madlib-1.17.0+2-gp6-rhel7-x86_64.tar.gz` and `madlib-1.17.0+2-gp6-rhel6-x86_64.tar.gz`, contained MADlib version 1.16 instead of version 1.17. This is resolved in Greenplum 6.7.1, and in Greenplum 6.7.0 with the newly-provided files `madlib-1.17.0+3-gp6-rhel7-x86_64.tar.gz` and `madlib-1.17.0+3-gp6-rhel6-x86_64.tar.gz`.

Resolved Issues

Pivotal Greenplum 6.7.0 resolves these issues:

8539 - Server

Using `NOWAIT` in a `SELECT FOR UPDATE` statement could result in the error, `ERROR: relation "<name>" does not exist`, because locking was not correctly handled for the `NOWAIT` clause. This problem has been resolved. Note, however, that `NOWAIT` only affects how the `SELECT` statement obtains row-level locks. A `SELECT FOR UPDATE NOWAIT` statement will always wait for the required table-level lock; it behaves as if `NOWAIT` was omitted.

9089 - Server

Fixed a problem where Greenplum Database failed to truncate an append-only, column-

oriented table if the `CREATE TABLE` and `TRUNCATE` statements were executed in the same transaction.

30305 - Resource Groups

A transaction may be queued for execution on a resource group for an extended period of time, particularly when the resource group reached its concurrent transaction limit. This could prevent queries initiated by Greenplum Database superusers from executing. Greenplum Database 6.7 resolves this issue by introducing the `gp_resource_group_queuing_timeout` server configuration parameter, which specifies the maximum amount of time a queued transaction waits for execution in a resource group before Greenplum cancels the transaction.

30531 - Query Optimizer

An out of memory error occurred when running some queries that contain joins that perform a comparison operation on `citext` data. The error occurred because the query falls back to the Postgres Planner. This issue is resolved. Now the query does not fall back to the Postgres planner, the query is executed using GPORCA.

30536 - PL/pgSQL

In a PL/pgSQL procedure, output text from a `RAISE NOTICE` statement was not displayed correctly if the text contained a newline (line feed) character. Only the text before the newline character was displayed. This issue is resolved.

Release 6.6

Release 6.6.0

Release Date: 2020-04-06

Pivotal Greenplum 6.6.0 is a minor release that includes changed features and resolves several issues.

Features

Greenplum Database 6.6.0 includes these new and changed features:

- For the `CREATE EXTERNAL TABLE` command, the `LOG ERRORS` clause now supports the `PERSISTENTLY` keyword. The `LOG ERRORS` clause logs information about external table data rows with formatting errors. The error log data is stored internally. When you specify `LOG ERRORS PERSISTENTLY`, the log data persists after the external table is dropped.

If you use the `PERSISTENTLY` keyword, you must install the functions that manage the persistent error log information.

For information about the error log information and built-in functions for viewing and managing error log information, see [CREATE EXTERNAL TABLE](#).

- PXF version 5.11.2 is included, which introduces these changes:
 - PXF no longer validates the JDBC `BATCH_SIZE` write option during a read operation.
 - PXF bundles a newer `jackson-databind` library.
 - PXF removes references to the unused `pxf-public.classpath` file. This in turn removes spurious `WARNING: Failed to read classpath file ...` log messages.
 - PXF now bundles Tomcat version 7.0.100.
- Greenplum Database 6.6 includes MADlib version 1.17, which introduces new Deep Learning features, k-Means clustering, and other improvements and bug fixes. See the [MADlib 1.17 Release Notes](#) for a complete list of changes.

Resolved Issues

Pivotal Greenplum 6.6.0 resolves these issues:

30483 - Query Optimizer

A query that specified multiple constants in an `IN` clause generated a large number of spill files and returned the error `workfile per query size limit exceeded` when GPORCA incorrectly normalized a histogram that was not well-defined. This issue is resolved.

30488 - DLL

For some append-optimized partitioned tables, performance was poor when adding a column to the table with the `ALTER TABLE... ADD COLUMN` command because the command performed a full table rewrite. Now only data corresponding to the new column is rewritten.

30518 - Query Optimizer

A query that specified an aggregate function such as `min()` or `count()` that was invoked on a `citext`-type column failed with the error `cache lookup failed for function 0` because GPORCA incorrectly generated a multi-stage aggregate for the query. This issue is resolved.

30525 - Logging

In some cases, Greenplum Database encountered a segmentation fault and rotated the log file early when the logging level was set to `WARNING` or less severe and Greenplum attempted to write to the alert log file after it failed to open the file. This issue is resolved.

171506474 - COPY

When `COPY FROM SEGMENT` command copied data into an append-only table, the command did not update the append-only table metadata `tupcount` (the number of tuples on a segment, including invisible tuples) and `modcount` (the number of data modification operations performed). This issue is resolved.

n/a - gpperfmon

The Ubuntu build of Greenplum Database 6.5.0 did not include the `gpperfmon` database, which is required for using Greenplum Command Center. This issue is resolved in version 6.6.0.

Release 6.5

Release 6.5.0

Release Date: 2020-03-20

Pivotal Greenplum 6.5.0 is a minor release that includes changed features and resolves several issues.

Warning: The Ubuntu build of Greenplum Database 6.5.0 does not include the `gpperfmon` database, which is required for using Greenplum Command Center. Customers deploying to Ubuntu should not install or upgrade to Greenplum Database 6.5 until a maintenance release is provided to resolve this issue.

Features

Greenplum Database 6.5.0 includes these new and changed features:

- When creating a user-defined function, you can specify the attribute `EXECUTE ON INITPLAN` to indicate that the function contains an SQL command that dispatches queries to the segment instances and requires special processing on the master instance by Greenplum Database. When possible, Greenplum Database handles the function on the master instance in the following manner:
 - First, Greenplum Database executes the function as part of an `InitPlan` node on the

master instance and holds the function output temporarily.

2. Then, in the MainPlan of the query plan, the function is called in an EntryDB (a special query executor (QE) that runs on the master instance) and Greenplum Database returns the data that was captured when the function was executed as part of the InitPlan node. The function is not executed in the MainPlan. For more information about the attribute and limitations when using the attribute, see [CREATE FUNCTION](#).
- GPORCA introduces a new costing model for bitmap indexes. The new model is designed to choose faster, bitmap nested loop joins instead of hash joins. The new costing model is implemented as a Beta feature, and it is used as a default only if you enable it by setting the configuration parameter:

```
set optimizer_cost_model = experimental
```

The `optimizer_cost_model` parameter is required only during the Beta test period for this cost model. After further testing and validation, the new cost model will be enabled by default.

- Greenplum Database includes the server configuration parameter `plan_cache_mode` that controls whether a prepared statement (either explicitly prepared or implicitly generated, for example by PL/pgSQL) can be executed using a *custom plan* or a *generic plan*.

Custom plans are created for each execution using its specific set of parameter values, while generic plans do not rely on the parameter values and can be re-used across executions. By default, choice between these options is made automatically, but it can be overridden by setting this parameter. If the prepared statement has no parameters, a generic plan is always used. The allowed values are `auto` (the default), `force_custom_plan` and `force_generic_plan`. This setting is considered when a cached plan is to be executed, not when it is prepared.

- PXF version 5.11.1 is included, which introduces new and changed features and bug fixes. See [PXF Version 5.11.1](#) below.
- The `s3` external table protocol automatically recognizes and uncompresses as deflate format any file that it reads that has a `.deflate` extension.
- Greenplum Database introduces the Greenplum R Client Beta, an interactive in-database data analytics tool. Refer to the [Greenplum Database R Client \(Beta\)](#) documentation for installation and usage information for this tool.

The Greenplum R Client (GreenplumR) is currently a Beta feature, and is not supported for production environments.

- `gpload` adds the `--max_retries` option to specify the number of times the utility attempts to connect to Greenplum Database after a connection timeout. The default value, 0, does not attempt a connection after a timeout.
- Greenplum Database introduces PL/Container version 3.0 Beta, which:
 - ◊ Provides support for the new GreenplumR interface.
 - ◊ Reduces the number of processes created by PL/Container, in order to save system resources.
 - ◊ Supports more containers running concurrently.
 - ◊ Includes improved log messages to help diagnose problems. PL/Container 3 is currently a Beta feature, and is not supported for production environments. It provides only an R Docker image for executing functions; Python images are not yet

available. See [PL/Container Language](#) for installation changes related to PL/Container 3.

PXF Version 5.11.1

PXF includes the following new and changed features:

- PXF provides a `restart` command to stop, and then restart, all PXF server instances in the cluster. See [Restarting PXF](#).
- The `pxf [cluster] sync` command now recognizes a `[-d | --delete]` option. When specified, PXF deletes files on the remote host(s) that are not present in the PXF user configuration on the Greenplum Database master host. Refer to [pxf](#) and [pxf cluster](#).
- PXF supports filter predicate pushdown for Parquet data that you access with the Hadoop and Object Store Connectors. Parquet [Data Type Mapping](#) describes filter pushdown support for Parquet data types in PXF.
- PXF includes improvements to error handling and error surfacing.
- PXF bundles newer `guava` and Google Cloud Storage `hadoop2` libraries.
- The PXF `pxf-log4j.properties` template file updates a log filter and changes the level from `INFO` to `WARN`.
- PXF removes unused and default Tomcat applications and files, hardening its default Tomcat security.
- PXF no longer requires a `$JAVA_HOME` setting in `gpadmin`'s `.bashrc` file on the master, standby master, and segment hosts. You can now specify `JAVA_HOME` before or during PXF initialization. Refer to the Initialization Overview in the PXF initialization documentation.

Resolved Issues

Pivotal Greenplum 6.5.0 resolves these issues:

307 - PXF

PXF did not correctly handle an external table that was created with the `ESCAPE 'OFF'` or `DELIMITER 'OFF'` formatting options. This issue is resolved. PXF now correctly neither escapes nor adds delimiters when reading external data with an external table created with these options.

30155 - gpstart

On systems that use a custom tablespace or filesystem, `gpstart` could fail to start a cluster if the standby master host was down (for example, if the standby was taken offline for maintenance), showing the error:

```
Error occurred while stopping the standby master: ExecutionError: 'non-zero rc: 255' occurred.
```

This problem occurred because `gpstart` was attempting to check and sync the filesystem or tablespace on the unavailable standby master host. `gpstart` was modified to skip filesystem and tablespace checks when the standby server is not available.

30255 - Query Optimizer

The GPORCA cost model for bitmap indexes could sometimes cost bitmap nested loop joins higher than hash joins, resulting in poor query performance. Greenplum Database 6.5 introduces a revised cost model for bitmap indexes to address this issue. See [Features](#).

30287 - Server: Execution

When GPORCA was enabled, queries against an append-only, column-oriented table could

cause a PANIC due to shared memory corruption. The code was modified to guard against out-of-bound writes that caused the memory corruption.

30367 - Query Optimizer

For GPORCA, query performance was poor for some queries against tables with columns that are defined with the `citext` datatype. The poor performance was because GPORCA did not gather statistics and calculate cardinalities for those columns. Now GPORCA gathers statistics and calculates cardinalities for columns defined with the `citext` datatype.

30369 - Query Execution

Greenplum Database generated a PANIC when executing a query that contains a `JOIN LATERAL` and the `LATERAL` subquery contains a `LIMIT` clause. Now the specified type of query completes.

30379 - ANALYZE

In some cases, performing an `ANALYZE` operation on a table with a column that is defined with the `citext` datatype returns the error `permission denied for schema <name>`. The error was generated when the user performing the operation did not have `USAGE` privilege in the schema where the `citext` datatype was defined with the `CREATE EXTENSION citext` command. Greenplum Database has been modified to not require `USAGE` privilege in the `citext` datatype schema for `ANALYZE` operations.

30382 - VACUUM, TRUNCATE

In some cases, performing a `VACUUM FULL` operation on the `pg_class` catalog table and concurrently performing a `TRUNCATE` operation on a user created heap table returned the error updated tuple is already `HEAP_MOVED_OFF` and caused the database to become unavailable. The `TRUNCATE` command did not properly manage the heap table entry in `pg_class` during the `TRUNCATE` operation. This issue is resolved.

30390 - gprecoverseg

In some cases, performance was poor when performing an incremental recovery with the `gprecoverseg` utility on a system with a large number of segment instances. Performance is improved, now the utility performs some recovery operations in parallel.

30405 - gpcheckcat

The `gpcheckcat` utility failed when the `dbid` of Greenplum Database master was not 1. Now the master `dbid` is not required to be 1.

30426 - Query Execution

Some queries that use the window function `cume_dist()` return the error `Backward scanning of tuplestores are not supported` if the query generates spill files. This issue is resolved and backward scanning of tuplestore spill files is allowed during query execution.

30437 - Query Optimizer

Queries using dynamic partition elimination (DPE) with range predicates were running slow. This issue has been fixed by allowing only equality comparisons with DPE.

30438 - Catalog and Metadata

If the server configuration parameter `gp_use_legacy_hashops` was set to `on`, Greenplum Database incorrectly used the non-legacy opclasses when redistributing a table with an `ALTER TABLE... (REORGANIZE = TRUE)` command if the command contained `DISTRIBUTED BY` clause the did not specify an opclass. This caused `SELECT` commands against a table with redistributed data to return incorrect results.

30441 - analyzedb

The `analyzedb` utility could fail with an error similar to `ERROR: relation "pg_aoseg.pg_aocsseg_XXXXXX" does not exist` if a table was dropped during the `analyzedb` operation. This problem was resolved by ensuring that `analyzedb` skips any dropped tables when determining the list of tables to analyze.

30450 - PXF

PXF initialization and reset failed when the default system Java version differed from that

specified in PXF' s `$JAVA_HOME`. This issue is resolved; PXF has added flexibility to the specification of the `$JAVA_HOME` setting.

30452 - Dispatch

If the server configuration parameter `check_function_bodies` was set in a session on the master, the parameter setting did not persist when a related segment instance session was reset. This caused some functions to fail. Now the parameter setting persists when a segment instance session is reset.

30464 - Query Optimizer

GPORCA incorrectly determined that the plan for a query with a filter on a window function over the distribution key column was direct dispatchable. Now direct dispatch requires the filter to be on a table scan.

30471, [8987](#) - Postgres Planner

When the Postgres Planner executed some queries that contain a subquery that contain both a distinct qualified aggregate expression and a `GROUP BY` clause, the Postgres Planner returned the error `could not find pathkey item to sort`. The error was returned when the Postgres Planner supply did not properly manage information used for sorting.

30474 - Query Execution

In some specific situations, some specific types of queries generated a Greenplum Database PANIC. The PANIC occurred when Greenplum Database did not properly handle skew optimization for multi-batch hash joins. Criteria for a query that caused the PANIC include the query contains a join, the join key has segment-local statistics (such as a catalog table), and the join key is one of the most common values, and the query plan is multi-batch hash join and the hash join is rescannable.

30477 - Query Analyze

While gathering statistics for a partitioned table, the `pg_class` columns `relpages` and `reltuples` were not populated for the root partition, only for leaf partitions. This issue has been fixed by changing the method to calculate if a partition table is empty or not.

30485 - gpinitssystem

When initializing a Greenplum Database system, the `gpinitssystem` utility failed to set the password for a user name when the name is numeric.

30493 - analyzedb

When used with the `--config-file` option, `analyzedb` did not enumerate the leaf partitions of a partitioned table and processed the root partition as a non-partitioned table. For heap tables this produced an error. For append-optimized tables, no error was raised, but DML changes to leaf partitions were not tracked properly. This issue has been resolved. Using the `--config-file` option correctly analyzes partitioned tables.

168199193 - COPY

In some cases, performance of the `COPY` command in Greenplum Database 6 was poor when compared to Greenplum Database 5. The performance of the `COPY` command is improved.

168828451, [8677](#) - Planner

Some queries returned incorrect results when the queries contain subqueries that perform a join and also contain one or more equality predicates, and optionally contain an `IS NULL` predicate. Incorrect results were returned when either a merge join or a nested loop join did not correctly process the predicates. This issue is resolved.

169030090 - Server

Superusers were limited to 3 connections by default, causing "too many clients" errors when users run maintenance scripts. The maximum number of superuser connections is set with the `superuser_default_connections` server configuration parameter. This issue is resolved. The default value for this parameter has changed from 3 to 10.

170745356, [9407](#) - Query Execution

With `gp_enable_global_deadlock_detector` set to `on`, concurrent updates to the same table could produce an incorrect query result. This issue is resolved. Segments report waited-for

transaction IDs to the master so that the master has the same transaction order as the segments.

170861600 - Server

Using `ALTER TABLE tablename SPLIT PARTITION` could cause rows to be assigned to the wrong partition, or could cause a crash, if one or more columns before the partition key were dropped. This issue is resolved.

171481916 - gpinitstandby

In some cases, utilities that checked for host IP address such as `gpinitstandby` failed. A Python utility (`ifaddrs`) that is used those Greenplum Database utilities caused the failure. `ifaddrs` has been updated.

171596248 9679 Query Execution

A Greenplum Database segment instance might generate a PANIC when a query that joins tables with a compound data type generates a query plan that performs a data motion and contains Nested Loop joins. The PANIC occurs due to an error in the prefetch logic for the motion. The prefetch logic issue has been corrected.

Release 6.4

Release 6.4.0

Release Date: 2020-02-11

Pivotal Greenplum 6.4.0 is a minor release that includes changed features and resolves several issues.

Features

Greenplum Database 6.4.0 includes these changed features:

- `DISCARD ALL` is not supported. The command returns a message that states that the command is not supported and to consider alternatives such as `DEALLOCATE ALL` or `DISCARD TEMP`. See [DISCARD](#).
- Greenplum Database resource groups support automatic query termination when resource group global shared memory is enabled. For resource groups that use global shared memory, Greenplum Database gracefully cancels running queries that are managed by those resource groups when the queries consume a large portion of the global shared memory. At this point, the queries would have already consumed available resource group slot memory and group shared memory. Greenplum Database cancels queries in order of memory used, from highest to lowest until the percentage of utilized global shared memory is below the percentage specified by the server configuration parameter `runaway_detector_activation_percent`.

Global shared memory is enabled for resource groups that are configured to use the `vmtracker` memory auditor, such as `admin_group` and `default_group` when the sum of the `MEMORY_LIMIT` attribute values configured for all resource groups is less than 100. If resource groups are not configured to use global shared memory pool, the resource group automatic query termination feature is not enabled.

For information about resource groups, see [Using Resource Groups](#).

- Greenplum Database supports creating the standby master or mirror segment instances on hosts that are in a different subnet from the master and primary segment instance hosts. Mirror segment instances can also be moved to hosts that are in a different subnet.

Resolved Issues

Pivotal Greenplum 6.4.0 resolves these issues:

30209, 170762049 - gpaddmirrors

The `gpaddmirrors` utility failed to add mirror segments to a Greenplum Database system, when the mirror segments are in a different subnet from the primary segments. This issue is resolved. Now Greenplum Database supports mirror segments in a different subnet from the primary segments.

30266 - Vacuum

The vacuum workflow changed in Greenplum Database 6 to dispatch once per auxiliary table in addition to the dispatch for the main table. This could cause performance problems and permission verification failures on auxiliary tables. This is fixed. The `VACUUM` command again dispatches once per segment.

30282 - Resource Management

For some queries managed by Greenplum Database resource groups, the query failed due to an out of memory condition. This caused a segment failure and other issues. This issue is resolved. Resource groups have been enhanced to handle queries that consume a large amount of memory. See [Features](#).

30299 - Server: Execution

For some queries against a partitioned table with multiple column indexes that perform a dynamic index scan, Greenplum Database generated a SIGSEGV. The error occurred when Greenplum Database did not correctly manage dynamic index scan pointer memory. This issue is resolved.

30325 - Query Optimizer

For some queries that reference a view that is defined with a CTE (common table expression) query, and the main query also contains a predicate that is a subquery that references the view, GPORCA returns an error that states `could not open temporary file`. The error was caused by incorrect predicate pushdown during preprocessing. This issue is resolved.

30359 - Server: Segment Mirroring

A panic occurred during crash recovery for a mirror when replaying WAL records for a transaction that created an append-optimized table, truncated the table, and then aborted the transaction. This issue is resolved.

30354 - DISCARD

`DISCARD TEMP` might not drop temporary tables on segment instances. This issue is resolved.

30360 - Server: Security

Greenplum Database incorrectly logged the message `time constraints added on superuser role` every time a superuser role was checked. Now the message is logged only when time constraints are added to a superuser role.

30366 - Server: Execution

Using GRANT commands on partitioned tables across segments would cause the system to PANIC due to alterations in the cached plan. This issue has been resolved.

30371 - Server: Execution

The `to_timestamp()` function did not return an error for an out of range value. For example, `select to_timestamp('20200340123456','YYYYMMDDHH24MISS');` returned a valid date and time `2020-04-09 12:34:56-07`. This issue is resolved. Now the function returns an error.

30387 - Server: DML

After completing the execution of a user-defined function that changed the value of a server configuration parameter, Greenplum Database restored the original parameter value on the query dispatcher, but did not synchronize and restore the value to the query executors. This issue is resolved.

170787232 - Server: Query Dispatcher

A Query Dispatcher (QD) would run into local deadlock for some prepared statements that execute an UPDATE or DELETE command. This issue has been fixed by taking into

consideration the server configuration parameter `gp_enable_global_deadlock_detector`.

Release 6.3

Release 6.3.0

Release Date: 2020-1-12

Pivotal Greenplum 6.3.0 is a minor release that includes new features and resolves several issues.

Features

Greenplum Database 6.3.0 includes these new features:

- The server configuration parameter `wait_for_replication_threshold` is introduced to improve performance for Greenplum Database systems with segment mirroring enabled. The parameter specifies the maximum amount of Write-Ahead Logging (WAL)-based records (in KB) written by a transaction on the primary segment instance before the records are written to the mirror segment instance for replication. As the default, Greenplum Database writes the records to the mirror segment instance when a checkpoint occurs or the `wait_for_replication_threshold` value is reached. See [wait_for_replication_threshold](#).
- The PL/Container version has been updated to 2.1.0. This version supports Docker images with Python 3 installed. These new PL/Container features enable support for Python 3:
 - A Docker image that is installed with Python 3 - `plcontainer-python3-images-2.1.0.tar.gz`
The Docker image can be downloaded from [Pivotal Network](#).
 - The new value `python3` for the `--language` option of `plcontainer runtime-add` command.
You specify this value when you add a Docker image that has Python 3 installed on to the Greenplum Database hosts with the `plcontainer runtime-add` command.
 - The GluonTS module has been added to Python Data Science Module package. The Python Data Science modules are installed with Python 3 in the Docker image on Pivotal Network.

Note: PL/Container 2.0.x and earlier do not support Python 3.

For information about PL/Container, see [PL/Container Language](#).

- PXF version 5.10.1 is included, which introduces bug fixes.
- The metrics collector extension included with Greenplum Database 6.3.0 adds a new `gpcc.enable_query_profiling` server configuration parameter that can be enabled to help with performance troubleshooting. When `off`, the default, the metrics collector does not collect queries executed by the `gpmon` user in the `gpperfmon` database or plan node history for queries that run in less than ten seconds. If you enable `gpcc.enable_query_profiling` in a session the metrics collector collects those queries in that session. See [Metrics Collector Server Configuration Parameters](#) in the Greenplum Command Center documentation for more information.

Resolved Issues

Pivotal Greenplum 6.3.0 is a minor release that resolves these issues:

30214 - Query Optimizer

The GPORCA algebraizer might generate a PANIC when optimizing a query involving a window function where one or more of the columns selected was a subquery. This issue is resolved.

30252 - Storage: Filespace / Tablespace

Data distribution errors could lead to data corruption if `UPDATE` or `DELETE` statements resulted in data movement between segments (for example, if the `UPDATE` of an affected tuple was distributed to another segment). The code was modified to check for distribution problems during `UPDATE` and `DELETE` operations, and to error out and cancel the operation in order to prevent data corruption. Problems detected in this manner are reported with the error:

```
distribution key of the tuple doesn't belong to current segment (actually from
segment_id)
```

30264 - Segment Mirroring

In some cases when Greenplum Database segment mirroring is enabled, loading a large amount of data caused mirror segment instances to fail due to a timeout issue. This issue has been resolved.

30300 - gpbackup/gprestore

When a view was restored from a backup and the view definition contained the function `gp_dist_random()`, the definition of the restored view did not contain the function. Greenplum Database has been updated to resolve this issue. Now the restored view contains the correct definition.

30301 - analyzedb

The `analyzedb` command could take a long time to complete when Greenplum Database incorrectly determined that the statistics for a child partition were not up to date and subsequently resampled the statistics for all partitions. This issue is resolved.

30320 - COPY

In some cases, Greenplum Database returned a `segment reject limit reached` error when a `COPY` operation specified a `SEGMENT REJECT LIMIT` and Greenplum encountered a data formatting error. Because Greenplum rescanned the offending line, it returned the error even before the error limit had been reached. This issue is resolved.

30321 - Query Optimizer

When computing the join order for certain queries, ORCA tries to create a set of all the tables that have a predicate in common with the current join tree, and then pick one of the tables from this set. In certain cases involving left joins, ORCA would error out if it was unable to pick a table to join from this set. This has now been fixed and ORCA no longer falls back for such queries.

30334 - Storage: DDL

A system panic could occur if `ALTER TABLE` was used to add a new partition, and `WITH (OIDS=FALSE)` was specified as the only storage parameter for the new partition. The problem was caused by code that failed to handle the possibility of a null `reloption` value, which is generated when the single default storage parameter is specified. The partitioning code was modified to correctly handle the possibility of such null values.

30348 - gpload

Attempting to run `gpload` installed with Greenplum Clients 6.2.1 returned this error: `No module named gppylib.gpversion`. This issue has been resolved.

169749131 - Segment Mirroring

When Greenplum Database segment mirroring is enabled, loading a large amount of data into append-optimized tables caused database performance issues and might have caused mirror instance failures with a walsender replication timeout error. The issues occurred because Greenplum Database was not efficiently writing transaction log records from primary to mirror segment instances. This issue has been resolved. Writing transaction log records from primary to mirror segment instances has been improved.

170021921 - Workload Manager

Transaction performance issues occurred when the `gp_wlm` extension was loaded and the

Greenplum Command Center workload management feature was not enabled. This is fixed in the `gp_wlm` extension included with Greenplum Database 6.3.0.

170346082 - PXF

The PXF JDBC Connector did not support dynamic session authorization in a remote SQL database. This issue is resolved; PXF now supports session authorization, and introduces the `${pxf.session.user}` value and the `jdbc.pool.qualifier` property as described in [About Session Authorization](#) in the JDBC Connector configuration documentation.

170476535 - PXF

PXF incorrectly wrote a Parquet decimal value that was specified with precision and scale settings, and was unable to read the decimal value back. This issue is resolved.

Release 6.2

Release 6.2.1

Release Date: 2019-12-12

Pivotal Greenplum 6.2.1 is a minor release that includes new features and resolves several issues.

New Features

Greenplum Database 6.2.1 includes these new features:

- Greenplum Database supports materialized views. Materialized views are similar to views. A materialized view enables you to save a frequently used or complex query, then access the query results in a `SELECT` statement as if they were a table. Materialized views persist the query results in a table-like form. Materialized view data cannot be directly updated. To refresh the materialized view data, use the `REFRESH MATERIALIZED VIEW` command. See [Creating and Managing Materialized Views](#).
- Note:** [Known Issues and Limitations](#) describes a limitation of materialized view support in Greenplum 6.2.1.
- The `gpinitssystem` utility supports the `--ignore-warnings` option. The option controls the value returned by `gpinitssystem` when warnings or an error occurs. If you specify this option, `gpinitssystem` returns 0 if warnings occurred during system initialization, and returns a non-zero value if a fatal error occurs. If this option is not specified, `gpinitssystem` returns 1 if initialization completes with warnings, and returns value of 2 or greater if a fatal error occurs.
- PXF version 5.10.0 is included, which introduces several new and changed features and bug fixes. See [PXF Version 5.10.0](#) below.

PXF Version 5.10.0

PXF 5.10.0 includes the following new and changed features:

- PXF has improved its performance when reading a large number of files from HDFS or an object store.
- PXF bundles newer `tomcat` and `jackson` libraries.
- The PXF JDBC Connector now supports pushdown of `OR` and `NOT` logical filter operators when specified in a JDBC named query or in an external table query filter condition.
- PXF supports writing Avro-format data to Hadoop and object stores. Refer to [Reading and Writing HDFS Avro Data](#) for more information about this feature.
- PXF is now certified with Hadoop 2.x and 3.1.x and Hive Server 2.x and 3.1, and bundles new and upgraded Hadoop libraries to support these versions.

- PXF supports Kerberos authentication to Hive Server 2.x and 3.1.x.
- PXF supports per-server user impersonation configuration.
- PXF supports concurrent access to multiple Kerberized Hadoop clusters. In previous releases of Greenplum Database, PXF supported accessing a single Hadoop cluster secured with Kerberos, and this Hadoop cluster must have been configured as the `default` PXF server.
- PXF introduces a new template file, `pxf-site.xml`, to specify the Kerberos and impersonation property settings for a Hadoop or JDBC server configuration. Refer to [About Kerberos and User Impersonation Configuration \(pxf-site.xml\)](#) for more information about this file.
- PXF now supports connecting to Hadoop with a configurable Hadoop user identity. PXF previously supported only proxy access to Hadoop via the `gpadmin` Greenplum user.
- PXF version 5.10.0 deprecates the following configuration properties.

Note: These property settings continue to work.

- The `PXF_USER_IMPERSONATION`, `PXF_PRINCIPAL`, and `PXF_KEYTAB` settings in the `pxf-env.sh` file. You can use the `pxf-site.xml` file to configure Kerberos and impersonation settings for your new Hadoop server configurations.
- The `pxf.impersonation.jdbc` property setting in the `jdbc-site.xml` file. You can use the `pxf.service.user.impersonation` property to configure user impersonation for a new JDBC server configuration.

Note: If you have previously configured a PXF JDBC server to access Kerberos-secured Hive, you must upgrade the server definition. See [Upgrading PXF in Greenplum 6.x](#) for more information.

Changed Features

Greenplum Database 6.2.1 includes these changed features:

- Greenplum Stream Server version 1.3.1 is included in the Greenplum distribution.

Resolved Issues

Pivotal Greenplum 6.2.1 is a minor release that resolves these issues:

29454 - gpstart

During Greenplum Database start up, the `gpstart` utility did not report when a segment instance failed to start. The utility always displayed 0 skipped segment starts. This issue has been resolved. `gpstart` output was also enhanced to provide additional warnings and summary information about the number of skipped segments. For example:

```
[WARNING] :-*****
*****
[WARNING] :-There are 1 segment(s) marked down in the database
[WARNING] :-To recover from this current state, review usage of the gprecoverseg
[WARNING] :-management utility which will recover failed segment instance database
s.
[WARNING] :-*****
*****
```

30248, 9022 - DLL

Greenplum Database might generate a PANIC when an index is created on a column of an append-optimized, column-oriented table if the index definition contains a `WHERE` clause that references multiple columns. This issue has been resolved.

7545 - Postgres Planner

The Postgres Planner might return incorrect results for queries that contain a subquery in an `EXISTS` clause if the subquery includes a `LIMIT [0 | ALL | NULL]` clause or an `OFFSET NULL` clause. This issue has been resolved.

8590 - Postgres Planner

A query that used the Postgres planner could return incorrect results if it specified a volatile function in a `LIMIT` clause (for example, `LIMIT (random() * 10)`). This occurred because Greenplum evaluated the `LIMIT` clause separately on each segment instance to obtain a preliminary limit, before evaluating it once again as the query was dispatched. The problem was fixed by ensuring that a volatile functions in a `LIMIT` clause functions are not pushed to segment instances for evaluation.

30083 - Postgres Planner

Fixed a problem in the Postgres planner that could result in the error `variable not found in subplan target list`. The issue applied to join queries where a table column had a user prescribed CAST applied to it while being both in the select list and in a join condition. At the same time, the column was also part of a motion operator in the query plan.

30200 - Metrics Collector

Greenplum Database 6 stores tablespaces with non-default names as symlinks in the `$MASTER_DATA_DIRECTORY/pg_tblspc` directory and the metrics collector did not detect these tablespaces. The metrics collector now follows the symlinks to find the names of the tablespace directories and the data directories located in those tablespaces. After enabling the new metrics collector the tablespaces may not be visible in Greenplum Command Center for up to four hours.

30203 - Query Optimizer

When updating a table's distribution column, Greenplum Database returned an error that states an `UPDATE` statement cannot update distribution columns if a btree index is defined on the distribution column and the `UPDATE` command contains an `IN` clause. The error was returned when Greenplum Database fell back to the Postgres planner to attempt the `UPDATE` operation. This issue has been resolved. Now GPORCA supports the specified type of updates.

30206 - gpinitssystem

An example in the `gpinitssystem` help output used an invalid option for specifying the placement of mirror segment instances in a spread configuration. The correct option is `--mirror_mode=spread`. This issue has been resolved.

30227 - Server

Greenplum Database with resource groups enabled might generate a PANIC when using an extension with improper `debug_query_string` settings. The cause was a message context issue and it has been resolved.

30256 - analyzedb

When executing some queries against partitioned tables, GPROCA would fail because of missing root partition statistics. This was caused by the `analyzedb` utility not updating the root partition statistics when generating the partitioned table statistics. This issue has now been resolved.

30292 - External Table

When Greenplum Database attempted to access data from an external table, a PANIC was generated when Greenplum Database could not resolve the host name that is specified in the external table definition. This issue has been resolved. Now Greenplum Database returns an error in the specified situation.

168881383 - PXF

PXF fixed a regression in file and directory name pattern matching that affected the `*:text:multi` profiles and S3 Select. This issue has been resolved. PXF now correctly handles wildcards specified in the `LOCATION` data path.

8918 - Postgres Planner

The Postgres Planner generated an incorrect result on a `JOIN` query when different data types were used in a table column or the query constraints included a constant, and the query required motion. This issue is resolved.

169694492 - Query Optimizer

For a table that has a column that is defined with a btree index, GPORCA fell back to the Postgres planner for queries that use `IN` clause against the column or an `OR` of simple comparisons on the column such as `col = 5 OR col = 7`. Now GPORCA attempts to generate a query plan that uses the index.

169806983 - Greenplum Stream Server

In some cases, reading from Kafka using the default `MINIMAL_INTERVAL` (0 seconds) caused GPSS to consume a large amount of CPU resources, even when no new messages existed in the Kafka topic. This issue is resolved in GPSS 1.3.1.

169807372, 169831558 - Greenplum Stream Server

GPSS 1.3.0 did not recognize internal history tables that were created with GPSS 1.2.6 and earlier. In some cases, this caused GPSS to load duplicate messages into Greenplum Database. This issue is resolved in GPSS 1.3.1.

170041280 - PXF

PXF was unable to read data from an encrypted HDFS zone and returned an `org.apache.hadoop.crypto.CryptoInputStream cannot be cast to org.apache.hadoop.hdfs.DFSInputStream` error in this situation. This issue is resolved.

Release 6.1

Release 6.1.0

Release Date: 2019-11-1

Pivotal Greenplum 6.1.0 is a minor release that includes new features and resolves several issues.

Features

Greenplum Database 6.1.0 includes these new features:

- Greenplum Stream Server 1.3 is included, which introduces new features and bug fixes.

Note: Greenplum Stream Server (GPSS) and Greenplum-Kafka Integration users: Do not upgrade to Greenplum Database 6.1 if you plan to re-submit Kafka load jobs that you initiated with GPSS in Greenplum 6.0.x. Due to a regression, GPSS may load duplicate Kafka messages into Greenplum. Refer to [Known Issues and Limitations](#) for more information.

New GPSS features include:

- GPSS now supports log rotation, utilizing a mechanism that you can easily integrate with the Linux `logrotate` system. See [Managing GPSS Log Files](#) for more information.
- GPSS has added the new `INPUT:FILTER` load configuration property. This property enables you to specify a filter that GPSS applies to Kafka input data before loading it into Greenplum Database.
- GPSS displays job progress by partition when you provide the `--partition` flag to the `gpsscli progress` command.
- GPSS enables you to load Kafka data that was emitted since a specific timestamp into Greenplum Database. To use this feature, you provide the `--force-reset-timestamp` flag when you run `gpsscli load`, `gpsscli start`, or `gp kafka load`.

- GPSS now supports update and merge operations on data stored in a Greenplum Database table. The load configuration file accepts `MODE`, `MATCH_COLUMNS`, `UPDATE_COLUMNS`, and `UPDATE_CONDITION` property values to direct these operations. [Example: Merging Data from Kafka into Greenplum Using the Greenplum Stream Server](#) provides an example merge scenario.
 - GPSS supports Kerberos authentication to both Kafka and Greenplum Database.
 - GPSS supports SSL encryption between GPSS and Kafka.
 - GPSS supports SSL encryption on the data channel between GPSS and Greenplum Database.
- The DataDirect JDBC and ODBC drivers were updated to versions 5.1.4.000270 (F000450.U000214) and 07.16.0334 (B0510, U0363), respectively.

The DataDirect JDBC driver introduces support for the `prepareThreshold` connection parameter, which specifies the number of prepared statement executions that can be performed before the driver switches to using server-side prepared statements. This parameter defaults to 0, which preserves the earlier driver behavior of always using server-side prepare for prepared statements. Set a number greater than 1 to set a threshold after which server-side prepare is used.

Note: `ExecuteBatch()` always uses server-side prepare for prepared statements. This matches the behavior of the Postgres open source driver.

When the `prepareThreshold` value is greater than 1, parameterized operations do not send any SQL prepare calls with `connection.prepareStatement()`. The driver instead sends the query all at once, at execution time. Because of this limitation, the driver must determine the type of every column using the JDBC API before sending the query to the server. This determination works for many data types, but does not work for the following types that could be mapped to multiple Greenplum data types: - BIT VARYING - BOOLEAN - JSON - TIME WITH TIME ZONE - UUIDCOL

You must set `prepareThreshold` to 0 before using parameterized operations with any of the above types. Examine the `ResultSetMetaData` object in advance to determine if any of the above types are used in a query. Also keep in mind that GPORCA does not support prepared statements that have parameterized values, and will fall back to using the Postgres Planner.

See [PrepareThreshold](#) in the DataDirect documentation.

Resolved Issues

Pivotal Greenplum 6.1.0 is a minor release that resolves these issues:

8804 - Server

In some cases, running the `EXPLAIN ANALYZE` command on a sorted query in utility mode would cause the segment to crash. This issue is fixed. Greenplum Database no longer crashes in this situation.

8636 - Server

Some users encountered `Error: unrecognized parameter "appendoptimized"` while creating a partitioned table that specified the `appendoptimized=true` storage parameter. This issue is fixed; the Greenplum Database server now properly recognizes the `appendoptimized` parameter when it is specified on partition table creation.

26225 - gpcheckcat

The `gpcheckcat` utility failed to generate a summary report if there was an orphan TOAST table entry in one of the segments. This is fixed. The string "N/A" is reported when there is

no relation OID to report.

29580 - Management and Monitoring

During Greenplum Database startup, an extra empty log file was produced ahead of the current date while performing time-based rotation of log files. For example, if Greenplum started at midnight September 2nd, two log files were generated, `gpdb-2019-09-02_000000.csv` and `gpdb-2019-09-03_000000.csv`. This issue has now been fixed.

29984 - Server

During startup, idle query executor (QE) processes can commit up to 16MB of memory each, but they are not tracked by the Linux virtual memory tracker. In a worst-case scenario, these idle processes could trigger OOM errors that were difficult to diagnose. To prevent these situations, Greenplum now hard-codes a startup memory cost to account for untracked QE processes.

30112 - Query Optimizer

For some queries against partitioned tables that contain a large amount of data, GPORCA generated a sub-optimal query plan because of inaccurate cardinality estimation. This issue has been resolved. GPORCA cardinality estimation has been improved.

30183, 30184 - analyzedb

When running the `analyzedb` command with the `--skip_root_stats` option, the command could take a long time to finish when analyzing a partitioned table with many partitions due to how the root partition statistics were handled when the partitions were analyzed. This issue has been resolved. Now, only partition statistics are updated.

Note: GPORCA uses root partition statistics. If you use `-skip_root_stats` option, you should ensure that root partition statistics are up to date so that GPORCA does not produce inferior query plans due to stale root partition statistics.

30149 - Query Execution

A query might fail and return an error with the message `invalid seek in sequential BufFile` when the server configuration file `gp_workfile_compression` is on and the query spills to temporary workfiles. The error was caused due to an issue working with workfiles that contain compressed data. The issue has been resolved by correctly handling the compressed workfile data.

30150 - Query Execution

A query might fail and return with the message `AssignTransactionId() called by Segment Reader process` when the server configuration parameter `temp_tablespace` is set. The error was caused by an internal locking and transaction ID issue. This issue has been resolved by removing the requirement to acquire the lock.

30160 - Query Optimizer

GPORCA might return incorrect results when a the query contains a join predicate where one side is distributed on a `citext` column, and the other is not. GPORCA did not use the correct hash when generating a plan that redistributes the `citext` column. Now Greenplum Database falls back to the Postgres Planner for the specified type of query.

30183 - analyzedb

The `analyzedb` command could take a long time to finish when analyzing a table with many partitions. The command's performance has been greatly improved by waiting to update the root partition statistics until all leaf partitions of a table have been analyzed.

164823612 - gpss

GPSS incorrectly treated Kafka jobs that specified the same Kafka topic and Greenplum output schema name and output table name, but different database names, as the same job. This issue has been resolved. GPSS now includes the Greenplum database name when constructing a job definition.

167997441 - gpss

GPSS did not save error data to the external table error log when it encountered an incorrectly-formatted JSON or Avro message. This issue has been fixed; invoking

`gp_read_error_log()` on the external table now displays the offending data.

168130147 - gpss

In some situations, specifying the `--force-reset-earliest` flag when loading data failed to read from the correct offset. This problem has been fixed. (Using the `--force-reset-xxx` flags outside of an offset mismatch scenario is discouraged.)

168393571 - Query Optimizer

Certain queries with btree indexes on Append Optimized (AO) tables were unnecessarily slow due to GPORCA selecting a scan with high transformation and cost impact. This issue has been fixed by improving GPORCA handling of btree type indexes.

168393645 - Query Optimizer

In some situations, a query ran slow because GPORCA did not produce an optimal plan when it encountered a null-rejecting predicate where an operand could be false or null, but not true. This issue is fixed; GPORCA now produces a more optimal plan when evaluating null-rejecting predicates for `AND` and `OR` operands.

168705484 - Query Optimizer

For certain queries with a UNION operator over a large number of children, GPORCA query optimization required a long time. This issue has been addressed by adding the ability to derive scalar properties on demand.

168707515 - Query Optimizer

Some queries in GPORCA were consuming more memory than necessary due to suboptimal memory tracking. This has been fixed by optimizing memory accounting inside GPORCA.

169081574 - Interconnect

Greenplum Database might generate a PANIC when the server configuration parameter `gp_interconnect_type` is `TCP` due to an issue with memory management during interconnect setup. The issue has been resolved by properly managing the internal interconnect object memory.

169117536 - Execution

Greenplum Database might generate a PANIC when the server configuration parameter `log_min_messages` is set to `debug5`. Greenplum Database did not properly handle a `debug5` message correctly. The issue is resolved.

169198230 - Plan Cache

A prepared statement might run slow because a cost model issue prevented Greenplum Database from generating a direct dispatch plan for the statement. This issue is fixed. Greenplum Database now introduces non-direct dispatch cost into the cost model only for cached plans, and tries to use direct dispatch for prepared statements when possible.

Release 6.0

Release 6.0.1

Release Date: 2019-10-11

Pivotal Greenplum 6.0.1 is a maintenance release that includes changed features and resolves several issues.

Changed Features

Greenplum Database 6.0.1 includes these changed features:

- The default value for the server configuration parameter `optimizer_use_gpdb_allocators` has been changed to `true`. Now, as the default, GPORCA uses Greenplum Database memory management when executing queries instead of GPORCA-specific memory management. Greenplum Database memory management has several enhancements when

compared to GPORCA-specific memory management. See [optimizer_use_gpdb_allocators](#).

- Writing parquet data using the PXF Hadoop and object store connectors is no longer considered a Beta feature in this release.

Resolved Issues

Pivotal Greenplum 6.0.1 is a maintenance release that resolves these issues:

29712 - Query Execution

Greenplum Database writes unnecessary `could not unlink file` log messages for spill files when `gp_enable_query_metrics` is on and `log_min_messages` is set to `INFO`. This issue has been resolved. Logging has been improved to not write the log message.

30058 - Query Execution

An internal `EXPLAIN` function, `cdbexplain_localExecStats`, operated under the assumption that it was always executed by a query dispatcher (QD) process. However, certain queries could generate plans where the function was executed by a query executor (QE) process. Running such queries with `EXPLAIN ANALYZE` would cause all segments to crash with segment faults, and error messages referencing `cdbexplain_localExecStats`. This problem has been resolved.

30094 - Resource Management

In some cases Greenplum Database generated a PANIC when a query was terminated and the query involved catalog tables. The PANIC was caused when a backend process did not properly clean up shared memory before exiting. This issue has been resolved. Now backend process memory management has been improved for the specified situation.

30098 - COPY

Greenplum Database generated a PANIC when a `COPY` command attempted to write to a catalog table. This issue has been resolved, now Greenplum Database returns an error.

30120 - GRANT

The command `GRANT ALL ON ALL TABLES IN SCHEMA <schema> TO <role>` caused a PANIC when tables are partitioned or inherited by child tables. This issue has been fixed.

30130 - gpexpand

The `gpexpand` utility might have failed with a `Cannot allocate memory` error when system memory or swap space is low. The error was due to an issue with a python process library. This has been resolved by updating the python library.

165660593 - Resource Groups

When resource groups are enabled, Greenplum Database might return an out of memory error when executing a `SET` or `SHOW` command, or when executing a query when the Greenplum Database server configuration parameter `gp_resource_group_bypass` is set to `true`. The error is due to an issue with resource group memory accounting. This issue has been resolved, resource group memory accounting has been improved for individual statements.

167847839 - gpconfig

The code dispatched from the master to segments to set a configuration parameter enclosed the value in single quotes. This did not handle values containing embedded single quotes, and parameters with the `GUC_LIST_QUOTE` flag, such as `search_path`, ended up having different values on the segments than on the master. For example,

```
SELECT set_config('search_path', 'my_schema,public', false);
```

was dispatched as

```
SET search_path TO 'my_schema,public';
```

instead of

```
SET search_path TO my_schema,public;
```

This is fixed. The `set_config()` call is now dispatched to the segments as well, passing the (quoted) arguments directly so that the same code runs on the master and segments.

Known Issue 167851039 - PXF

`pxf cluster reset` did not reset PXF configuration on the standby master. This issue is fixed; the command now resets PXF configuration on all hosts in the Greenplum cluster, including the standby master.

Known Issue 167851065 - PXF

PXF allowed you to initialize PXF without setting `PXF_CONF`. This issue has been resolved. PXF now correctly checks for this setting before continuing with initialization.

Known Issue 167948506 - PXF

In some cases, accessing an S3 object store with PXF failed when PXF was configured for Kerberized Hadoop. This issue is fixed. PXF now handles token renewal appropriately on concurrent access to S3 and a Kerberized Hadoop cluster.

While not required, if you have previously instituted any of the workarounds identified for this issue that are described in [Known Issues and Limitations](#), you may consider reverting the `s3-site.xml` modifications or removing the `yarn-site.xml` file from your S3 server directory.

168167337- gpinitssystem

When running `gpinitssystem` to initialize a Greenplum Database system with mirroring enabled, the utility configured the `pg_hba.conf` file in a manner that did not permit incremental recovery of the primary segment instances. This issue is fixed in release 6.0.1. The `gpexpand`, `gprecoverseg`, and `gpaddmirrors` utilities were also updated to ensure that primary and mirror segments always have compatible `pg_hba.conf` entries in place after performing their respective operations.

Known Issue 168271005 - PXF

The PXF JDBC Connector failed to access any database when PXF was configured to use the MapR Hadoop distribution, and MapR libraries were present in `$PXF_CONF/lib`. This issue has been resolved. A PXF MapR server configuration no longer affects JDBC access using PXF.

168759361 - psql

Greenplum Database was previously built and dynamically linked against `libedit` as a required dependency. However, the version of `libedit` that is available on Redhat 7 is not compatible with features such as tab-completion in `psql`. The `readline` library provides the same functionality as `libedit`, and all versions available across all supported platforms are compatible with the desired features. Therefore, instead of dynamically linking to `libedit`, Greenplum Database is now being built and dynamically linked to `readline`. This changes the required dependencies for the installers from `libedit` to `readline`.

Release 6.0.0

Release Date: 2019-09-03

Pivotal Greenplum 6.0.0 is a major new release of Greenplum that includes new and changed features.

New Features

Pivotal Greenplum 6 includes these new features.

- [PostgreSQL Core Features](#)

- [Zstandard Compression Algorithm](#)
- [Relaxed Rules for Specifying Table Distribution Columns](#)
- [Replicated Table Data](#)
- [Resource Groups Features](#)
- [PL/pgSQL Procedural Language Enhancements](#)
- [Concurrency Improvements in Greenplum 6](#)
- [Additional Contrib Modules](#)
- [PXF Version 5.8.1](#)
- [Additional Greenplum Database Features](#)

PostgreSQL Core Features

Pivotal Greenplum 6 incorporates several new features from PostgreSQL versions 8.4 through version 9.4.

INTERVAL Data Type Handling

PostgreSQL 8.4 improves the parsing of `INTERVAL` literals to align with SQL standards. This changes the output for queries that use `INTERVAL` labels between versions 5.x and 6.x. For example:

```
$ psql
psql (8.3.23)
Type "help" for help.

gpadmin=# select INTERVAL '1' YEAR;
 interval
-----
 00:00:00
(1 row)
```

```
$ psql
psql (9.2beta2)
Type "help" for help.

gpadmin=# select INTERVAL '1' YEAR;
 interval
-----
 1 year
(1 row)
```

See [Date/Time Types](#) for more information.

Additional PostgreSQL Features

Greenplum Database 6.0 also includes these features and changes from PostgreSQL:

- Support for user-defined I/O conversion casts. (PostgreSQL 8.4).
- Support for column-level privileges (PostgreSQL 8.4).
- The `pg_db_role_setting` catalog table, which provides support for setting server configuration parameters for a specific database and role combination (PostgreSQL 9.0).
- Values in the `relkind` column of the `pg_class` catalog table were changed to match entries in PostgreSQL 9.3.

- Support for GIN index method (PostgreSQL 8.3).
- Postgres Planner support for the SP-GiST index access method (PostgreSQL 9.2). (GPORCA ignores SP-GiST indexes.)
- Postgres Planner support for ordered-set aggregates and moving-aggregates (PostgreSQL 9.4).
- Support for `jsonb` data type (PostgreSQL 9.4).
- `DELETE`, `INSERT`, and `UPDATE` supports the `WITH` clause, CTE (common table expression) (PostgreSQL 9.1).
- Collation support to specify sort order and character classification behavior for data at the column level (PostgreSQL 9.1).

Note: GPORCA supports collation only when all columns in the query use the same collation. If columns in the query use different collations, then Greenplum uses the Postgres Planner.

Zstandard Compression Algorithm

Greenplum Database 6.0 adds support for `zstd` (Zstandard) compression for some database operations. See [Enabling Compression](#).

Relaxed Rules for Specifying Table Distribution Columns

In previous releases, if you specified both a `UNIQUE` constraint and a `DISTRIBUTED BY` clause in a `CREATE TABLE` statement, then the `DISTRIBUTED BY` clause was required to be equal to or a left-subset of the `UNIQUE` columns. Greenplum 6.x relaxes this rule so that any subset of the `UNIQUE` columns is accepted.

This change also affects the rules for how Greenplum 6.x selects a default distribution key. If `gp_create_table_random_default_distribution` is off (the default) and you do not include a `DISTRIBUTED BY` clause, then Greenplum chooses the table distribution key based on the command:

- If a `LIKE` or `INHERITS` clause is specified, then Greenplum copies the distribution key from the source or parent table.
- If a `PRIMARY KEY` or `UNIQUE` constraints are specified, then Greenplum chooses the largest subset of all the key columns as the distribution key.
- If neither constraints nor a `LIKE` or `INHERITS` clause is specified, then Greenplum chooses the first suitable column as the distribution key. (Columns with geometric or user-defined data types are not eligible as Greenplum distribution key columns.)

Resource Groups Features

Greenplum Database includes these new resource group features:

- You no longer are required to specify a `MEMORY_LIMIT` when you configure a Greenplum Database resource group. When you specify `MEMORY_LIMIT=0`, Greenplum Database will use the resource group global shared memory pool to service queries running in the group.
- When you specify `MEMORY_SPILL_RATIO=0`, Greenplum Database will now use the `statement_mem` server configuration parameter setting to identify the initial amount of query operator memory.

When used together to configure a resource group (`MEMORY_LIMIT=0` and `MEMORY_SPILL_RATIO=0`), these new capabilities provide a memory management scheme similar to that provided by Greenplum Database resource queues.

The default values of the `MEMORY_SHARED_QUOTA`, `MEMORY_SPILL_RATIO`, and `MEMORY_LIMIT` attributes for the `admin_group` and `default_group` resource groups have been set to use this resource queue-like memory management scheme so that when you initially enable resource groups, your queries will run in a memory environment similar to before.

Resource Group	admin_group	default_group
MEMORY_LIMIT	10	0
MEMORY_SHARED_QUOTA	80	80
MEMORY_SPILL_RATIO	0	0

PL/pgSQL Procedural Language Enhancements

PL/pgSQL in Greenplum Database 6.0 includes support for the following new features:

- Attaching `DETAIL` and `HINT` text to user-thrown error messages. You can also specify the `SQLSTATE` and `SQLERRMSG` codes to return on a user-thrown error (PostgreSQL 8.4).
- The `RETURN QUERY EXECUTE` statement, which specifies a query to execute dynamically (PostgreSQL 8.4).
- Conditional execution using the `CASE` statement (PostgreSQL 8.4). See [Conditionals](#) in the PostgreSQL documentation.

Replicated Table Data

The `CREATE TABLE` command supports `DISTRIBUTED REPLICATED` as a distribution policy. If this distribution policy is specified, Greenplum Database distributes all rows of the table to all segment instances in the Greenplum Database system.

Note: The hidden system columns (`ctid`, `cmin`, `cmax`, `xmin`, `xmax`, and `gp_segment_id`) cannot be referenced in user queries on replicated tables because they have no single, unambiguous value. Greenplum Database returns a `column does not exist` error for the query.

Concurrency Improvements in Greenplum 6

Greenplum Database 6 includes the following concurrency improvements:

- **Global Deadlock Detector** - Previous versions of Greenplum Database prevented global deadlock by holding exclusive table locks for `UPDATE` and `DELETE` operations. While this strategy did prevent deadlocks, it came at the cost of poor performance on concurrent updates. Greenplum Database 6 includes a global deadlock detector. This backend process collects and analyzes lock waiting data in the Greenplum cluster. If the Global Deadlock Detector determines that deadlock exists, it breaks the deadlock by cancelling one or more backend processes. By default, the global deadlock detector is disabled and table-level exclusive locks are held for table updates. When the global deadlock detector is enabled, Greenplum Database holds row-level exclusive locks and concurrent updates are allowed. See [Global Deadlock Detector](#).
- **Transaction Lock Optimization** - Greenplum Database 6 optimizes transaction lock usage both when you `BEGIN` and `COMMIT` a transaction. This benefits highly concurrent mixed workloads.
- **Upstream PostgreSQL Features** - Greenplum 6 includes upstream PostgreSQL features, including those for fastpath lock, which reduce lock contention. This benefits concurrent short queries and mixed workloads.

- `VACUUM` can more easily skip pages it cannot lock. This reduces the frequency of a vacuum appearing to be “stuck,” which occurs when `VACUUM` waits to lock a block for cleanup and another session has held a lock on the block for a long time. Now `VACUUM` skips a block it cannot lock and retries the block later.
- `VACUUM` rechecks block visibility after it has removed dead tuples. If all remaining tuples in the block are visible to current and future transactions, the block is marked as all-visible.
- The tables that are part of a partitioned table hierarchy, but that do not contain data, are age-frozen so that they do not have to be vacuumed separately and do not affect calculation of the number of remaining transaction IDs before wraparound occurs. These tables include the root and intermediate tables in the partition hierarchy and, if they are append-optimized, their associated meta-data tables. This makes it unnecessary to vacuum the root partition to reduce the table’s age, and eliminates the possibly needless vacuuming of all of the child tables.

Additional Contrib Modules

Greenplum Database 6 is distributed with these additional PostgreSQL and Greenplum `contrib` modules:

- `auto_explain`
- `diskquota`
- `fuzzystrmatch`
- `gp_sparse_vector`
- `pageinspect`
- `sslnfo`

PXF Version 5.8.1

Greenplum Database 6.0 includes PXF 5.8.1, which introduces the following new and changed features:

- The PXF S3 Connector now supports accessing CSV and Parquet data on S3 using the Amazon S3 Select service. Refer to [Reading CSV and Parquet Data on S3 Using S3 Select](#).
- PXF bundles new and upgraded libraries to provide Java 11 support.
- PXF has added support for the `timestampz` type when writing Parquet data to an external data source.
- PXF now provides a `reset` command to reset your local PXF server instance, or all PXF server instances in the cluster, to an uninitialized state. See [Resetting PXF](#).
- PXF no longer supports specifying a `DELIMITER` in the `CREATE EXTERNAL TABLE` command `LOCATION` URI.

Additional Greenplum Database Features

Greenplum Database 6.0 also includes these features and changes from version 5.x:

- Recursive `WITH` Queries (Common Table Expressions) are no longer considered a Beta feature, and are now enabled by default. See [WITH Queries \(Common Table Expressions\)](#).
- `VACUUM` was updated to more easily skip pages that cannot be locked. This change should greatly reduce the incidence of `VACUUM` getting “stuck” while waiting for other sessions.

- `appendoptimized` alias for the `appendonly` table storage option.
- New `gp_resgroup_status_per_host` and `gp_resgroup_status_per_segment` `gp_toolkit` views to display resource group CPU and memory usage on a per-host and/or per-segment basis.
- The new `gp_stat_replication` view contains replication statistics when master or segment mirroring is enabled. The `pg_stat_replication` view contains only master replication statistics.
- The `gpfdists` and `psql` programs in the Greenplum Client and Loader Tools package for Windows support OpenSSL encryption.
- Greenplum 6 includes some PostgreSQL 9.6 aggregate-related performance improvements.
- The `gpload` utility program provided in the Greenplum Client and Loader Tools package for Windows is compatible with Greenplum Database 5.

Greenplum 6.0 Beta Features

Because Pivotal Greenplum Database is based on the open source [Greenplum Database project](#) code, it includes several Beta features to allow interested developers to experiment with their use on development systems. Feedback will help drive development of these features, and they may become supported in future versions of the product.

Warning: Beta features are not recommended or supported for production deployments.

Key experimental features in Greenplum Database 6.0 include:

- Storage plugin API for `gpbackup` and `gprestore`. Partners, customers, and OSS developers can develop plugins to use in conjunction with `gpbackup` and `gprestore`.

For information about the storage plugin API, see [Backup/Restore Storage Plugin API](#).

- Using the Greenplum Platform Extension (PXF) connectors to write Parquet data is a Beta feature.

Changed Features

Greenplum Database 6.0 includes these feature changes:

- The performance characteristics of Greenplum Database under heavy loads have changed in version 6 as compared to previous versions. In particular, you may notice increased I/O operations on primary segments for changes related to GPSS, WAL replication, and other features. All customers are encouraged to perform load testing with real-world data to ensure that the new Greenplum 6 cluster configuration meets their performance needs.
- `gpbackup` and `gprestore` are no longer installed with Greenplum Database 6, but are available separately on [Pivotal Network](#) and can be upgraded separately from the core database installation.
- Greenplum 6 uses a new *jump consistent hash* algorithm to map hashed data values to Greenplum segments. The new algorithm ensures that, after new segments are added to the Greenplum 6 cluster, only those rows that hash to the new segment need to be moved. Greenplum 6 hashing has performance characteristics similar to earlier Greenplum releases, but should enable faster database expansion. Note that the new algorithm is more CPU intensive than the previous algorithm, so `COPY` performance may degrade somewhat on CPU-bound systems.
- The older, legacy hash functions are represented as non-default hash operator classes, named `cdbhash_*_ops`. The non-default operator classes are used when upgrading from Greenplum Database earlier than 6.0. The legacy operator classes are compatible with each

other, but if you mix the legacy operator classes with the new ones, queries will require Redistribute Motions.

The server configuration parameter `gp_use_legacy_hashops` controls whether the legacy or default hash functions are used when creating tables that are defined with a distribution column.

The `gp_distribution_policy` system table now contains more information about Greenplum Database tables and the policy for distributing table data across the segments including the operator class of the distribution hash functions.

- The `gpcheck` utility is no longer included in Greenplum Database 6.
- The input file format for the `gpmovemirrors`, `gpaddmirrors`, `gprecoverseg` and `gpexpand` utilities has changed. Instead of using a colon character `:` as a separator, the new file format uses a pipe character `|`. For example, in previous releases a line in a `gpexpand` input file would resemble:

```
sdw5:sdw5-1:50011:/gpdata/primary/gp9:11:9:p
```

The updated file format is:

```
sdw5|sdw5-1|50011|/gpdata/primary/gp9|11|9|p
```

In addition, `gpaddmirrors` removes the `mirror` prefix from lines in its input file. Whereas a line from the previous release might resemble:

```
mirror0=0:sdw1:sdw1-1:52001:53001:54001:/gpdata/mir1/gp0
```

The revised format is:

```
0=0|sdw1|sdw1-1|52001|53001|54001|/gpdata/mir1/gp0
```

- Greenplum uses direct dispatch to target queries that use `IS NULL`, similar to queries that filter on the table distribution key column(s).
- The `gpinitssystem` option to specify the standby master data directory changed from `-F` to `-S`. The `-S` option no longer specifies spread mirroring. A new `gpinitssystem` option is introduced to specify the mirroring configuration: `--mirror-mode={group|spread}`.
- The default value of the server configuration parameter `log_rotation_size` has changed from 0 to 1GB. This changes the default log rotation behavior so that a new log file is opened when more than 1GB has been written to the current log file or when the current log file has been open for 24 hours.
- The default value of the server configuration parameter `effective_cache_size` has changed from 512MB to 16GB.
- The `gpssh-exkeys` utility now requires that you have already set up passwordless SSH from the master host to every other host in the cluster. Running `gpssh-exkeys` then sets up passwordless SSH from every host to every other host.
- The `gpstop` smart shutdown behavior has changed. Previously, if you ran `gpstop -M smart` (or just `gpstop`), the utility exited with a message if there were any active client connections. Now, `gpstop` waits for current connections to finish before completing the shutdown. If any connections remain open after the timeout period, or if you interrupt with CTRL-C, `gpstop` lists the open connections and prompts whether to continue waiting for connections to finish, or to perform a fast or immediate shutdown. The default timeout period is 120 seconds and

can be changed with the `-t timeout_seconds` option.

- In the `pg_stat_activity` and `pg_stat_replication` system views, the `procpid` column was renamed to `pid` to match the associated change in PostgreSQL 9.2.
- In the `pg_proc` system table, the `proiswin` column was renamed to `proiswindow` and relocated in the table to match the `pg_proc` system table in PostgreSQL 8.4.
- Queries that use `SELECT DISTINCT` and `UNION/INTERSECT/EXCEPT` no longer necessarily return sorted output. Previously these queries always removed duplicate rows by using Sort/Unique processing. They now implement hashing to conform to behavior introduced in PostgreSQL 8.4; this method does not produce sorted output. If your application requires sorted output for these queries, alter the queries to use an explicit `ORDER BY` clause. Note that `SELECT DISTINCT ON` never uses hashing, so its behavior is unchanged from previous versions.
- In the `gp_toolkit` schema, the `gp_resgroup_config` view no longer contains the columns `proposed_concurrency`, `proposed_memory_limit`, `proposed_memory_shared_quota` and `proposed_memory_spill_ratio`.
- In the `pg_resgroupcapability` system table, the `proposed` column has been removed.
- The `pg_database` system table `datconfig` column was removed. Greenplum Database now uses the `pg_db_role_setting` system table to keep track of per-database and per-role server configuration settings (PostgreSQL 9.0).
- The `pg_aggregate` system table `aggordered` column was removed, and several new columns were added to the table to support ordered-set aggregates and moving-aggregates with the Postgres Planner (PostgreSQL 9.4). The `ALTER/CREATE/DROP AGGREGATE` SQL command signatures have also been updated to reflect the `pg_aggregate` catalog changes.
- The `pg_authid` system table `rolconfig` column was removed. Greenplum Database now uses the `pg_db_role_setting` system table to keep track of per-database and per-role server configuration settings (PostgreSQL 9.0).
- When creating and altering a table that has a distribution column, you can now specify the hash function used to distribute data across segment instances.
- Pivotal Greenplum Database 6 removes the `RECHECK` option from `ALTER OPERATOR FAMILY` and `CREATE OPERATOR CLASS` DDL (PostgreSQL 8.4). Greenplum now determines whether an index operator is “lossy” on-the-fly at runtime.
- Operator-related system catalog tables are modified to support operator families, compatibility, and types (ordering or search).
- System catalog table entries for HyperLogLog (HLL) functions, aggregates, and types are modified to prefix names with `gp_`. Renaming the HLL functions prevents name collisions with external Greenplum Database extensions that use HLL. Any user code written to use the built-in Greenplum Database HLL functions must be updated to use the new `gp_` names.
- The data-type-specific `lag()` and `lead()` functions are removed and replaced with more generic function signatures. Additionally, the `offset` argument to the functions is changed from `bigint` to the `integer` data type. Refer to [pg_upgrade Checks - Views with lead/lag functions using bigint](#) in the `gpupgrade` documentation or [About Migrating Views Created with lag\(\)/lead\(\) Functions](#) in the Greenplum Database documentation for information about these changes and the required upgrade or migration actions.
- The “legacy optimizer” from previous releases of Greenplum is now referred to as the Postgres planner in both the code and documentation.
- The transaction isolation levels in Greenplum Database 6.0 are changed to align with

PostgreSQL transaction isolation levels since the introduction of the serializable snapshot isolation (SSI) mode in PostgreSQL 9.1. The new SSI mode, which is *not* implemented in Greenplum Database, provides true serializability by monitoring concurrent transactions and rolling back transactions that could introduce a serialization anomaly. The existing snapshot isolation (SI) mode guarantees that transactions operate on a single, consistent snapshot of the database, but does not guarantee a consistent result when a set of concurrent transactions is executed in any given sequence.

Greenplum Database 6.0 now allows the `REPEATABLE READ` keywords with SQL statements such as `BEGIN` and `SET TRANSACTION`. A `SERIALIZABLE` transaction in PostgreSQL 9.1 or later uses the new SSI mode. A `SERIALIZABLE` transaction in Greenplum Database 6.0 falls back to `REPEATABLE READ`, using the SI mode. The following table shows the SQL standard compliance for each transaction isolation level in Greenplum Database 6.0 and PostgreSQL 9.1.

Requested Transaction Isolation Level	Greenplum Database 6.0 Compliance	PostgreSQL 9.1 Compliance
READ UNCOMMITTED	READ COMMITTED	READ COMMITTED
READ COMMITTED	READ COMMITTED	READ COMMITTED
REPEATABLE READ	REPEATABLE READ (SI)	REPEATABLE READ (SI)
SERIALIZABLE	Falls back to REPEATABLE READ (SI)	SERIALIZABLE (SSI)

- The `CREATE TABLESPACE` command has changed.
 - ◊ The command no longer requires a file space created with the `gpfilespace` utility.
 - ◊ The `FILESPACE` clause has been removed.
 - ◊ The `WITH` clause has been added to allow specifying a tablespace location for a specific segment instance.
 - ◊ A primary-mirror pair sharing the same content ID must use the same tablespace location.
- The `ALTER SEQUENCE` SQL command has new clauses `START [WITH] start` and `OWNER TO new_owner` (PostgreSQL 8.4). The `START` clause sets the start value that will be used by future `ALTER SEQUENCE RESTART` commands, but does not change the current value of the sequence. The `OWNER TO` clause changes the sequence's owner.
- The `ALTER TABLE` SQL command has a `SET WITH OIDS` clause to add an `oid` system column to a table (PostgreSQL 8.4). Note that using oids with Greenplum Database tables is strongly discouraged.
- The `CREATE DATABASE` SQL command has new parameters `LC_COLLATE` and `LC_CTYPE` to specify the collation order and character classification for the new database.
- The `CREATE FUNCTION` SQL command has a new keyword `WINDOW`, which indicates that the function is a window function rather than a plain function (PostgreSQL 8.4).
- Specifying the index name in the `CREATE INDEX` SQL command is now optional. Greenplum Database constructs a default index name from the table name and indexed columns.
- In the `CREATE TABLE` command, the Greenplum Database parser allows commas to be placed between a `SUBPARTITION TEMPLATE` clause and its corresponding `SUBPARTITION BY` clause, and between consecutive `SUBPARTITION BY` clauses. Using this undocumented syntax will generate a deprecation warning message.

- Superuser privileges are now required to create a protocol. See [CREATE PROTOCOL](#).
- The `CREATE TYPE` SQL command has a new `LIKE=type` clause that copies the new type's representation (`INTERNALLENGTH`, `PASSEDBYVALUE`, `ALIGNMENT`, and `STORAGE`) from an existing type (PostgreSQL 8.4).
- The `GRANT` SQL command has new syntax to grant privileges on truncate, foreign data wrappers, and foreign data servers (PostgreSQL 8.4).
- The `LOCK` SQL command has an optional `ONLY` keyword (PostgreSQL 8.4). When specified, the table is locked without locking any tables that inherit from it.
- Using the `LOCK table` statement outside of a transaction raises an error in Greenplum Database 6.0. In earlier releases, the statement executed, although it is only useful when executed inside of a transaction.
- The `SELECT` and `VALUES` SQL commands support the SQL 2008 `OFFSET` and `FETCH` syntax (PostgreSQL 8.4). These clauses provide an alternative syntax for limiting the results returned by a query.
- The `FROM` clause can be omitted from a `SELECT` command, but Greenplum Database no longer allows queries that omit the `FROM` clause and also reference database tables.
- The `ROWS` and `RANGE` SQL keywords have changed from reserved to unreserved, and may be used as table or column names without quoting.
- In Greenplum 6, a query on an external table with descendants will by default recurse into the descendant tables. This is a change from previous Greenplum Database versions, which *never* recursed into descendants. To get the previous behavior in Greenplum 6, you must include the `ONLY` keyword in the query to restrict the query to the parent table.
- The default value for the `optimizer_force_multistage_agg` server configuration parameter has changed from `true` to `false`. GPORCA will now by default choose between a one-stage or two-stage aggregate plan for a scalar distinct qualified aggregate based on cost.
- The `TRUNCATE` SQL command has an optional `ONLY` keyword (PostgreSQL 8.4). When specified, the table is truncated without truncating any tables that inherit from it.
- The `createdb` command-line utility has new options `-l (--locale)`, `--lc-collate`, and `--lc-ctype` to specify the locale and character classification for the database (PostgreSQL 8.4).
- The `pg_dump`, `pg_dumpall`, and `pg_restore` utilities have a new `--role=rolename` option that instructs the utility to execute `SET ROLE rolename` after connecting to the database and before starting the dump or restore operation (PostgreSQL 8.4).
- The `pg_dump` and `pg_dumpall` command-line utilities have a new option `--lock-wait-timeout=timeout` (PostgreSQL 8.4). When specified, instead of waiting indefinitely the dump fails if the utility cannot acquire shared table locks within the specified number of milliseconds.
- The `-d` and `-D` command-line options are removed from the `pg_dump` and `pg_dumpall` utilities. The corresponding long versions, `--inserts` and `--column-inserts` are still supported. A new `--binary-upgrade` option is added, for use by in-place upgrade utilities.
- The `-w (--no-password)` option was added to the `pg_dump`, `pg_dumpall`, and `pg_restore` utilities.
- The `-D` option is removed from the `gpexpand` utility. The expansion schema will be created in the `postgres` database.
- The `gpstate` utility has a new `-x` option, which displays details of an in-progress system

expansion. `gpstate -s` and `gpstate` with no options specified also report if a system expansion is in progress.

- The `pg_restore` utility has a new option `-j` (`--number-of-jobs`) parameter. This option can reduce time to restore a large database by running tasks such as loading data, creating indexes, and creating constraints concurrently.
- The `vacuumdb` utility has a new `-F` (`--freeze`) option to freeze row transaction information.
- `ALTER DATABASE` includes the `SET TABLESPACE` clause to change the default tablespace.
- `CREATE DATABASE` includes the `COLLATE` and `CTYPE` options for setting the collation order and character classification of the new database.
- In the `gp_toolkit` schema, the `gp_workfile_*` views have changed due to Greenplum Database 6 workfile enhancements. See [Checking Query Disk Spill Space Usage](#) for information about `gp_workfile_*` views.
- The server configuration parameter `gp_workfile_compress_algorithm` has been changed to `gp_workfile_compression`. When workfile compression is enabled, Greenplum Database uses Zstandard compression.
- The Oracle Compatibility Functions are now available in Greenplum Database as an extension, based on the PostgreSQL orafce project at <https://github.com/orafce/orafce>. Instead of executing a SQL script to install the compatibility functions in a database, you now execute the SQL command `CREATE EXTENSION orafce`. The Greenplum Database 6.0 orafce extension is based on the orafce 3.7 release. See [Oracle Compatibility Functions](#) for information about differences between the Greenplum Database compatibility functions and the PostgreSQL orafce extension.
- Greenplum Database 6 supports specifying a table column of the `citext` data type as a distribution key.
- Greenplum Database 6 provides a single client and loader tool package that you can download and install on a client system. Previous Greenplum releases provided separate client and loader packages. For more information about the Greenplum 6 Clients package, refer to [Client Tools](#) in the platform requirements documentation.
- Greenplum Database 6 includes both PostgreSQL-sourced and Greenplum-sourced `contrib` modules. Most of these modules are now packaged as extensions, and you register an extension in Greenplum with the `CREATE EXTENSION name` command. Refer to [Installing Additional Supplied Modules](#) for more information about registering `contrib` modules in Greenplum Database 6.
- When Greenplum Database High Availability is enabled, a primary segment instance is kept up to date with the mirror segment instance using Write-Ahead Logging (WAL)-based streaming replication. See [Overview of Segment Mirroring](#).

The `gp_stat_replication` view contains replication statistics when master or segment mirroring is enabled.

In previous releases, segment mirroring employed a physical file replication scheme.

- In the `gp_segment_configuration` table, the `replication_port` has been removed. The `datadir` column has been added to display the segment instance data directory. The `mode` column values are now s (synchronized) or n (not synchronized). Use the `gp_stat_replication` view to determine the synchronization state.
- The Greenplum Database 6 Client and Loader Tools package for Windows does not support running the `gpfdist` program as a native Windows service.

Removed Features

Pivotal Greenplum Database 6.0 removes these features:

- The `gpsegininstall` utility is no longer included. You must install the Greenplum software RPM on each segment host, as described in [Installing the Greenplum Database Software](#).
- The `gptransfer` utility is no longer included; use `gpcopy` for all functionality that was provided with `gptransfer`.
- The `gp_fault_strategy` system table is no longer used. Greenplum Database now uses the `gp_segment_configuration` system table to determine if mirroring is enabled.
- Pivotal Greenplum Database 6 removes the `gpcrondump`, `gpdbrestore`, and `gpmfr` management utilities. Use `gpbackup` and `gprestore` to back up and restore Greenplum Database.
- Pivotal Greenplum Database 6 no longer supports Veritas NetBackup.
- Pivotal Greenplum Database 6 no longer supports the use of direct I/O to bypass the buffering of memory within the file system cache for backup.
- Pivotal Greenplum Database 6 no longer supports the `gphdfs` external table protocol to access a Hadoop system. Use the Greenplum Platform Extension Framework (PXF) to access Hadoop in version 6. Refer to [pxf:// Protocol](#) for information about using the `pxf` external table protocol.
- Pivotal Greenplum Database 6 no longer supports SSLv3.
- Pivotal Greenplum Database 6 removes the following server configuration parameters:
 - ◊ `gp_analyze_relative_error`
 - ◊ `gp_backup_directIO`
 - ◊ `gp_backup_directIO_read_chunk_mb`
 - ◊ `gp_connections_per_thread`
 - ◊ `gp_enable_sequential_window_plans`
 - ◊ `gp_idf_deduplicate`
 - ◊ `gp_snmp_community`
 - ◊ `gp_snmp_monitor_address`
 - ◊ `gp_snmp_use_inform_or_trap`
 - ◊ `gp_workfile_checksumming`
- The undocumented `gp_cancel_query()` function, and the configuration parameters `gp_cancel_query_print_log` and `gp_cancel_query_delay_time`, are removed in Greenplum Database 6.
- The `string_agg(expression)` function is removed from Greenplum 6. The function concatenates text values into a string. The `string_agg(expression, delimiter)` function is still supported.
- Pivotal Greenplum Database 6 no longer supports the ability to configure a Greenplum Database system to trigger SNMP (Simple Network Management Protocol) alerts or send email notifications to system administrators if certain database events occur. Use Pivotal Greenplum Command Center alerts to detect and respond to events that occur in a Greenplum system.

- Pivotal Greenplum Database 6 removes the `gpfilespace` utility. The `CREATE TABLESPACE` command no longer requires a filespace created with the utility.
- Pivotal Greenplum Database 6 no longer automatically casts text from the deprecated timestamp format `YYYYMMDDHH24MISS`. The format could not be parsed unambiguously in previous Greenplum Database releases. The format is not supported in PostgreSQL 9.4.

For example, this command returns an error in Greenplum Database 6. In previous releases, a timestamp is returned.

```
# select to_timestamp('20190905140000');
```

In Greenplum Database 6, this command returns a timestamp.

```
# select to_timestamp('20190905140000','YYYYMMDDHH24MISS');
```

- Pivotal Greenplum Database 6 removes the `--ignore-version` option from the `pg_dump`, `pg_dumpall`, and `pg_restore` utilities.
- The `gpcheck` utility is no longer included.

Deprecated Features

Deprecated features will be removed in a future major release of Greenplum Database. VMware Tanzu Greenplum 6.x deprecates:

- The `gpsys1` utility.
- The `analyzedb` option `--skip_root_stats` (deprecated since 6.2).
If the option is specified, a warning is issued stating that the option will be ignored.
- The server configuration parameter `gp_statistics_use_fkeys` (deprecated since 6.2).
- The server configuration parameter `gp_ignore_error_table` (deprecated since 6.0).
To avoid a Greenplum Database syntax error, set the value of this parameter to `true` when you run applications that execute `CREATE EXTERNAL TABLE` or `COPY` commands that include the now removed Greenplum Database 4.3.x `INTO ERROR TABLE` clause.
- Specifying `=>` as an operator name in the `CREATE OPERATOR` command (deprecated since 6.0).
- The Greenplum external table C API (deprecated since 6.0).
Any developers using this API are encouraged to use the new Foreign Data Wrapper API in its place.
- Commas placed between a `SUBPARTITION TEMPLATE` clause and its corresponding `SUBPARTITION BY` clause, and between consecutive `SUBPARTITION BY` clauses in a `CREATE TABLE` command (deprecated since 6.0).
Using this undocumented syntax will generate a deprecation warning message.
- The timestamp format `YYYYMMDDHH24MISS` (deprecated since 6.0).
This format could not be parsed unambiguously in previous Greenplum Database releases, and is not supported in PostgreSQL 9.4.
- The `createlang` and `droplang` utilities (deprecated since 6.0).
- The `pg_resqueue_status` system view (deprecated since 6.0).
Use the `gp_toolkit.pg_resqueue_status` view instead.

- The `GLOBAL` and `LOCAL` modifiers when creating a temporary table with the `CREATE TABLE` and `CREATE TABLE AS` commands (deprecated since 6.0).

These keywords are present for SQL standard compatibility, but have no effect in Greenplum Database.

- Using `WITH OIDS` or `oids=TRUE` to assign an OID system column when creating or altering a table (deprecated since 6.0).
- Allowing superusers to specify the `SQL_ASCII` encoding regardless of the locale settings (deprecated since 6.0).

This choice may result in misbehavior of character-string functions when data that is not encoding-compatible with the locale is stored in the database.

- The `@@@` text search operator (deprecated since 6.0).

This operator is currently a synonym for the `@@` operator.

- The unparenthesized syntax for option lists in the `VACUUM` command (deprecated since 6.0).

This syntax requires that the options to the command be specified in a specific order.

- The `plain pgbouncer` authentication type (`auth_type = plain`) (deprecated since 4.x).

Known Issues and Limitations

VMware Tanzu Greenplum 6 has these limitations:

- Upgrading a Greenplum Database 4 release to VMware Tanzu Greenplum 6 is not supported. Upgrading a Greenplum Database 5.x release to VMware Tanzu Greenplum 6 is supported via `gpupgrade`. For more information, see the [gpupgrade documentation](#).
- MADlib, GPText, and PostGIS are not yet provided for installation on Ubuntu systems.

The following table lists key known issues in VMware Tanzu Greenplum 6.x.

Table 1. Key Known Issues in VMware Tanzu Greenplum 6.x

Issue	Category	Description
31010	Query Optimizer	<p>A view created in Greenplum Database 5.28.3 or older that specified an external table in the <code>FROM</code> clause, and that was migrated to Greenplum Database 6.x, always falls back to the Postgres Planner when queried.</p> <p>Workaround: If you migrated a view from Greenplum Database 5.28.3 or earlier, and the view specified an external table in the <code>FROM</code> clause, you must drop and recreate the view in Greenplum 6.x to ensure that the Query Optimizer is exercised when you query the view.</p>

Table 1. Key Known Issues in VMware Tanzu Greenplum 6.x

Issue	Category	Description
N/A	Backup/Restore	<p>Restoring the Greenplum Database backup for a table fails in Greenplum 6 versions earlier than version 6.10 when a replicated table has an inheritance relationship to/from another table that was assigned via an <code>ALTER TABLE ... INHERIT</code> statement after table creation.</p> <p>Workaround: Use the following SQL commands to determine if Greenplum Database includes any replicated tables that inherit from a parent table, or if there are replicated tables that are inherited by a child table:</p> <pre>SELECT inhrelid::regclass FROM pg_inherits, gp_distribution_policy dp WHERE inhrelid=dp.localoid AND dp.policytype= 'r' ; SELECT inhparent::regclass FROM pg_inherits , gp_distribution_policy dp WHERE inhparent=dp.localoid AND dp.policytype= 'r' ;</pre> <p>If these queries return any tables, you may choose to run <code>gprestore</code> with the <code>--on-error-continue</code> flag to not fail the entire restore when this issue is hit. Or, you can specify the list of tables returned by the queries to the <code>--exclude-table-file</code> option to skip those tables during restore. You must recreate and repopulate the affected tables after restore.</p>
N/A	Spark Connector	This version of Greenplum is not compatible with Greenplum-Spark Connector versions earlier than version 1.7.0, due to a change in how Greenplum handles distributed transaction IDs.
N/A	Greenplum on vSphere	Due to a corruption issue in vSAN 7.0.3., the most recent supported version of vSAN for Greenplum on vSphere is vSAN 7.0.2.
N/A	PXF	<p>Starting in 6.x, Greenplum does not bundle <code>cURL</code> and instead loads the system-provided library. PXF requires <code>cURL</code> version 7.29.0 or newer. The officially-supported <code>cURL</code> for the CentOS 6.x and Red Hat Enterprise Linux 6.x operating systems is version 7.19.*. Greenplum Database 6 does not support running PXF on CentOS 6.x or RHEL 6.x due to this limitation.</p> <p>Workaround: Upgrade the operating system of your Greenplum Database 6 hosts to CentOS 7+ or RHEL 7+, which provides a <code>cURL</code> version suitable to run PXF.</p>
29703	Loading Data from External Tables	<p>Due to limitations in the Greenplum Database external table framework, Greenplum Database cannot log the following types of errors that it encounters while loading data:</p> <ul style="list-style-type: none"> data type parsing errors unexpected value type errors data type conversion errors errors returned by native and user-defined functions <p><code>LOG ERRORS</code> returns error information for data exceptions only. When it encounters a parsing error, Greenplum terminates the load job, but it cannot log and propagate the error back to the user via <code>gp_read_error_log()</code>.</p> <p>Workaround: Clean the input data before loading it into Greenplum Database.</p>
30594	Resource Management	Resource queue-related statistics may be inaccurate in certain cases. VMware recommends that you use the resource group resource management scheme that is available in Greenplum 6.

Table 1. Key Known Issues in VMware Tanzu Greenplum 6.x

Issue	Category	Description
30522	Logging	Greenplum Database may write a FATAL message to the standby master or mirror log stating that <i>the database system is in recovery mode</i> when the instance is synchronizing with the master and Greenplum attempts to contact it before the operation completes. Ignore these messages and use <code>gpstate -f</code> output to determine if the standby successfully synchronized with the Greenplum master; the command returns <code>Sync state: sync</code> if it is synchronized.
30537	Postgres Planner	<p>The Postgres Planner generates a very large query plan that causes out of memory issues for the following type of CTE (common table expression) query: the WITH clause of the CTE contains a partitioned table with a large number partitions, and the WITH reference is used in a subquery that joins another partitioned table.</p> <p>Workaround: If possible, use the GPORCA query optimizer. With the server configuration parameter <code>optimizer=on</code>, Greenplum Database attempts to use GPORCA for query planning and optimization when possible and falls back to the Postgres Planner when GPORCA cannot be used. Also, the specified type of query might require a long time to complete.</p>
170824967	gpfdists	For Greenplum Database 6.x, a command that accesses an external table that uses the <code>gpfdists</code> protocol fails if the external table does not use an IP address when specifying a host system in the LOCATION clause of the external table definition.
n/a	Materialized Views	By default, certain <code>gp_toolkit</code> views do not display data for materialized views. If you want to include this information in <code>gp_toolkit</code> view output, you must redefine a <code>gp_toolkit</code> internal view as described in Including Data for Materialized Views .
168957894	PXF	<p>The PXF Hive Connector does not support using the <code>Hive*</code> profiles to access Hive transactional tables.</p> <p>Workaround: Use the PXF JDBC Connector to access Hive.</p>
168548176	gpbackup	When using <code>gpbackup</code> to back up a Greenplum Database 5.7.1 or earlier 5.x release with resource groups enabled, <code>gpbackup</code> returns a column not found error for <code>t6.value AS memoryauditor</code> .
164791118	PL/R	<p>PL/R cannot be installed using the deprecated <code>createlang</code> utility, and displays the error:</p> <pre>createlang: language installation failed: ERROR: no schema has been selected to create in</pre> <p>Workaround: Use <code>CREATE EXTENSION</code> to install PL/R, as described in the documentation.</p>
N/A	Greenplum Client/Load Tools on Windows	The Greenplum Database client and load tools on Windows have not been tested with Active Directory Kerberos authentication.
N/A	Greenplum Installation	For Greenplum Database 6.16.1 and 6.16.2, the library <code>libevent</code> is not listed as a dependency for the rpm for RHEL 7. Resolved in 6.16.3.

Platform Requirements

This topic describes the Greenplum Database 6 platform and operating system software requirements for three primary deployment scenarios:

- [Tanzu Greenplum deployed to Dell EMC VxRail](#)
- [Tanzu Greenplum deployed to on-premise hardware](#)
- [Tanzu Greenplum deployed to cloud services such as AWS, GCP, or Azure](#)

Supported Platforms

VMware Tanzu Greenplum on vSphere is compatible with these operating system and Greenplum Database versions:

OS Version	Greenplum Version
CentOS 7.x ,RHEL 7.x, Oracle Linux 7.x	6.x

VMware Tanzu Greenplum on vSphere is compatible with these VMware vSphere versions:

VMware vSphere component	Version
VMware ESXi	Greater then or equal to 6.7 Update 3
vCenter Server	Greater then or equal to 7.0 GA (7.0.0.10100)

VMware Tanzu Greenplum on vSphere is compatible with these storage systems and versions:

Storage System	Version
VMware vSAN	Less then or equal to 7.0 Update 2
Dell EMC PowerFlex	Greater then or equal to 3.6.0

The following table displays the compatible editions for vSphere, vSAN and vCenter Server based on the supported versions:

Product	Supported Edition and Product Features	References
VMware vSphere	VMware vSphere Enterprise Plus - Distributed Switch - Virtual Machine Encryption - Distributed Resource Scheduler	See more
vSAN	Enterprise - RAID-5/6 Erasure Coding - Data-at-Rest and Data-in-Transit encryption	See more
vCenter Server	vCenter Server Foundation (up to 4 hosts) vCenter Server Standard (more than 4 hosts)	See more

Platform Requirements for On-Premise Hardware

This topic describes the Greenplum Database 6 platform and operating system software

requirements.

- [Operating Systems](#)
 - [Software Dependencies](#)
 - [Java](#)
- [Hardware and Network](#)
- [Storage](#)
- [Tanzu Greenplum Tools and Extensions Compatibility](#)
 - [Client Tools](#)
 - [Extensions](#)
 - [Data Connectors](#)
 - [Tanzu Greenplum Text](#)
 - [Greenplum Command Center](#)
- [Hadoop Distributions](#)

Parent topic: [Installing and Upgrading Greenplum](#)

Operating Systems

Greenplum Database 6 runs on the following operating system platforms:

- Red Hat Enterprise Linux 64-bit 8.x (as of Greenplum Database version 6.20)
- Red Hat Enterprise Linux 64-bit 7.x (See the following [Note](#).)
- Red Hat Enterprise Linux 64-bit 6.x
- CentOS 64-bit 7.x
- CentOS 64-bit 6.x
- Ubuntu 18.04 LTS
- Oracle Linux 64-bit 7, using the Red Hat Compatible Kernel (RHCK)

Important: Significant Greenplum Database performance degradation has been observed when enabling resource group-based workload management on RedHat 6.x and CentOS 6.x systems. This issue is caused by a Linux cgroup kernel bug. This kernel bug has been fixed in CentOS 7.x and Red Hat 7.x/8.x systems.

If you use RedHat 6 and the performance with resource groups is acceptable for your use case, upgrade your kernel to version 2.6.32-696 or higher to benefit from other fixes to the cgroups implementation.

Note: For Greenplum Database that is installed on Red Hat Enterprise Linux 7.x or CentOS 7.x prior to 7.3, an operating system issue might cause Greenplum Database that is running large workloads to hang in the workload. The Greenplum Database issue is caused by Linux kernel bugs.

RHEL 7.3 and CentOS 7.3 resolves the issue.

Note: Do not install anti-virus software on Greenplum Database hosts as the software might cause extra CPU and IO load that interferes with Greenplum Database operations.

Greenplum Database server supports TLS version 1.2 on RHEL/CentOS systems, and TLS version 1.3 on Ubuntu systems.

Software Dependencies

Greenplum Database 6 requires the following software packages on RHEL/CentOS 6/7 systems which are installed automatically as dependencies when you install the Greenplum RPM package):

- apr
- apr-util
- bash
- bzip2
- curl
- krb5
- libcurl
- libevent
- libxml2
- libyaml
- zlib
- openldap
- openssh-client
- openssl
- openssl-libs (RHEL7/Centos7)
- perl
- readline
- rsync
- R
- sed (used by `gpinitssystem`)
- tar
- zip

Tanzu Greenplum Database 6 client software requires these operating system packages:

- apr
- apr-util
- libyaml
- libevent

On Ubuntu systems, Greenplum Database 6 requires the following software packages, which are installed automatically as dependencies when you install Greenplum Database with the Debian package installer:

- libapr1
- libaprutil1
- bash
- bzip2
- krb5-multidev
- libcurl3-gnutls

- libcurl4
- libevent-2.1-6
- libxml2
- libyaml-0-2
- zlib1g
- libldap-2.4-2
- openssh-client
- openssl
- perl
- readline
- rsync
- sed
- tar
- zip
- net-tools
- less
- iproute2

Greenplum Database 6 uses Python 2.7.12, which is included with the product installation (and not installed as a package dependency).

Important: SSL is supported only on the Greenplum Database master host system. It cannot be used on the segment host systems.

Important: For all Greenplum Database host systems, if SELinux is enabled in [Enforcing](#) mode then the Greenplum process and users can operate successfully in the default [Unconfined](#) context. If increased confinement is required, then you must configure SELinux contexts, policies, and domains based on your security requirements, and test your configuration to ensure there is no functionality or performance impact to Greenplum Database. Similarly, you should either disable or configure firewall software as needed to allow communication between Greenplum hosts. See [Disable or Configure SELinux](#).

Java

Greenplum Database 6 supports these Java versions for PL/Java and PXF:

- Open JDK 8 or Open JDK 11, available from [AdoptOpenJDK](#)
- Oracle JDK 8 or Oracle JDK 11

Hardware and Network

The following table lists minimum recommended specifications for hardware servers intended to support Greenplum Database on Linux systems in a production environment. All host servers in your Greenplum Database system must have the same hardware and software configuration. Greenplum also provides hardware build guides for its certified hardware platforms. It is recommended that you work with a Greenplum Systems Engineer to review your anticipated environment to ensure an appropriate hardware configuration for Greenplum Database.

Minimum Hardware Requirements

Minimum CPU	Any x86_64 compatible CPU
Minimum Memory	16 GB RAM per server
Disk Space Requirements	<ul style="list-style-type: none"> 150MB per host for Greenplum installation Approximately 300MB per segment instance for metadata Cap disk capacity at 70% full to accommodate temporary files and prevent performance degradation
Network Requirements	10 Gigabit Ethernet within the array NIC bonding is recommended when multiple interfaces are present Greenplum Database can use either IPV4 or IPV6 protocols.

Tanzu Greenplum on DCA Systems

You must run Tanzu Greenplum version 6.9 or later on Dell EMC DCA systems, with software version 4.2.0.0 and later.

Storage

The only file system supported for running Greenplum Database is the XFS file system. All other file systems are explicitly *not* supported by VMware.

Greenplum Database is supported on network or shared storage if the shared storage is presented as a block device to the servers running Greenplum Database and the XFS file system is mounted on the block device. Network file systems are *not* supported. When using network or shared storage, Greenplum Database mirroring must be used in the same way as with local storage, and no modifications may be made to the mirroring scheme or the recovery scheme of the segments.

Other features of the shared storage such as de-duplication and/or replication are not directly supported by Greenplum Database, but may be used with support of the storage vendor as long as they do not interfere with the expected operation of Greenplum Database at the discretion of VMware.

Greenplum Database can be deployed to virtualized systems only if the storage is presented as block devices and the XFS file system is mounted for the storage of the segment directories.

Greenplum Database is supported on Amazon Web Services (AWS) servers using either Amazon instance store (Amazon uses the volume names `ephemeral[0-23]`) or Amazon Elastic Block Store (Amazon EBS) storage. If using Amazon EBS storage the storage should be RAID of Amazon EBS volumes and mounted with the XFS file system for it to be a supported configuration.

Data Domain Boost (Tanzu Greenplum)

Tanzu Greenplum 6 supports Data Domain Boost for backup on Red Hat Enterprise Linux. This table lists the versions of Data Domain Boost SDK and DDOS supported by Tanzu Greenplum 6.

Tanzu Greenplum	Data Domain Boost	DDOS
6.x	3.3	6.1 (all versions), 6.0 (all versions)

Note: In addition to the DDOS versions listed in the previous table, Tanzu Greenplum supports all minor patch releases (fourth digit releases) later than the certified version.

Tanzu Greenplum Tools and Extensions Compatibility

- [Client Tools](#) (Tanzu Greenplum)

- [Extensions](#)
- [Data Connectors](#)
- [Tanzu Greenplum Text](#)
- [Greenplum Command Center](#)

Client Tools

VMware releases a Clients tool package on various platforms that can be used to access Greenplum Database from a client system. The Greenplum 6 Clients tool package is supported on the following platforms:

- Red Hat Enterprise Linux x86_64 6.x (RHEL 6)
- Red Hat Enterprise Linux x86_64 7.x (RHEL 7)
- Red Hat Enterprise Linux x86_64 8.x (RHEL 8)
- Ubuntu 18.04 LTS
- SUSE Linux Enterprise Server x86_64 12 (SLES 12)
- Windows 10 (32-bit and 64-bit)
- Windows 8 (32-bit and 64-bit)
- Windows Server 2012 (32-bit and 64-bit)
- Windows Server 2012 R2 (32-bit and 64-bit)
- Windows Server 2008 R2 (32-bit and 64-bit)

The Greenplum 6 Clients package includes the client and loader programs provided in the Greenplum 5 packages plus the addition of database/role/language commands and the Greenplum Streaming Server command utilities. Refer to [Greenplum Client and Loader Tools Package](#) for installation and usage details of the Greenplum 6 Client tools.

Extensions

This table lists the versions of the Greenplum Extensions that are compatible with this release of Greenplum Database 6.

Greenplum Extensions Compatibility

Component	Package Version	Additional Information
PL/Java	2.0.4	Supports Java 8 and 11.
Python Data Science Module Package	2.0.2	
PL/R	3.0.3	(CentOS) R 3.3.3 (Ubuntu) You install R 3.5.1+.
R Data Science Library Package	2.0.2	
PL/Container	2.1.2	
PL/Container Image for R	2.1.2	R 3.6.3
PL/Container Images for Python	2.1.2	Python 2.7.12 Python 3.7
PL/Container Beta	3.0.0-beta	

Greenplum Extensions Compatibility

Component	Package Version	Additional Information
PL/Container Beta Image for R	3.0.0-beta	R 3.4.4
GreenplumR	1.1.0	Supports R 3.6+.
MADlib Machine Learning	1.19, 1.18, 1.17, 1.16	Support matrix at MADlib FAQ .
PostGIS Spatial and Geographic Objects	2.5.4+pivotal.7.build.1, 2.1.5+pivotal.3.build.3	

For information about the Oracle Compatibility Functions, see [Oracle Compatibility Functions](#).

These Greenplum Database extensions are installed with Greenplum Database

- Fuzzy String Match Extension
- PL/Python Extension
- pgcrypto Extension

Data Connectors

- Greenplum Platform Extension Framework (PXF) - PXF provides access to Hadoop, object store, and SQL external data stores. Refer to [Accessing External Data with PXF](#) in the *Greenplum Database Administrator Guide* for PXF configuration and usage information.
Note: VMware Tanzu Greenplum Database versions starting with 6.19.0 no longer bundle a version of PXF. You can install PXF in your Greenplum cluster by installing [the independent distribution of PXF](#) as described in the PXF documentation.
- Greenplum Streaming Server v1.5.3 - The Tanzu Greenplum Streaming Server is an ETL tool that provides high speed, parallel data transfer from Informatica, Kafka, Apache NiFi and custom client data sources to a Tanzu Greenplum cluster. Refer to the [Tanzu Greenplum Streaming Server](#) Documentation for more information about this feature.
- Greenplum Streaming Server Kafka integration - The Kafka integration provides high speed, parallel data transfer from a Kafka cluster to a Greenplum Database cluster for batch and streaming ETL operations. It requires Kafka version 0.11 or newer for exactly-once delivery assurance. Refer to the [Tanzu Greenplum Streaming Server](#) Documentation for more information about this feature.
- Greenplum Connector for Apache Spark v1.6.2 - The Tanzu Greenplum Connector for Apache Spark supports high speed, parallel data transfer between Greenplum and an Apache Spark cluster using Spark's Scala API.
- Greenplum Connector for Apache NiFi v1.0.0 - The Tanzu Greenplum Connector for Apache NiFi enables you to set up a NiFi dataflow to load record-oriented data from any source into Greenplum Database.
- Greenplum Informatica Connector v1.0.5 - The Tanzu Greenplum Connector for Informatica supports high speed data transfer from an Informatica PowerCenter cluster to a Tanzu Greenplum cluster for batch and streaming ETL operations.
- Progress DataDirect JDBC Drivers v5.1.4+275, v6.0.0+181 - The Progress DataDirect JDBC drivers are compliant with the Type 4 architecture, but provide advanced features that define them as Type 5 drivers.
- Progress DataDirect ODBC Drivers v7.1.6+7.16.389 - The Progress DataDirect ODBC drivers enable third party applications to connect via a common interface to the Tanzu Greenplum system.

- R2B X-LOG v5.x and v6.x - Real-time data replication solution that achieves high-speed database replication through the use of Redo Log Capturing method.

Note: Tanzu Greenplum 6 does not support the ODBC driver for Cognos Analytics V11.

Connecting to IBM Cognos software with an ODBC driver is not supported. Greenplum Database supports connecting to IBM Cognos software with the DataDirect JDBC driver for Tanzu Greenplum. This driver is available as a download from [VMware Tanzu Network](#).

Tanzu Greenplum Text

Tanzu Greenplum 6.0 through 6.4 are compatible with Tanzu Greenplum Text 3.3.1 through 3.4.1. Tanzu Greenplum 6.5 and later are compatible with Tanzu Greenplum Text 3.4.2 and later. See the [Greenplum Text documentation](#) for additional compatibility information.

Greenplum Command Center

Tanzu Greenplum 6.15 is compatible only with Tanzu Greenplum Command Center 6.4.0 and later. See the [Greenplum Command Center documentation](#) for additional compatibility information.

Hadoop Distributions

Greenplum Database provides access to HDFS with the [Greenplum Platform Extension Framework \(PXF\)](#).

PXF can use Cloudera, Hortonworks Data Platform, MapR, and generic Apache Hadoop distributions. PXF bundles all of the JAR files on which it depends, including the following Hadoop libraries:

PXF Version	Hadoop Version	Hive Server Version	HBase Server Version
6.x, 5.15.x, 5.14.0, 5.13.0, 5.12.0, 5.11.1, 5.10.1	2.x, 3.1+	1.x, 2.x, 3.1+	1.3.2
5.8.2	2.x	1.x	1.3.2
5.8.1	2.x	1.x	1.3.2

Note: If you plan to access JSON format data stored in a Cloudera Hadoop cluster, PXF requires a Cloudera version 5.8 or later Hadoop distribution.

Greenplum Database Cloud Technical Recommendations

Operating System

The operating system parameters for cloud deployments are the same as on-premise with a few modifications. Use the [Greenplum Database Installation Guide](#) for reference. Additional changes are as follows:

Add the following line to `sysctl.conf`:

```
net.ipv4.ip_local_reserved_ports=65330
```

AWS requires loading network drivers and also altering the Amazon Machine Image (AMI) to use the faster networking capabilities. More information on this is provided in the AWS documentation.

Storage

The disk settings for cloud deployments are the same as on-premise with a few modifications. Use the [Greenplum Database Installation Guide](#) for reference. Additional changes are as follows:

- Mount options:

```
rw,noatime,nobarrier,nodev,inode64
```

Note: The `nobarrier` option is not supported on RHEL 8 or Ubuntu nodes.

- Use mq-deadline instead of the deadline scheduler for the R5 series instance type in AWS
- Use a swap disk per VM (32GB size works well)

Security

It is highly encouraged to disable SSH password authentication to the virtual machines in the cloud and use SSH keys instead. Using MD5-encrypted passwords for Greenplum Database is also a good practice.

Amazon Web Services (AWS)

Virtual Machine Type

AWS provides a wide variety of virtual machine types and sizes to address virtually every use case. Testing in AWS has found that the optimal instance types for Greenplum are “Memory Optimized” . These provide the ideal balance of Price, Memory, Network, and Storage throughput, and Compute capabilities.

Price, Memory, and number of cores typically increase in a linear fashion, but the network speed and disk throughput limits do not. You may be tempted to use the largest instance type to get the highest network and disk speed possible per VM, but better overall performance for the same spend on compute resources can be obtained by using more VMs that are smaller in size.

Compute

AWS uses Hyperthreading when reporting the number of vCPUs, therefore 2 vCPUs equates to 1 Core. The processor types are frequently getting faster so using the latest instance type will be not only faster, but usually less expensive. For example, the R5 series provides faster cores at a lower cost compared to R4.

Memory

This variable is pretty simple. Greenplum needs at least 8GB of RAM per segment process to work optimally. More RAM per segment helps with concurrency and also helps hide disk performance deficiencies.

Network

AWS provides 25Gbit network performance on the largest instance types, but the network is typically not the bottleneck in AWS. The “up to 10Gbit” network is sufficient in AWS.

Installing network drivers in the VM is also required in AWS, and depends on the instance type. Some instance types use an Intel driver while others use an Amazon ENA driver. Loading the driver requires modifying the machine image (AMI) to take advantage of the driver.

Storage

Elastic Block Storage (EBS)

The AWS default disk type is General Performance (GP2) which is ideal for IOP dependent applications. GP2 uses SSD disks and relative to other disk types in AWS, is expensive. The operating system and swap volumes are ideal for GP2 disks because of the size and higher random I/O needs.

Throughput Optimized Disks (ST1) are a disk type designed for high throughput needs such as Greenplum. These disks are based on HDD rather than SSD, and are less expensive than GP2. Use this disk type for the optimal performance of loading and querying data in AWS.

Cold Storage (SC1) provides the best value for EBS storage in AWS. Using multiple 2TB or larger disks provides enough disk throughput to reach the throughput limit of many different instance types. Therefore, it is possible to reach the throughput limit of a VM by using SC1 disks.

EBS storage is durable so data is not lost when a virtual machine is stopped. EBS also provides infrastructure snapshot capabilities that can be used to create volume backups. These snapshots can be copied to different regions to provide a disaster recovery solution. The Greenplum Cloud utility `gpsnap`, available in the AWS Cloud Marketplace, automates backup, restore, delete, and copy functions using EBS snapshots.

Storage can be grown in AWS with “`gpgrow`”. This tool is included with the Greenplum on AWS deployment and allows you to grow the storage independently of compute. This is an online operation in AWS too.

Ephemeral

Ephemeral Storage is directly attached to VMs, but has many drawbacks: - Data loss when stopping a VM with ephemeral storage - Encryption is not supported - No Snapshots - Same speed can be achieved with EBS storage - Not recommended

AWS Recommendations

Master

Instance Type	Memory	vCPUs	Data Disks
r5.xlarge	32	4	1
r5.2xlarge	64	8	1
r5.4xlarge	128	16	1

Segments

Instance Type	Memory	vCPUs	Data Disks
r5.4xlarge	128	16	3

Performance testing has indicated that the Master node can be deployed on the smallest r5.xlarge instance type to save money without a measurable difference in performance. Testing was performed using the TPC-DS benchmark.

The Segment instances run optimally on the r5.4xlarge instance type. This provides the highest performance given the cost of the AWS resources.

Google Compute Platform (GCP)

Virtual Machine Type

The two most common instance types in GCP are “Standard” or “HighMem” instance types. The only difference is the ratio of Memory to Cores. Each offer 1 to 64 vCPUs per VM.

Compute

Like AWS, GCP uses Hyperthreading, so 2 vCPUs equates to 1 Core. The CPU clock speed is determined by the region in which you deploy.

Memory

Instance type n1-standard-8 has 8 vCPUs with 30GB of RAM while n1-highmem-8 also has 8 vCPUs with 52GB of RAM. There is also a HighCPU instance type that generally isn't ideal for Greenplum. Like AWS and Azure, the machines with more vCPUs will have more RAM.

Network

GCP network speeds are dependent on the instance type but the maximum network performance is possible (10Gbit) with a virtual machine as small as only 8 vCPUs.

Storage

Standard (HDD) and SSD disks are available in GCP. SSD is slightly faster in terms of throughput but comes at a premium. The size of the disk does not impact performance.

The biggest obstacle to maximizing storage performance is the throughput limit placed on every virtual machine. Unlike AWS and Azure, the storage throughput limit is relatively low, consistent across all instance types, and only a single disk is needed to reach the VM limit.

GCP Recommendations

Testing has revealed that *while using the same number of vCPUs*, a cluster using a large instance type like n1-highmem-64 (64 vCPUs) will have lower performance than a cluster using more of the smaller instance types like n1-highmem-8 (8 vCPUs). In general, use 8x more nodes in GCP than you would in another environment like AWS while using the 8 vCPU instance types.

The HighMem instance type is slightly faster for higher concurrency. Furthermore, SSD disks are slightly faster also but come at a cost.

Master and Segment Instances

Instance Type	Memory	vCPUs	Data Disks
n1-standard-8	30	8	1
n1-highmem-8	52	8	1

Azure

Note: On the Azure platform, in addition to bandwidth, the number of network connections present on a VM at any given moment can affect the VM's network performance. The Azure networking stack maintains the state for each direction of a TCP/UDP connection in a data structures called a *flow*. A typical TCP/UDP connection will have 2 flows created: one for the inbound direction and another for the outbound direction. The number of network flows on Azure is limited to an upper bound. See [Virtual machine network bandwidth](#) in the Azure documentation for more details. In practice this can present scalability challenges for workloads based on the number of concurrent queries, and on the complexity of those queries. Always test your workload on Azure to validate that you are within the Azure limits, and be advised that if your workload increases you may hit Azure flow count boundaries at which point your workload may fail. VMware recommends using the UDP interconnect, and not the TCP interconnect, when using Azure. A connection pooler and resource group settings can also be used to help keep flow counts at a lower level.

Virtual Machine Type

Each VM type has limits on disk throughput so picking a VM that doesn't have a limit that is too low is essential. Most of Azure is designed for OLTP or Application workloads, which limits the choices for databases like Greenplum where throughput is more important. Disk type also plays a part in the throughput cap, so that needs to be considered too.

Compute

Most instance types in Azure have hyperthreading enabled, which means 1 vCPU equates to 2 cores. However, not all instance types have this feature, so for these others, 1 vCPU equates to 1 core.

The High Performance Compute (HPC) instance types have the fastest cores in Azure.

Memory

In general, the larger the virtual machine type, the more memory the VM will have.

Network

The Accelerated Networking option offloads CPU cycles for networking to "FPGA-based SmartNICs". Virtual machine types either support this or do not, but most do support it. Testing of Greenplum hasn't shown much difference and this is probably because of Azure's preference for TCP over UDP. Despite this, UDPIFC interconnect is the ideal protocol to use in Azure.

There is an undocumented process in Azure that periodically runs on the host machines on UDP port 65330. When a query runs using UDP port 65330 and this undocumented process runs, the query will fail after one hour with an interconnect timeout error. This is fixed by reserving port 65330 so that Greenplum doesn't use it.

Storage

Storage in Azure is either Premium (SSD) or Regular Storage (HDD). The available sizes are the same and max out at 4TB. Instance types either do or do not support Premium but, interestingly, the instance types that do support Premium storage, have a *lower* throughput limit. For example:

- Standard_E32s_v3 has a limit of 768 MB/s.
- Standard_E32_v3 was tested with `gpcheckperf` to have 1424 write and 1557 read MB/s performance.

To get the maximum throughput from a VM in Azure, you have to use multiple disks. For larger instance types, you have to use upwards of 32 disks to reach the limit of a VM. Unfortunately, the memory and CPU constraints on these machines means that you have to run fewer segments than you have disks, so you have to use software RAID to utilize all of these disks. Performance takes a hit with software RAID, too, so you have to try multiple configurations to optimize.

The size of the disk also impacts performance, but not by much.

Software RAID not only is a little bit slower, but it also requires `umount` to take a snapshot. This greatly lengthens the time it takes to take a snapshot backup.

Disks use the same network as the VMs so you start running into the Azure limits in bigger clusters when using big virtual machines with 32 disks on each one. The overall throughput drops as you hit this limit and is most noticeable during concurrency testing.

Azure Recommendations

The best instance type to use in Azure is “Standard_H8” which is one of the High Performance Compute instance types. This instance series is the only one utilizing InfiniBand, but this does not include IP traffic. Because this instance type is not available in all regions, the “Standard_D13_v2” is also available.

Master

Instance Type	Memory	vCPUs	Data Disks
D13_v2	56	8	1
H8	56	8	1

Segments

Instance Type	Memory	vCPUs	Data Disks
D13_v2	56	8	2
H8	56	8	2

Greenplum Database Concepts

This section provides an overview of Greenplum Database components and features such as high availability, parallel data loading features, and management utilities.

- **About the Greenplum Architecture**
Greenplum Database is a massively parallel processing (MPP) database server with an architecture specially designed to manage large-scale analytic data warehouses and business intelligence workloads.
- **About Management and Monitoring Utilities**
Greenplum Database provides standard command-line utilities for performing common monitoring and administration tasks.
- **About Concurrency Control in Greenplum Database**
Greenplum Database uses the PostgreSQL Multiversion Concurrency Control (MVCC) model to manage concurrent transactions for heap tables.
- **About Parallel Data Loading**
This topic provides a short introduction to Greenplum Database data loading features.
- **About Redundancy and Failover in Greenplum Database**
This topic provides a high-level overview of Greenplum Database high availability features.
- **About Database Statistics in Greenplum Database**
An overview of statistics gathered by the ANALYZE command in Greenplum Database.

Parent topic: [Greenplum Database Administrator Guide](#)

About the Greenplum Architecture

Greenplum Database is a massively parallel processing (MPP) database server with an architecture specially designed to manage large-scale analytic data warehouses and business intelligence workloads.

MPP (also known as a *shared nothing* architecture) refers to systems with two or more processors that cooperate to carry out an operation, each processor with its own memory, operating system and disks. Greenplum uses this high-performance system architecture to distribute the load of multi-terabyte data warehouses, and can use all of a system's resources in parallel to process a query.

Greenplum Database is based on PostgreSQL open-source technology. It is essentially several PostgreSQL disk-oriented database instances acting together as one cohesive database management system (DBMS). It is based on PostgreSQL 9.4, and in most cases is very similar to PostgreSQL with regard to SQL support, features, configuration options, and end-user functionality. Database users interact with Greenplum Database as they would with a regular PostgreSQL DBMS.

Greenplum Database can use the append-optimized (AO) storage format for bulk loading and reading of data, and provides performance advantages over HEAP tables. Append-optimized storage provides checksums for data protection, compression and row/column orientation. Both row-oriented or column-oriented append-optimized tables can be compressed.

The main differences between Greenplum Database and PostgreSQL are as follows:

- GPORCA is leveraged for query planning, in addition to the Postgres Planner.
- Greenplum Database can use append-optimized storage.
- Greenplum Database has the option to use column storage, data that is logically organized as a table, using rows and columns that are physically stored in a column-oriented format, rather than as rows. Column storage can only be used with append-optimized tables. Column storage is compressible. It also can provide performance improvements as you only need to return the columns of interest to you. All compression algorithms can be used with either row or column-oriented tables, but Run-Length Encoded (RLE) compression can only be used with column-oriented tables. Greenplum Database provides compression on all Append-Optimized tables that use column storage.

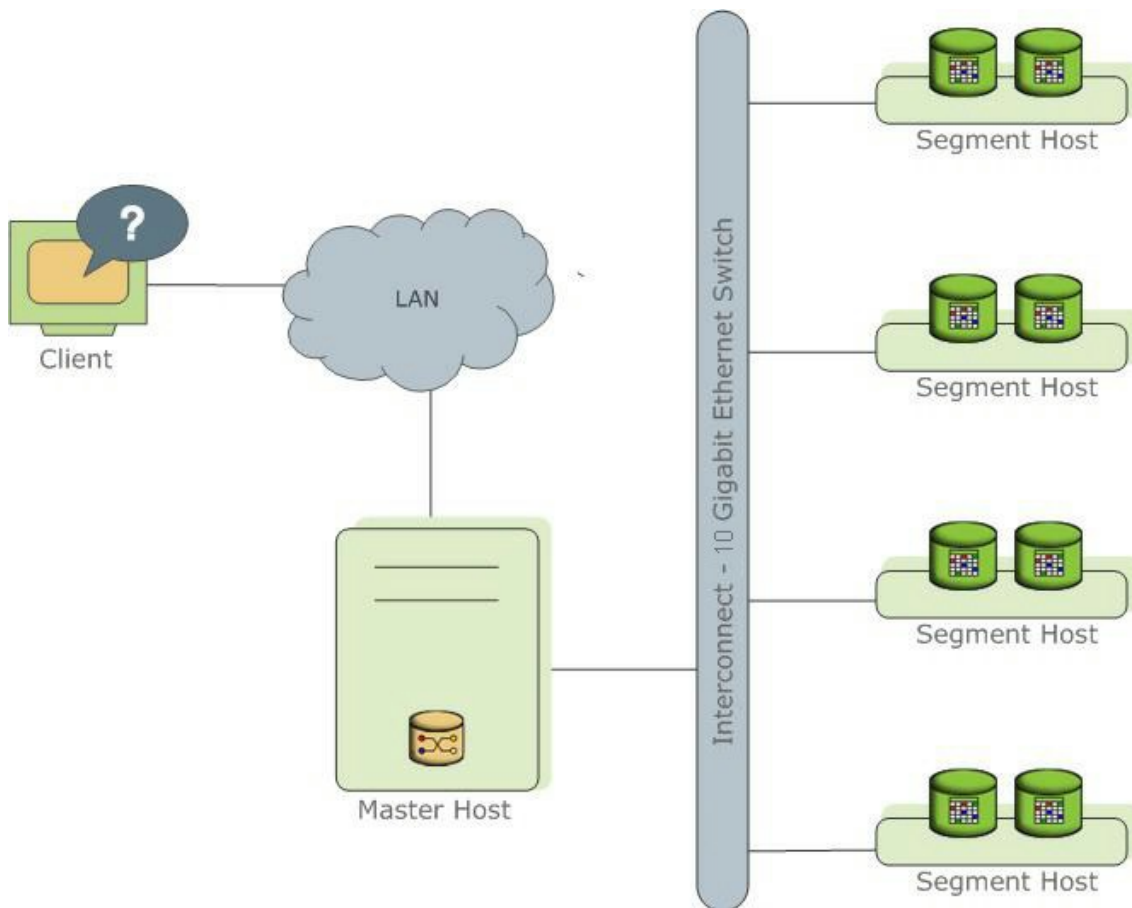

The internals of PostgreSQL have been modified or supplemented to support the parallel structure of Greenplum Database. For example, the system catalog, optimizer, query executor, and transaction manager components have been modified and enhanced to be able to run queries simultaneously across all of the parallel PostgreSQL database instances. The Greenplum *interconnect* (the networking layer) enables communication between the distinct PostgreSQL instances and allows the system to behave as one logical database.

Greenplum Database also can use declarative partitions and sub-partitions to implicitly generate partition constraints.

Greenplum Database also includes features designed to optimize PostgreSQL for business intelligence (BI) workloads. For example, Greenplum has added parallel data loading (external tables), resource management, query optimizations, and storage enhancements, which are not found in standard PostgreSQL. Many features and optimizations developed by Greenplum make their way into the PostgreSQL community. For example, table partitioning is a feature first developed by Greenplum, and it is now in standard PostgreSQL.

Greenplum Database queries use a Volcano-style query engine model, where the execution engine takes an execution plan and uses it to generate a tree of physical operators, evaluates tables through physical operators, and delivers results in a query response.

Greenplum Database stores and processes large amounts of data by distributing the data and processing workload across several servers or *hosts*. Greenplum Database is an *array* of individual databases based upon PostgreSQL 9.4 working together to present a single database image. The *master* is the entry point to the Greenplum Database system. It is the database instance to which clients connect and submit SQL statements. The master coordinates its work with the other database instances in the system, called *segments*, which store and process the data.

The following topics describe the components that make up a Greenplum Database system and how they work together.

- [About the Greenplum Master](#)
- [About the Greenplum Segments](#)
- [About the Greenplum Interconnect](#)
- [About ETL Hosts for Data Loading](#)
- [About Tanzu Greenplum Performance Monitoring](#)

About the Greenplum Master

The Greenplum Database master is the entry to the Greenplum Database system, accepting client connections and SQL queries, and distributing work to the segment instances.

Greenplum Database end-users interact with Greenplum Database (through the master) as they would with a typical PostgreSQL database. They connect to the database using client programs such as `psql` or application programming interfaces (APIs) such as JDBC, ODBC or `libpq` (the PostgreSQL C API).

The master is where the *global system catalog* resides. The global system catalog is the set of system tables that contain metadata about the Greenplum Database system itself. The master does not contain any user data; data resides only on the *segments*. The master authenticates client connections, processes incoming SQL commands, distributes workloads among segments, coordinates the results returned by each segment, and presents the final results to the client program.

Greenplum Database uses Write-Ahead Logging (WAL) for master/standby master mirroring. In WAL-based logging, all modifications are written to the log before being applied, to ensure data

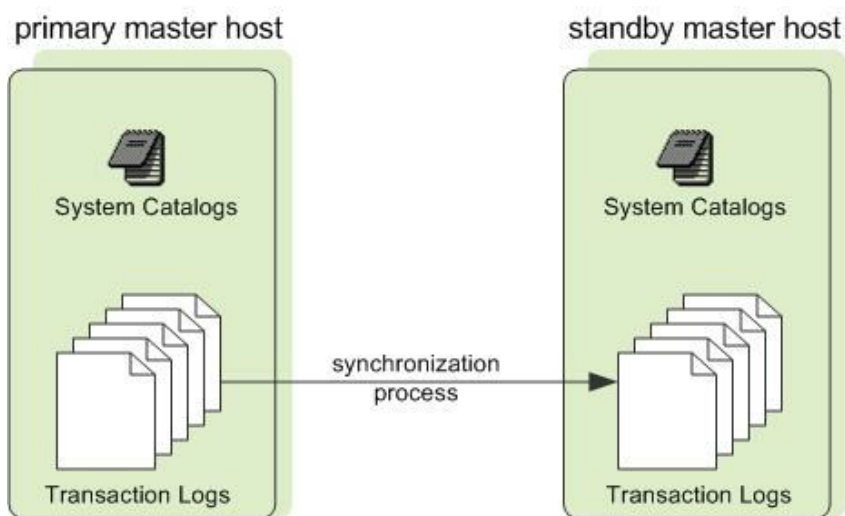

integrity for any in-process operations.

Master Redundancy

You may optionally deploy a *backup* or *mirror* of the master instance. A backup master host serves as a *warm standby* if the primary master host becomes nonoperational. You can deploy the standby master on a designated redundant master host or on one of the segment hosts.

The standby master is kept up to date by a transaction log replication process, which runs on the standby master host and synchronizes the data between the primary and standby master hosts. If the primary master fails, the log replication process shuts down, and an administrator can activate the standby master in its place. When the standby master is active, the replicated logs are used to reconstruct the state of the master host at the time of the last successfully committed transaction.

Since the master does not contain any user data, only the system catalog tables need to be synchronized between the primary and backup copies. When these tables are updated, changes automatically copy over to the standby master so it is always synchronized with the primary.

About the Greenplum Segments

Greenplum Database segment instances are independent PostgreSQL databases that each store a portion of the data and perform the majority of query processing.

When a user connects to the database via the Greenplum master and issues a query, processes are created in each segment database to handle the work of that query. For more information about query processes, see [About Greenplum Query Processing](#).

User-defined tables and their indexes are distributed across the available segments in a Greenplum Database system; each segment contains a distinct portion of data. The database server processes that serve segment data run under the corresponding segment instances. Users interact with segments in a Greenplum Database system through the master.

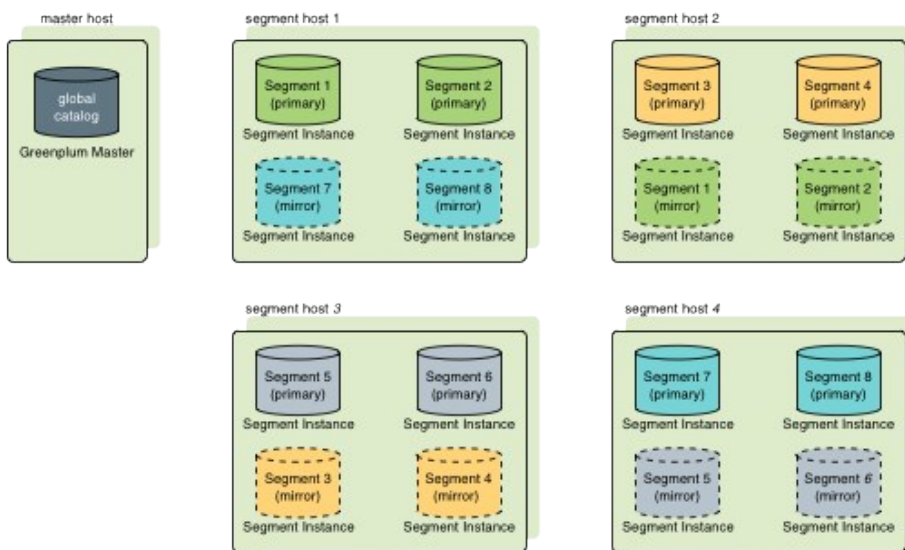

Segments run on a server called *segment hosts*. A segment host typically runs from two to eight Greenplum segments, depending on the CPU cores, RAM, storage, network interfaces, and workloads. Segment hosts are expected to be identically configured. The key to obtaining the best performance from Greenplum Database is to distribute data and workloads *evenly* across a large number of equally capable segments so that all segments begin working on a task simultaneously and complete their work at the same time.

Segment Redundancy

When you deploy your Greenplum Database system, you have the option to configure *mirror*

segments. Mirror segments allow database queries to fail over to a backup segment if the primary segment becomes unavailable. Mirroring is a requirement for VMware-supported production Greenplum systems.

A mirror segment must always reside on a different host than its primary segment. Mirror segments can be arranged across the hosts in the system in one of two standard configurations, or in a custom configuration you design. The default configuration, called *group mirroring*, places the mirror segments for all primary segments on one other host. Another option, called *spread mirroring*, spreads mirrors for each host's primary segments over the remaining hosts. Spread mirroring requires that there be more hosts in the system than there are primary segments on the host. On hosts with multiple network interfaces, the primary and mirror segments are distributed equally among the interfaces. [Figure 2](#) shows how table data is distributed across the segments when the default group mirroring option is configured.

Segment Failover and Recovery

When mirroring is enabled in a Greenplum Database system, the system automatically fails over to the mirror copy if a primary copy becomes unavailable. A Greenplum Database system can remain operational if a segment instance or host goes down only if all portions of data are available on the remaining active segments.

If the master cannot connect to a segment instance, it marks that segment instance as *invalid* in the Greenplum Database system catalog. The segment instance remains invalid and out of operation until an administrator brings that segment back online. An administrator can recover a failed segment while the system is up and running. The recovery process copies over only the changes that were missed while the segment was nonoperational.

If you do not have mirroring enabled and a segment becomes invalid, the system automatically shuts down. An administrator must recover all failed segments before operations can continue.

Example Segment Host Hardware Stack

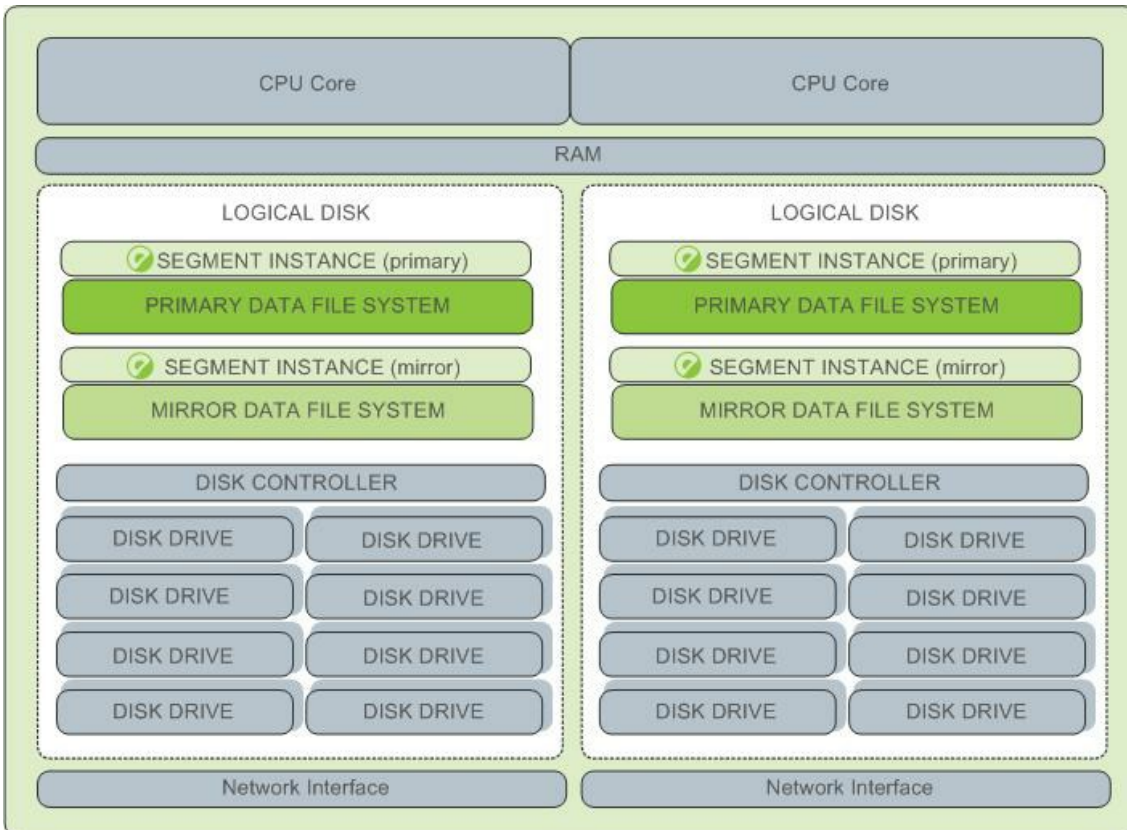

Regardless of the hardware platform you choose, a production Greenplum Database processing node (a segment host) is typically configured as described in this section.

The segment hosts do the majority of database processing, so the segment host servers are configured in order to achieve the best performance possible from your Greenplum Database system. Greenplum Database's performance will be as fast as the slowest segment server in the array. Therefore, it is important to ensure that the underlying hardware and operating systems that are running Greenplum Database are all running at their optimal performance level. It is also advised

that all segment hosts in a Greenplum Database array have identical hardware resources and configurations.

Segment hosts should also be dedicated to Greenplum Database operations only. To get the best query performance, you do not want Greenplum Database competing with other applications for machine or network resources.

The following diagram shows an example Greenplum Database segment host hardware stack. The number of effective CPUs on a host is the basis for determining how many primary Greenplum Database segment instances to deploy per segment host. This example shows a host with two effective CPUs (one dual-core CPU). Note that there is one primary segment instance (or primary/mirror pair if using mirroring) per CPU core.

Example Segment Disk Layout

Each CPU is typically mapped to a logical disk. A logical disk consists of one primary file system (and optionally a mirror file system) accessing a pool of physical disks through an I/O channel or disk controller. The logical disk and file system are provided by the operating system. Most operating systems provide the ability for a logical disk drive to use groups of physical disks arranged in RAID arrays.

Depending on the hardware platform you choose, different RAID configurations offer different performance and capacity levels. Greenplum supports and certifies a number of reference hardware platforms and operating systems. Check with your sales account representative for the recommended configuration on your chosen platform.

About the Greenplum Interconnect

The interconnect is the networking layer of the Greenplum Database architecture.

The *interconnect* refers to the inter-process communication between segments and the network infrastructure on which this communication relies. The Greenplum interconnect uses a standard Ethernet switching fabric. For performance reasons, a 10-Gigabit system, or faster, is recommended.

By default, the interconnect uses User Datagram Protocol with flow control (UDPIFC) for interconnect traffic to send messages over the network. The Greenplum software performs packet verification beyond what is provided by UDP. This means the reliability is equivalent to Transmission Control Protocol (TCP), and the performance and scalability exceeds TCP. If the interconnect is changed to TCP, Greenplum Database has a scalability limit of 1000 segment instances. With UDPIFC as the default protocol for the interconnect, this limit is not applicable.

Interconnect Redundancy

A highly available interconnect can be achieved by deploying dual 10 Gigabit Ethernet switches on your network, and redundant 10 Gigabit connections to the Greenplum Database master and segment host servers.

Network Interface Configuration

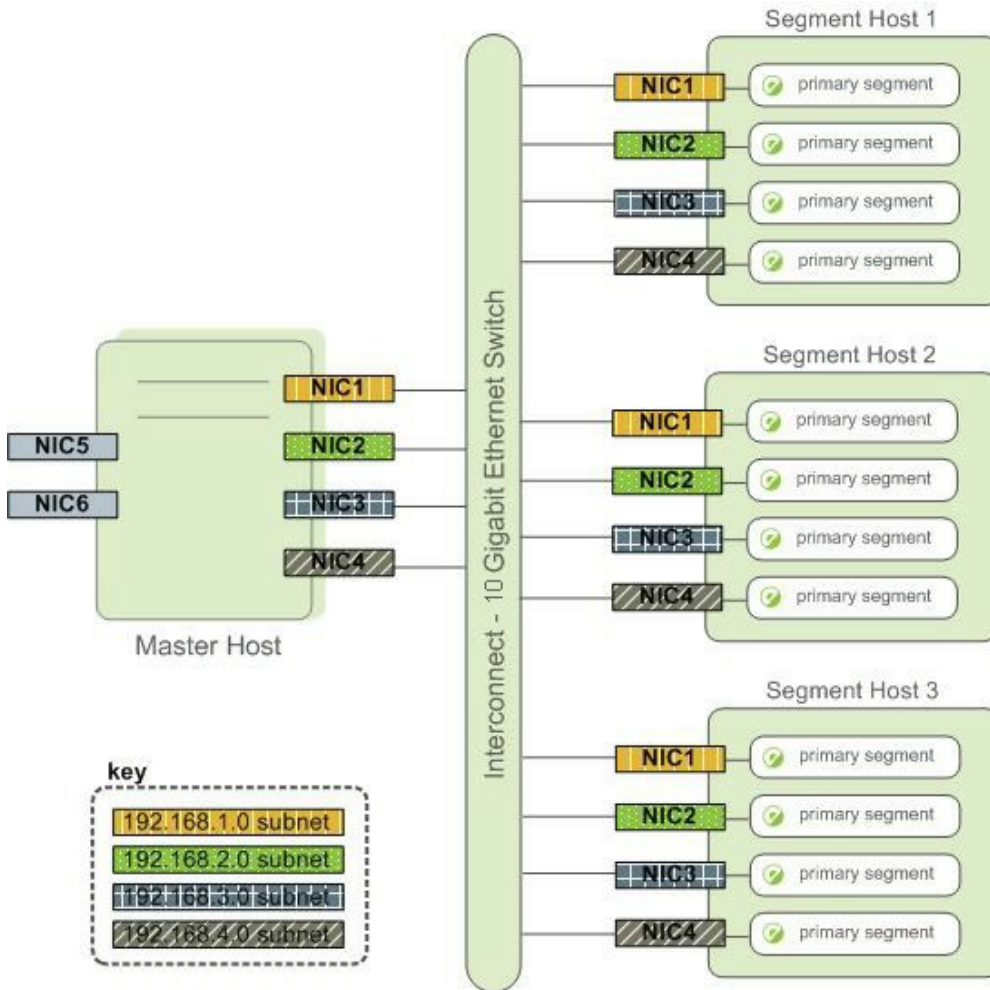

A segment host typically has multiple network interfaces designated to Greenplum interconnect traffic. The master host typically has additional external network interfaces in addition to the interfaces used for interconnect traffic.

Depending on the number of interfaces available, you will want to distribute interconnect network traffic across the number of available interfaces. This is done by assigning segment instances to a particular network interface and ensuring that the primary segments are evenly balanced over the number of available interfaces.

This is done by creating separate host address names for each network interface. For example, if a host has four network interfaces, then it would have four corresponding host addresses, each of which maps to one or more primary segment instances. The `/etc/hosts` file should be configured to contain not only the host name of each machine, but also all interface host addresses for all of the Greenplum Database hosts (master, standby master, segments, and ETL hosts).

With this configuration, the operating system automatically selects the best path to the destination.

Greenplum Database automatically balances the network destinations to maximize parallelism.

Switch Configuration

When using multiple 10 Gigabit Ethernet switches within your Greenplum Database array, evenly divide the number of subnets between each switch. In this example configuration, if we had two switches, NICs 1 and 2 on each host would use switch 1 and NICs 3 and 4 on each host would use switch 2. For the master host, the host name bound to NIC 1 (and therefore using switch 1) is the effective master host name for the array. Therefore, if deploying a warm standby master for redundancy purposes, the standby master should map to a NIC that uses a different switch than the primary master.

About ETL Hosts for Data Loading

Greenplum supports fast, parallel data loading with its external tables feature. By using external tables in conjunction with Greenplum Database's parallel file server (`gpfdist`), administrators can achieve maximum parallelism and load bandwidth from their Greenplum Database system. Many production systems deploy designated ETL servers for data loading purposes. These machines run the Greenplum parallel file server (`gpfdist`), but not Greenplum Database instances.

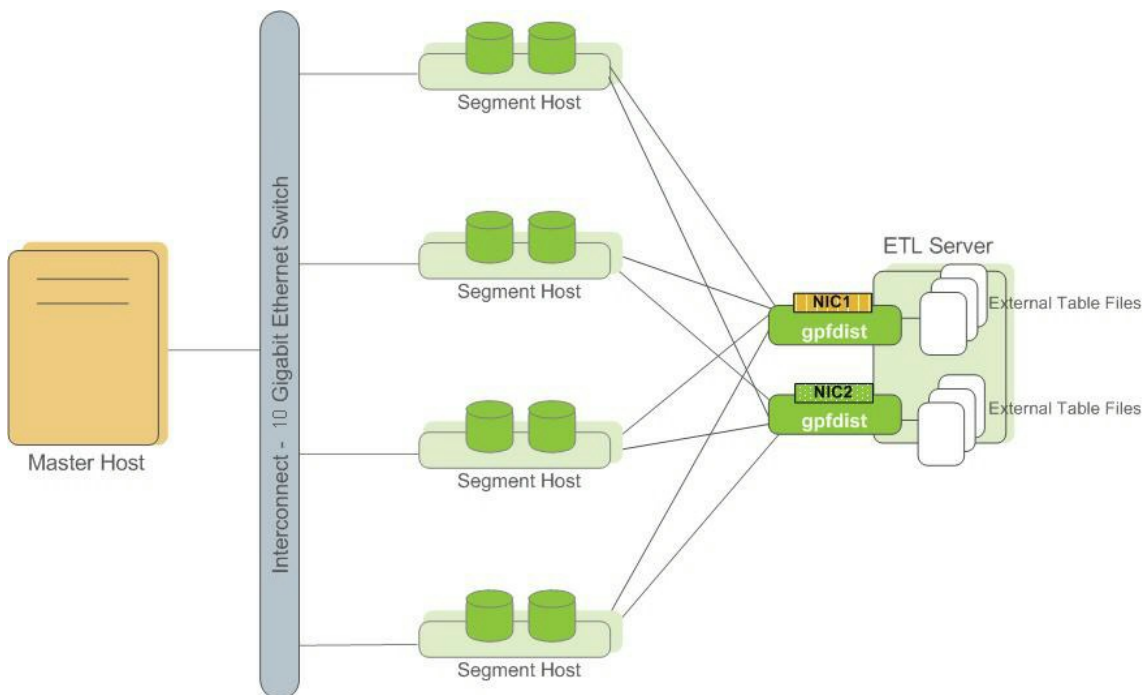

One advantage of using the `gpfdist` file server program is that it ensures that all of the segments in your Greenplum Database system are fully utilized when reading from external table data files.

The `gpfdist` program can serve data to the segment instances at an average rate of about 350 MB/s for delimited text formatted files and 200 MB/s for CSV formatted files. Therefore, you should consider the following options when running `gpfdist` in order to maximize the network bandwidth of your ETL systems:

- If your ETL machine is configured with multiple network interface cards (NICs) as described in [Network Interface Configuration](#), run one instance of `gpfdist` on your ETL host and then define your external table definition so that the host name of each NIC is declared in the `LOCATION` clause (see `CREATE EXTERNAL TABLE` in the *Greenplum Database Reference Guide*). This allows network traffic between your Greenplum segment hosts and your ETL host to use all NICs simultaneously.

- Run multiple `gpfdist` instances on your ETL host and divide your external data files equally between each instance. For example, if you have an ETL system with two network interface cards (NICs), then you could run two `gpfdist` instances on that machine to maximize your load performance. You would then divide the external table data files evenly between the two `gpfdist` programs.

About Tanzu Greenplum Performance Monitoring

Tanzu Greenplum Greenplum Command Center is an optional web-based performance monitoring and management tool for Greenplum Database. Administrators can install Command Center separately from Greenplum Database.

About Management and Monitoring Utilities

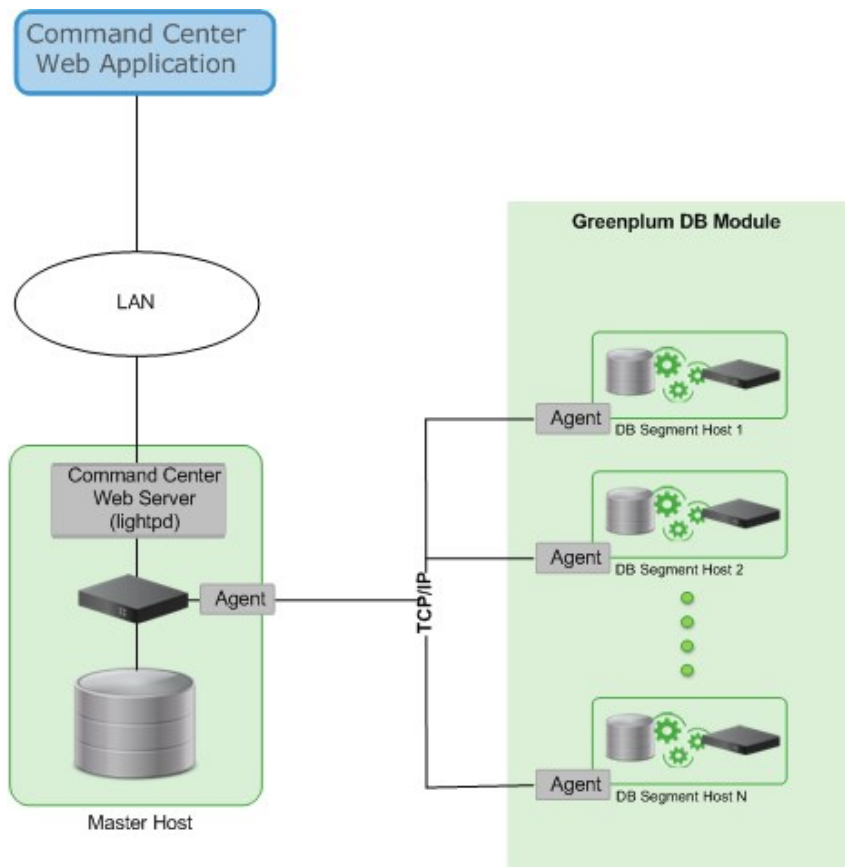

Greenplum Database provides standard command-line utilities for performing common monitoring and administration tasks.

Greenplum command-line utilities are located in the `$GPHOME/bin` directory and are run on the master host. Greenplum provides utilities for the following administration tasks:

- Installing Greenplum Database on an array
- Initializing a Greenplum Database System
- Starting and stopping Greenplum Database
- Adding or removing a host
- Expanding the array and redistributing tables among new segments
- Managing recovery for failed segment instances
- Managing failover and recovery for a failed master instance
- Backing up and restoring a database (in parallel)
- Loading data in parallel
- Transferring data between Greenplum databases
- System state reporting

Greenplum Database includes an optional system monitoring and management database, `gpperfmon`, that administrators can enable. The `gpperfmon_install` command-line utility creates the `gpperfmon` database and enables data collection agents that collect and store query and system metrics in the database. Administrators can query metrics in the `gpperfmon` database. See the documentation for the `gpperfmon` database in the *Greenplum Database Reference Guide*.

VMware provides an optional system monitoring and management tool, Greenplum Command Center, which administrators can install and enable with Greenplum Database. Greenplum Command Center provides a web-based user interface for viewing system metrics and allows administrators to perform additional system management tasks. For more information about Greenplum Command Center, see the [Greenplum Command Center documentation](#).

Parent topic: [Greenplum Database Concepts](#)

About Concurrency Control in Greenplum Database

Greenplum Database uses the PostgreSQL Multiversion Concurrency Control (MVCC) model to manage concurrent transactions for heap tables.

Concurrency control in a database management system allows concurrent queries to complete with correct results while ensuring the integrity of the database. Traditional databases use a two-phase locking protocol that prevents a transaction from modifying data that has been read by another concurrent transaction and prevents any concurrent transaction from reading or writing data that another transaction has updated. The locks required to coordinate transactions add contention to the database, reducing overall transaction throughput.

Greenplum Database uses the PostgreSQL Multiversion Concurrency Control (MVCC) model to manage concurrency for heap tables. With MVCC, each query operates on a snapshot of the database when the query starts. While it runs, a query cannot see changes made by other concurrent transactions. This ensures that a query sees a consistent view of the database. Queries that read rows can never block waiting for transactions that write rows. Conversely, queries that write rows cannot be blocked by transactions that read rows. This allows much greater concurrency than traditional database systems that employ locks to coordinate access between transactions that read and write data.

Note: Append-optimized tables are managed with a different concurrency control model than the MVCC model discussed in this topic. They are intended for “write-once, read-many” applications

that never, or only very rarely, perform row-level updates.

Snapshots

The MVCC model depends on the system's ability to manage multiple versions of data rows. A query operates on a snapshot of the database at the start of the query. A snapshot is the set of rows that are visible at the beginning of a statement or transaction. The snapshot ensures the query has a consistent and valid view of the database for the duration of its execution.

Each transaction is assigned a unique *transaction ID* (XID), an incrementing 32-bit value. When a new transaction starts, it is assigned the next XID. An SQL statement that is not enclosed in a transaction is treated as a single-statement transaction—the `BEGIN` and `COMMIT` are added implicitly. This is similar to autocommit in some database systems.

Note: Greenplum Database assigns XID values only to transactions that involve DDL or DML operations, which are typically the only transactions that require an XID.

When a transaction inserts a row, the XID is saved with the row in the `xmin` system column. When a transaction deletes a row, the XID is saved in the `xmax` system column. Updating a row is treated as a delete and an insert, so the XID is saved to the `xmax` of the current row and the `xmin` of the newly inserted row. The `xmin` and `xmax` columns, together with the transaction completion status, specify a range of transactions for which the version of the row is visible. A transaction can see the effects of all transactions less than `xmin`, which are guaranteed to be committed, but it cannot see the effects of any transaction greater than or equal to `xmax`.

Multi-statement transactions must also record which command within a transaction inserted a row (`cmin`) or deleted a row (`cmax`) so that the transaction can see changes made by previous commands in the transaction. The command sequence is only relevant during the transaction, so the sequence is reset to 0 at the beginning of a transaction.

XID is a property of the database. Each segment database has its own XID sequence that cannot be compared to the XIDs of other segment databases. The master coordinates distributed transactions with the segments using a cluster-wide *session ID number*, called `gp_session_id`. The segments maintain a mapping of distributed transaction IDs with their local XIDs. The master coordinates distributed transactions across all of the segment with the two-phase commit protocol. If a transaction fails on any one segment, it is rolled back on all segments.

You can see the `xmin`, `xmax`, `cmin`, and `cmax` columns for any row with a `SELECT` statement:

```
SELECT xmin, xmax, cmin, cmax, * FROM <tablename>;
```

Because you run the `SELECT` command on the master, the XIDs are the distributed transactions IDs. If you could run the command in an individual segment database, the `xmin` and `xmax` values would be the segment's local XIDs.

Note: Greenplum Database distributes all of a replicated table's rows to every segment, so each row is duplicated on every segment. Each segment instance maintains its own values for the system columns `xmin`, `xmax`, `cmin`, and `cmax`, as well as for the `gp_segment_id` and `ctid` system columns. Greenplum Database does not permit user queries to access these system columns for replicated tables because they have no single, unambiguous value to evaluate in a query.

Transaction ID Wraparound

The MVCC model uses transaction IDs (XIDs) to determine which rows are visible at the beginning of a query or transaction. The XID is a 32-bit value, so a database could theoretically run over four billion transactions before the value overflows and wraps to zero. However, Greenplum Database

uses *modulo 232* arithmetic with XIDs, which allows the transaction IDs to wrap around, much as a clock wraps at twelve o' clock. For any given XID, there could be about two billion past XIDs and two billion future XIDs. This works until a version of a row persists through about two billion transactions, when it suddenly appears to be a new row. To prevent this, Greenplum has a special XID, called `FrozenXID`, which is always considered older than any regular XID it is compared with. The `xmin` of a row must be replaced with `FrozenXID` within two billion transactions, and this is one of the functions the `VACUUM` command performs.

Vacuuming the database at least every two billion transactions prevents XID wraparound. Greenplum Database monitors the transaction ID and warns if a `VACUUM` operation is required.

A warning is issued when a significant portion of the transaction IDs are no longer available and before transaction ID wraparound occurs:

```
WARNING: database "<database_name>" must be vacuumed within <number_of_transactions> transactions
```

When the warning is issued, a `VACUUM` operation is required. If a `VACUUM` operation is not performed, Greenplum Database stops creating transactions to avoid possible data loss when it reaches a limit prior to when transaction ID wraparound occurs and issues this error:

```
FATAL: database is not accepting commands to avoid wraparound data loss in database "<database_name>"
```

See [Recovering from a Transaction ID Limit Error](#) for the procedure to recover from this error.

The server configuration parameters `xid_warn_limit` and `xid_stop_limit` control when the warning and error are displayed. The `xid_warn_limit` parameter specifies the number of transaction IDs before the `xid_stop_limit` when the warning is issued. The `xid_stop_limit` parameter specifies the number of transaction IDs before wraparound would occur when the error is issued and new transactions cannot be created.

Transaction Isolation Modes

The SQL standard describes three phenomena that can occur when database transactions run concurrently:

- *Dirty read* – a transaction can read uncommitted data from another concurrent transaction.
- *Non-repeatable read* – a row read twice in a transaction can change because another concurrent transaction committed changes after the transaction began.
- *Phantom read* – a query run twice in the same transaction can return two different sets of rows because another concurrent transaction added rows.

The SQL standard defines four transaction isolation levels that database systems can support, with the phenomena that are allowed when transactions run concurrently for each level.

Level	Dirty Read	Non-Repeatable	Phantom Read
Read Uncommitted	Possible	Possible	Possible
Read Committed	Impossible	Possible	Possible
Repeatable Read	Impossible	Impossible	Possible
Serializable	Impossible	Impossible	Impossible

Greenplum Database `READ UNCOMMITTED` and `READ COMMITTED` isolation modes behave like the SQL standard `READ COMMITTED` mode. Greenplum Database `SERIALIZABLE` and `REPEATABLE READ` isolation

modes behave like the SQL standard `READ COMMITTED` mode, except that Greenplum Database also prevents phantom reads.

The difference between `READ COMMITTED` and `REPEATABLE READ` is that with `READ COMMITTED`, each statement in a transaction sees only rows committed before the *statement* started, while in `READ COMMITTED` mode, statements in a transaction see only rows committed before the *transaction* started.

With `READ COMMITTED` isolation mode the values in a row retrieved twice in a transaction can differ if another concurrent transaction has committed changes since the transaction began. `READ COMMITTED` mode also permits *phantom reads*, where a query run twice in the same transaction can return two different sets of rows.

The `REPEATABLE READ` isolation mode prevents non-repeatable reads and phantom reads, although the latter is not required by the standard. A transaction that attempts to modify data modified by another concurrent transaction is rolled back. Applications that run transactions in `REPEATABLE READ` mode must be prepared to handle transactions that fail due to serialization errors. If `REPEATABLE READ` isolation mode is not required by the application, it is better to use `READ COMMITTED` mode.

`SERIALIZABLE` mode, which Greenplum Database does not fully support, guarantees that a set of transactions run concurrently produces the same result as if the transactions ran sequentially one after the other. If `SERIALIZABLE` is specified, Greenplum Database falls back to `REPEATABLE READ`. The MVCC Snapshot Isolation (SI) model prevents dirty reads, non-repeatable reads, and phantom reads without expensive locking, but there are other interactions that can occur between some `SERIALIZABLE` transactions in Greenplum Database that prevent them from being truly serializable. These anomalies can often be attributed to the fact that Greenplum Database does not perform *predicate locking*, which means that a write in one transaction can affect the result of a previous read in another concurrent transaction.

Note: The PostgreSQL 9.1 `SERIALIZABLE` isolation level introduces a new Serializable Snapshot Isolation (SSI) model, which is fully compliant with the SQL standard definition of serializable transactions. This model is not available in Greenplum Database. SSI monitors concurrent transactions for conditions that could cause serialization anomalies. When potential serialization problems are found, one transaction is allowed to commit and others are rolled back and must be retried.

Greenplum Database transactions that run concurrently should be examined to identify interactions that may update the same data concurrently. Problems identified can be prevented by using explicit table locks or by requiring the conflicting transactions to update a dummy row introduced to represent the conflict.

The SQL `SET TRANSACTION ISOLATION LEVEL` statement sets the isolation mode for the current transaction. The mode must be set before any `SELECT`, `INSERT`, `DELETE`, `UPDATE`, or `COPY` statements:

```
BEGIN;
SET TRANSACTION ISOLATION LEVEL REPEATABLE READ;
...
COMMIT;
```

The isolation mode can also be specified as part of the `BEGIN` statement:

```
BEGIN TRANSACTION ISOLATION LEVEL REPEATABLE READ;
```

The default transaction isolation mode can be changed for a session by setting the `default_transaction_isolation` configuration property.

Removing Dead Rows from Tables

Updating or deleting a row leaves an expired version of the row in the table. When an expired row is no longer referenced by any active transactions, it can be removed and the space it occupied can be reused. The `VACUUM` command marks the space used by expired rows for reuse.

When expired rows accumulate in a table, the disk files must be extended to accommodate new rows. Performance degrades due to the increased disk I/O required to run queries. This condition is called *bloat* and it should be managed by regularly vacuuming tables.

The `VACUUM` command (without `FULL`) can run concurrently with other queries. It marks the space previously used by the expired rows as free, and updates the free space map. When Greenplum Database later needs space for new rows, it first consults the table's free space map to find pages with available space. If none are found, new pages will be appended to the file.

`VACUUM` (without `FULL`) does not consolidate pages or reduce the size of the table on disk. The space it recovers is only available through the free space map. To prevent disk files from growing, it is important to run `VACUUM` often enough. The frequency of required `VACUUM` runs depends on the frequency of updates and deletes in the table (inserts only ever add new rows). Heavily updated tables might require several `VACUUM` runs per day, to ensure that the available free space can be found through the free space map. It is also important to run `VACUUM` after running a transaction that updates or deletes a large number of rows.

The `VACUUM FULL` command rewrites the table without expired rows, reducing the table to its minimum size. Every page in the table is checked, and visible rows are moved up into pages which are not yet fully packed. Empty pages are discarded. The table is locked until `VACUUM FULL` completes. This is very expensive compared to the regular `VACUUM` command, and can be avoided or postponed by vacuuming regularly. It is best to run `VACUUM FULL` during a maintenance period. An alternative to `VACUUM FULL` is to recreate the table with a `CREATE TABLE AS` statement and then drop the old table.

You can run `VACUUM VERBOSE tablename` to get a report, by segment, of the number of dead rows removed, the number of pages affected, and the number of pages with usable free space.

Query the `pg_class` system table to find out how many pages a table is using across all segments. Be sure to `ANALYZE` the table first to get accurate data.

```
SELECT relname, relpages, reltuples FROM pg_class WHERE relname='<tablename>';
```

Another useful tool is the `gp_bloat_diag` view in the `gp_toolkit` schema, which identifies bloat in tables by comparing the actual number of pages used by a table to the expected number. See “The `gp_toolkit` Administrative Schema” in the *Greenplum Database Reference Guide* for more about `gp_bloat_diag`.

- [Example of Managing Transaction IDs](#)

Parent topic: [Greenplum Database Concepts](#)

Example of Managing Transaction IDs

For Greenplum Database, the transaction ID (XID) value is an incrementing 32-bit (2^{32}) value. The maximum unsigned 32-bit value is 4,294,967,295, or about four billion. The XID values restart at 3 after the maximum is reached. Greenplum Database handles the limit of XID values with two features:

- Calculations on XID values using modulo- 2^{32} arithmetic that allow Greenplum Database to reuse XID values. The modulo calculations determine the order of transactions, whether one transaction has occurred before or after another, based on the XID.

Every XID value can have up to two billion (2^{31}) XID values that are considered previous transactions and two billion ($2^{31} - 1$) XID values that are considered newer transactions. The XID values can be considered a circular set of values with no endpoint similar to a 24 hour clock.

Using the Greenplum Database modulo calculations, as long as two XIDs are within 2^{31} transactions of each other, comparing them yields the correct result.

- A frozen XID value that Greenplum Database uses as the XID for current (visible) data rows. Setting a row's XID to the frozen XID performs two functions.
 - When Greenplum Database compares XIDs using the modulo calculations, the frozen XID is always smaller, earlier, when compared to any other XID. If a row's XID is not set to the frozen XID and 2^{31} new transactions are run, the row appears to be run in the future based on the modulo calculation.
 - When the row's XID is set to the frozen XID, the original XID can be used, without duplicating the XID. This keeps the number of data rows on disk with assigned XIDs below (2^{32}).

Note: Greenplum Database assigns XID values only to transactions that involve DDL or DML operations, which are typically the only transactions that require an XID.

Parent topic: [About Concurrency Control in Greenplum Database](#)

Simple MVCC Example

This is a simple example of the concepts of a MVCC database and how it manages data and transactions with transaction IDs. This simple MVCC database example consists of a single table:

- The table is a simple table with 2 columns and 4 rows of data.
- The valid transaction ID (XID) values are from 0 up to 9, after 9 the XID restarts at 0.
- The frozen XID is -2. This is different than the Greenplum Database frozen XID.
- Transactions are performed on a single row.
- Only insert and update operations are performed.
- All updated rows remain on disk, no operations are performed to remove obsolete rows.

The example only updates the amount values. No other changes to the table.

The example shows these concepts.

- [How transaction IDs are used to manage multiple, simultaneous transactions on a table.](#)
- [How transaction IDs are managed with the frozen XID](#)
- [How the modulo calculation determines the order of transactions based on transaction IDs](#)

Managing Simultaneous Transactions

This table is the initial table data on disk with no updates. The table contains two database columns for transaction IDs, `xmin` (transaction that created the row) and `xmax` (transaction that updated the row). In the table, changes are added, in order, to the bottom of the table.

item	amount	xmin	xmax
widget	100	0	null
giblet	200	1	null

item	amount	xmin	xmax
sprocket	300	2	null
gizmo	400	3	null

The next table shows the table data on disk after some updates on the amount values have been performed.

- `xid = 4: update tbl set amount=208 where item = 'widget'`
- `xid = 5: update tbl set amount=133 where item = 'sprocket'`
- `xid = 6: update tbl set amount=16 where item = 'widget'`

In the next table, the bold items are the current rows for the table. The other rows are obsolete rows, table data that on disk but is no longer current. Using the xmax value, you can determine the current rows of the table by selecting the rows with `null` value. Greenplum Database uses a slightly different method to determine current table rows.

item	amount	xmin	xmax
widget	100	0	4
giblet	200	1	null
sprocket	300	2	5
gizmo	400	3	null
widget	208	4	6
sprocket	133	5	null
widget	16	6	null

The simple MVCC database works with XID values to determine the state of the table. For example, both these independent transactions run concurrently.

- `UPDATE` command changes the sprocket amount value to `133` (xmin value 5)
- `SELECT` command returns the value of sprocket.

During the `UPDATE` transaction, the database returns the value of sprocket `300`, until the `UPDATE` transaction completes.

Managing XIDs and the Frozen XID

For this simple example, the database is close to running out of available XID values. When Greenplum Database is close to running out of available XID values, Greenplum Database takes these actions.

- Greenplum Database issues a warning stating that the database is running out of XID values.

```
WARNING: database "<database_name>" must be vacuumed within <number_of_transactions> transactions
```

- Before the last XID is assigned, Greenplum Database stops accepting transactions to prevent assigning an XID value twice and issues this message.

```
FATAL: database is not accepting commands to avoid wraparound data loss in database "<database_name>"
```

To manage transaction IDs and table data that is stored on disk, Greenplum Database provides the

`VACUUM` command.

- A `VACUUM` operation frees up XID values so that a table can have more than 10 rows by changing the xmin values to the frozen XID.
- A `VACUUM` operation manages obsolete or deleted table rows on disk. This database's `VACUUM` command changes the XID values `obsolete` to indicate obsolete rows. A Greenplum Database `VACUUM` operation, without the `FULL` option, deletes the data opportunistically to remove rows on disk with minimal impact to performance and data availability.

For the example table, a `VACUUM` operation has been performed on the table. The command updated table data on disk. This version of the `VACUUM` command performs slightly differently than the Greenplum Database command, but the concepts are the same.

- For the widget and sprocket rows on disk that are no longer current, the rows have been marked as `obsolete`.
- For the giblest and gizmo rows that are current, the xmin has been changed to the frozen XID.

The values are still current table values (the row's xmax value is `null`). However, the table row is visible to all transactions because the xmin value is frozen XID value that is older than all other XID values when modulo calculations are performed.

After the `VACUUM` operation, the XID values 0, 1, 2, and 3 available for use.

item	amount	xmin	xmax
widget	100	obsolete	obsolete
giblest	200	-2	null
sprocket	300	obsolete	obsolete
gizmo	400	-2	null
widget	208	4	6
sprocket	133	5	null
widget	16	6	null

When a row disk with the xmin value of -2 is updated, the xmax value is replaced with the transaction XID as usual, and the row on disk is considered obsolete after any concurrent transactions that access the row have completed.

Obsolete rows can be deleted from disk. For Greenplum Database, the `VACUUM` command, with `FULL` option, does more extensive processing to reclaim disk space.

Example of XID Modulo Calculations

The next table shows the table data on disk after more `UPDATE` transactions. The XID values have rolled over and start over at 0. No additional `VACUUM` operations have been performed.

item	amount	xmin	xmax
widget	100	obsolete	obsolete
giblest	200	-2	1
sprocket	300	obsolete	obsolete
gizmo	400	-2	9

item	amount	xmin	xmax
widget	208	4	6
sprocket	133	5	null
widget	16	6	7
widget	222	7	null
giblet	233	8	0
gizmo	18	9	null
giblet	88	0	1
giblet	44	1	null

When performing the modulo calculations that compare XIDs, Greenplum Database, considers the XIDs of the rows and the current range of available XIDs to determine if XID wrapping has occurred between row XIDs.

For the example table XID wrapping has occurred. The XID **1** for giblet row is a later transaction than the XID **7** for widget row based on the modulo calculations for XID values even though the XID value **7** is larger than **1**.

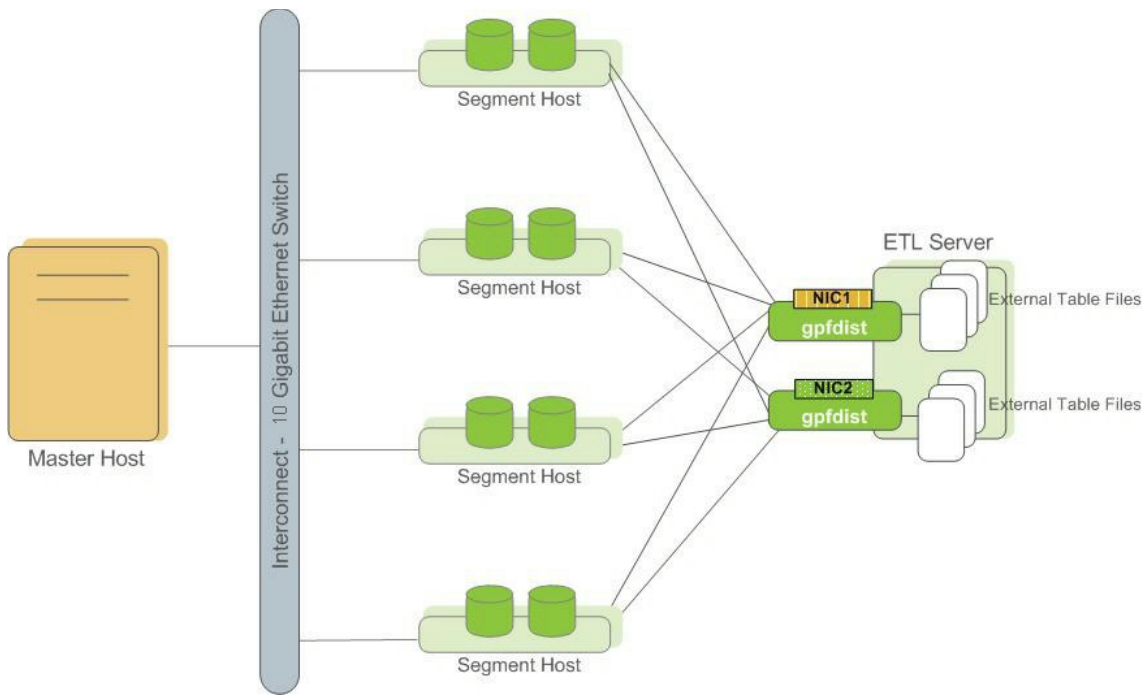

For the widget and sprocket rows, XID wrapping has not occurred and XID **7** is a later transaction than XID **5**.

About Parallel Data Loading

This topic provides a short introduction to Greenplum Database data loading features.

In a large scale, multi-terabyte data warehouse, large amounts of data must be loaded within a relatively small maintenance window. Greenplum supports fast, parallel data loading with its external tables feature. Administrators can also load external tables in single row error isolation mode to filter bad rows into a separate error log while continuing to load properly formatted rows. Administrators can specify an error threshold for a load operation to control how many improperly formatted rows cause Greenplum to cancel the load operation.

By using external tables in conjunction with Greenplum Database's parallel file server (`gpfdist`), administrators can achieve maximum parallelism and load bandwidth from their Greenplum Database system.

Another Greenplum utility, `gpload`, runs a load task that you specify in a YAML-formatted control file. You describe the source data locations, format, transformations required, participating hosts, database destinations, and other particulars in the control file and `gpload` runs the load. This allows you to describe a complex task and run it in a controlled, repeatable fashion.

Parent topic: [Greenplum Database Concepts](#)

About Redundancy and Failover in Greenplum Database

This topic provides a high-level overview of Greenplum Database high availability features.

You can deploy Greenplum Database without a single point of failure by mirroring components. The following sections describe the strategies for mirroring the main components of a Greenplum system. For a more detailed overview of Greenplum high availability features, see [Overview of Greenplum Database High Availability](#).

Important: When data loss is not acceptable for a Greenplum Database cluster, Greenplum master and segment mirroring is recommended. If mirroring is not enabled then Greenplum stores only one copy of the data, so the underlying storage media provides the only guarantee for data availability and correctness in the event of a hardware failure.

The VMware Tanzu Greenplum on vSphere virtualized environment ensures the enforcement of anti-affinity rules required for Greenplum mirroring solutions and fully supports mirrorless deployments. Other virtualized or containerized deployment environments are generally not supported for production use unless both Greenplum master and segment mirroring are enabled.

About Segment Mirroring

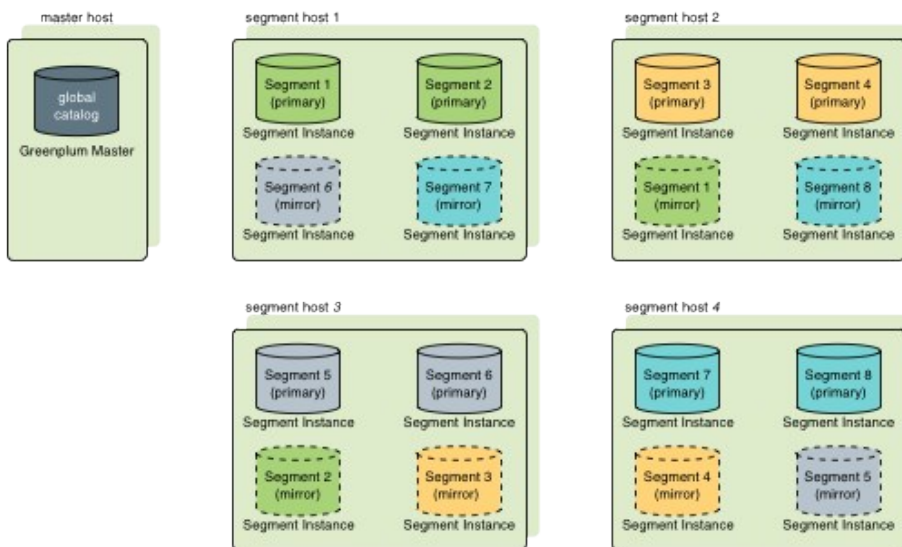

When you deploy your Greenplum Database system, you can configure *mirror* segment instances. Mirror segments allow database queries to fail over to a backup segment if the primary segment becomes unavailable. The mirror segment is kept current by a transaction log replication process, which synchronizes the data between the primary and mirror instances. Mirroring is strongly recommended for production systems and required for VMware support.

As a best practice, the secondary (mirror) segment instance must always reside on a different host than its primary segment instance to protect against a single host failure. In virtualized environments,

the secondary (mirror) segment must always reside on a different storage system than the primary. Mirror segments can be arranged over the remaining hosts in the cluster in configurations designed to maximize availability, or minimize the performance degradation when hosts or multiple primary segments fail.

Two standard mirroring configurations are available when you initialize or expand a Greenplum system. The default configuration, called *group mirroring*, places all the mirrors for a host's primary segments on one other host in the cluster. The other standard configuration, *spread mirroring*, can be selected with a command-line option. Spread mirroring spreads each host's mirrors over the remaining hosts and requires that there are more hosts in the cluster than primary segments per host.

Figure 1 shows how table data is distributed across segments when spread mirroring is configured.

Segment Failover and Recovery

When segment mirroring is enabled in a Greenplum Database system, the system will automatically fail over to the *mirror segment* instance if a *primary segment* instance becomes unavailable. A Greenplum Database system can remain operational if a segment instance or host goes down as long as all the data is available on the remaining active segment instances.

If the master cannot connect to a segment instance, it marks that segment instance as down in the Greenplum Database system catalog and brings up the mirror segment in its place. A failed segment instance will remain out of operation until an administrator takes steps to bring that segment back online. An administrator can recover a failed segment while the system is up and running. The recovery process copies over only the changes that were missed while the segment was out of operation.

If you do not have mirroring enabled, the system will automatically shut down if a segment instance becomes invalid. You must recover all failed segments before operations can continue.

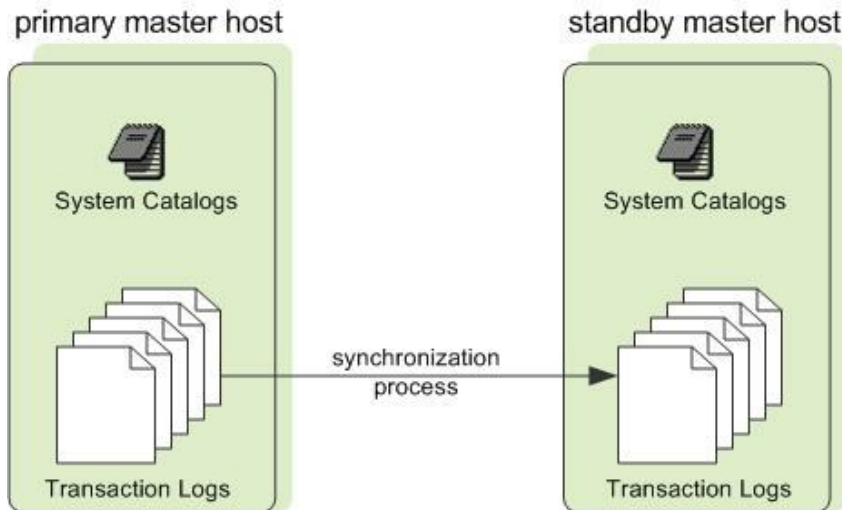

About Master Mirroring

You can also optionally deploy a backup or mirror of the master instance on a separate host from the master host. The backup master instance (the *standby master*) serves as a *warm standby* in the event that the primary master host becomes non-operational. The standby master is kept current by a transaction log replication process, which synchronizes the data between the primary and standby master.

If the primary master fails, the log replication process stops, and the standby master can be activated

in its place. The switchover does not happen automatically, but must be triggered externally. Upon activation of the standby master, the replicated logs are used to reconstruct the state of the master host at the time of the last successfully committed transaction. The activated standby master effectively becomes the Greenplum Database master, accepting client connections on the master port (which must be set to the same port number on the master host and the backup master host).

Since the master does not contain any user data, only the system catalog tables need to be synchronized between the primary and backup copies. When these tables are updated, changes are automatically copied over to the standby master to ensure synchronization with the primary master.

About Interconnect Redundancy

The *interconnect* refers to the inter-process communication between the segments and the network infrastructure on which this communication relies. You can achieve a highly available interconnect using by deploying dual Gigabit Ethernet switches on your network and redundant Gigabit connections to the Greenplum Database host (master and segment) servers. For performance reasons, 10-Gb Ethernet, or faster, is recommended.

Parent topic: [Greenplum Database Concepts](#)

About Database Statistics in Greenplum Database

An overview of statistics gathered by the `ANALYZE` command in Greenplum Database.

Statistics are metadata that describe the data stored in the database. The query optimizer needs up-to-date statistics to choose the best execution plan for a query. For example, if a query joins two tables and one of them must be broadcast to all segments, the optimizer can choose the smaller of the two tables to minimize network traffic.

The statistics used by the optimizer are calculated and saved in the system catalog by the `ANALYZE` command. There are three ways to initiate an analyze operation:

- You can run the `ANALYZE` command directly.
- You can run the `analyzedb` management utility outside of the database, at the command line.
- An automatic analyze operation can be triggered when DML operations are performed on tables that have no statistics or when a DML operation modifies a number of rows greater than a specified threshold.

These methods are described in the following sections. The `VACUUM ANALYZE` command is another way to initiate an analyze operation, but its use is discouraged because vacuum and analyze are

different operations with different purposes.

Calculating statistics consumes time and resources, so Greenplum Database produces estimates by calculating statistics on samples of large tables. In most cases, the default settings provide the information needed to generate correct execution plans for queries. If the statistics produced are not producing optimal query execution plans, the administrator can tune configuration parameters to produce more accurate statistics by increasing the sample size or the granularity of statistics saved in the system catalog. Producing more accurate statistics has CPU and storage costs and may not produce better plans, so it is important to view explain plans and test query performance to ensure that the additional statistics-related costs result in better query performance.

Parent topic: [Greenplum Database Concepts](#)

System Statistics

Table Size

The query planner seeks to minimize the disk I/O and network traffic required to run a query, using estimates of the number of rows that must be processed and the number of disk pages the query must access. The data from which these estimates are derived are the `pg_class` system table columns `reltuples` and `relpages`, which contain the number of rows and pages at the time a `VACUUM` or `ANALYZE` command was last run. As rows are added or deleted, the numbers become less accurate. However, an accurate count of disk pages is always available from the operating system, so as long as the ratio of `reltuples` to `relpages` does not change significantly, the optimizer can produce an estimate of the number of rows that is sufficiently accurate to choose the correct query execution plan.

When the `reltuples` column differs significantly from the row count returned by `SELECT COUNT(*)`, an analyze should be performed to update the statistics.

When a `REINDEX` command finishes recreating an index, the `relpages` and `reltuples` columns are set to zero. The `ANALYZE` command should be run on the base table to update these columns.

The `pg_statistic` System Table and `pg_stats` View

The `pg_statistic` system table holds the results of the last `ANALYZE` operation on each database table. There is a row for each column of every table. It has the following columns:

`starelid`

The object ID of the table or index the column belongs to.

`staattnum`

The number of the described column, beginning with 1.

`stainherit`

If true, the statistics include inheritance child columns, not just the values in the specified relation.

`stanullfrac`

The fraction of the column's entries that are null.

`stawidth`

The average stored width, in bytes, of non-null entries.

`stadistinct`

A positive number is an estimate of the number of distinct values in the column; the number is not expected to vary with the number of rows. A negative value is the number of distinct values divided by the number of rows, that is, the ratio of rows with distinct values for the column, negated. This form is used when the number of distinct values increases with the number of rows. A unique column, for example, has an `n_distinct` value of -1.0. Columns

with an average width greater than 1024 are considered unique.

`stakindN`

A code number indicating the kind of statistics stored in the *N*th slot of the `pg_statistic` row.

`staopN`

An operator used to derive the statistics stored in the *N*th slot. For example, a histogram slot would show the `<` operator that defines the sort order of the data.

`stanumbersN`

float4 array containing numerical statistics of the appropriate kind for the *N*th slot, or `NULL` if the slot kind does not involve numerical values.

`stavaluesN`

Column data values of the appropriate kind for the *N*th slot, or `NULL` if the slot kind does not store any data values. Each array's element values are actually of the specific column's data type, so there is no way to define these columns' types more specifically than *anyarray*.

The statistics collected for a column vary for different data types, so the `pg_statistic` table stores statistics that are appropriate for the data type in four *slots*, consisting of four columns per slot. For example, the first slot, which normally contains the most common values for a column, consists of the columns `stakind1`, `staop1`, `stanumbers1`, and `stavalues1`.

The `stakindN` columns each contain a numeric code to describe the type of statistics stored in their slot. The `stakind` code numbers from 1 to 99 are reserved for core PostgreSQL data types. Greenplum Database uses code numbers 1, 2, 3, 4, 5, and 99. A value of 0 means the slot is unused. The following table describes the kinds of statistics stored for the three codes.

Table 1. Contents of `pg_statistic` "slots"

stakind Code	Description
1	<p><i>Most Common Values (MCV) Slot</i></p> <ul style="list-style-type: none"> <code>staop</code> contains the object ID of the <code>"="</code> operator, used to decide whether values are the same or not. <code>stavalues</code> contains an array of the <i>K</i> most common non-null values appearing in the column. <code>stanumbers</code> contains the frequencies (fractions of total row count) of the values in the <code>stavalues</code> array. <p>The values are ordered in decreasing frequency. Since the arrays are variable-size, <i>K</i> can be chosen by the statistics collector. Values must occur more than once to be added to the <code>stavalues</code> array; a unique column has no MCV slot.</p>
2	<p><i>Histogram Slot</i> – describes the distribution of scalar data.</p> <ul style="list-style-type: none"> <code>staop</code> is the object ID of the <code>"<"</code> operator, which describes the sort ordering. <code>stavalues</code> contains <i>M</i> (where <i>M</i> ≥ 2) non-null values that divide the non-null column data values into <i>M</i> - 1 bins of approximately equal population. The first <code>stavalues</code> item is the minimum value and the last is the maximum value. <code>stanumbers</code> is not used and should be <code>NULL</code>. <p>If a Most Common Values slot is also provided, then the histogram describes the data distribution after removing the values listed in the MCV array. (It is a <i>compressed histogram</i> in the technical parlance). This allows a more accurate representation of the distribution of a column with some very common values. In a column with only a few distinct values, it is possible that the MCV list describes the entire data population; in this case the histogram reduces to empty and should be omitted.</p>

Table 1. Contents of pg_statistic "slots"

stakind Code	Description
3	<p><i>Correlation Slot</i> – describes the correlation between the physical order of table tuples and the ordering of data values of this column.</p> <ul style="list-style-type: none"> <code>staop</code> is the object ID of the "<" operator. As with the histogram, more than one entry could theoretically appear. <code>stavalues</code> is not used and should be <code>NULL</code>. <code>stanumbers</code> contains a single entry, the correlation coefficient between the sequence of data values and the sequence of their actual tuple positions. The coefficient ranges from +1 to -1.
4	<p><i>Most Common Elements Slot</i> - is similar to a Most Common Values (MCV) Slot, except that it stores the most common non-null <i>elements</i> of the column values. This is useful when the column datatype is an array or some other type with identifiable elements (for instance, <code>tsvector</code>).</p> <ul style="list-style-type: none"> <code>staop</code> contains the equality operator appropriate to the element type. <code>stavalues</code> contains the most common element values. <code>stanumbers</code> contains common element frequencies. <p>Frequencies are measured as the fraction of non-null rows the element value appears in, not the frequency of all rows. Also, the values are sorted into the element type's default order (to support binary search for a particular value). Since this puts the minimum and maximum frequencies at unpredictable spots in <code>stanumbers</code>, there are two extra members of <code>stanumbers</code> that hold copies of the minimum and maximum frequencies. Optionally, there can be a third extra member that holds the frequency of null elements (the frequency is expressed in the same terms: the fraction of non-null rows that contain at least one null element). If this member is omitted, the column is presumed to contain no <code>NULL</code> elements.</p> <p>Note: For <code>tsvector</code> columns, the <code>stavalues</code> elements are of type <code>text</code>, even though their representation within <code>tsvector</code> is not exactly <code>text</code>.</p>
5	<p><i>Distinct Elements Count Histogram Slot</i> - describes the distribution of the number of distinct element values present in each row of an array-type column. Only non-null rows are considered, and only non-null elements.</p> <ul style="list-style-type: none"> <code>staop</code> contains the equality operator appropriate to the element type. <code>stavalues</code> is not used and should be <code>NULL</code>. <code>stanumbers</code> contains information about distinct elements. The last member of <code>stanumbers</code> is the average count of distinct element values over all non-null rows. The preceding <i>M</i> (where <i>M</i> >=2) members form a histogram that divides the population of distinct-elements counts into <i>M-1</i> bins of approximately equal population. The first of these is the minimum observed count, and the last the maximum.
99	<p><i>Hyperloglog Slot</i> - for child leaf partitions of a partitioned table, stores the <code>hyperloglog_counter</code> created for the sampled data. The <code>hyperloglog_counter</code> data structure is converted into a <code>bytea</code> and stored in a <code>stavalues5</code> slot of the <code>pg_statistic</code> catalog table.</p>

The `pg_stats` view presents the contents of `pg_statistic` in a friendlier format. The `pg_stats` view has the following columns:

schemaname

The name of the schema containing the table.

tablename

The name of the table.

attname

The name of the column this row describes.

inherited

If true, the statistics include inheritance child columns.

null_frac

The fraction of column entries that are null.

avg_width

The average storage width in bytes of the column's entries, calculated as

```
avg(pg_column_size(column_name)).
```

n_distinct

A positive number is an estimate of the number of distinct values in the column; the number is not expected to vary with the number of rows. A negative value is the number of distinct values divided by the number of rows, that is, the ratio of rows with distinct values for the column, negated. This form is used when the number of distinct values increases with the number of rows. A unique column, for example, has an `n_distinct` value of -1.0. Columns with an average width greater than 1024 are considered unique.

most_common_vals

An array containing the most common values in the column, or null if no values seem to be more common. If the `n_distinct` column is -1, `most_common_vals` is null. The length of the array is the lesser of the number of actual distinct column values or the value of the `default_statistics_target` configuration parameter. The number of values can be overridden for a column using `ALTER TABLE table SET COLUMN column SET STATISTICS N`.

most_common_freqs

An array containing the frequencies of the values in the `most_common_vals` array. This is the number of occurrences of the value divided by the total number of rows. The array is the same length as the `most_common_vals` array. It is null if `most_common_vals` is null.

histogram_bounds

An array of values that divide the column values into groups of approximately the same size. A histogram can be defined only if there is a `max()` aggregate function for the column. The number of groups in the histogram is the same as the `most_common_vals` array size.

correlation

Greenplum Database computes correlation statistics for both heap and AO/AOCO tables, but the Postgres Planner uses these statistics only for heap tables.

most_common_elems

An array that contains the most common element values.

most_common_elem_freqs

An array that contains common element frequencies.

elem_count_histogram

An array that describes the distribution of the number of distinct element values present in each row of an array-type column.

Newly created tables and indexes have no statistics. You can check for tables with missing statistics using the `gp_stats_missing` view, which is in the `gp_toolkit` schema:

```
SELECT * from gp_toolkit.gp_stats_missing;
```

Sampling

When calculating statistics for large tables, Greenplum Database creates a smaller table by sampling the base table. If the table is partitioned, samples are taken from all partitions.

Updating Statistics

Running `ANALYZE` with no arguments updates statistics for all tables in the database. This could take a very long time, so it is better to analyze tables selectively after data has changed. You can also analyze a subset of the columns in a table, for example columns used in joins, `WHERE` clauses, `SORT` clauses, `GROUP BY` clauses, or `HAVING` clauses.

Analyzing a severely bloated table can generate poor statistics if the sample contains empty pages, so it is good practice to vacuum a bloated table before analyzing it.

See the *SQL Command Reference* in the *Greenplum Database Reference Guide* for details of running the `ANALYZE` command.

Refer to the *Greenplum Database Management Utility Reference* for details of running the `analyzedb` command.

Analyzing Partitioned Tables

When the `ANALYZE` command is run on a partitioned table, it analyzes each child leaf partition table, one at a time. You can run `ANALYZE` on just new or changed partition tables to avoid analyzing partitions that have not changed.

The `analyzedb` command-line utility skips unchanged partitions automatically. It also runs concurrent sessions so it can analyze several partitions concurrently. It runs five sessions by default, but the number of sessions can be set from 1 to 10 with the `-p` command-line option. Each time `analyzedb` runs, it saves state information for append-optimized tables and partitions in the `db_analyze` directory in the master data directory. The next time it runs, `analyzedb` compares the current state of each table with the saved state and skips analyzing a table or partition if it is unchanged. Heap tables are always analyzed.

If GPORCA is enabled (the default), you also need to run `ANALYZE` or `ANALYZE ROOTPARTITION` on the root partition of a partitioned table (not a leaf partition) to refresh the root partition statistics. GPORCA requires statistics at the root level for partitioned tables. The Postgres Planner does not use these statistics.

The time to analyze a partitioned table is similar to the time to analyze a non-partitioned table since `ANALYZE ROOTPARTITION` does not collect statistics on the leaf partitions (the data is only sampled).

The Greenplum Database server configuration parameter `optimizer_analyze_root_partition` affects when statistics are collected on the root partition of a partitioned table. If the parameter is `on` (the default), the `ROOTPARTITION` keyword is not required to collect statistics on the root partition when you run `ANALYZE`. Root partition statistics are collected when you run `ANALYZE` on the root partition, or when you run `ANALYZE` on a child leaf partition of the partitioned table and the other child leaf partitions have statistics. If the parameter is `off`, you must run `ANALYZE ROOTPARTITION` to collect root partition statistics.

If you do not intend to run queries on partitioned tables with GPORCA (setting the server configuration parameter `optimizer` to `off`), you can also set the server configuration parameter `optimizer_analyze_root_partition` to `off` to limit when `ANALYZE` updates the root partition statistics.

Configuring Statistics

There are several options for configuring Greenplum Database statistics collection.

Statistics Target

The statistics target is the size of the `most_common_vals`, `most_common_freqs`, and `histogram_bounds` arrays for an individual column. By default, the target is 25. The default target can be changed by setting a server configuration parameter and the target can be set for any column using the `ALTER TABLE` command. Larger values increase the time needed to do `ANALYZE`, but may improve the quality of the Postgres Planner estimates.

Set the system default statistics target to a different value by setting the `default_statistics_target` server configuration parameter. The default value is usually sufficient, and you should only raise or lower it if your tests demonstrate that query plans improve with the new target. For example, to raise the default statistics target from 100 to 150 you can use the `gpconfig` utility:

```
gpconfig -c default_statistics_target -v 150
```

The statistics target for individual columns can be set with the `ALTER TABLE` command. For example, some queries can be improved by increasing the target for certain columns, especially columns that have irregular distributions. You can set the target to zero for columns that never contribute to query optimization. When the target is 0, `ANALYZE` ignores the column. For example, the following `ALTER TABLE` command sets the statistics target for the `notes` column in the `emp` table to zero:

```
ALTER TABLE emp ALTER COLUMN notes SET STATISTICS 0;
```

The statistics target can be set in the range 0 to 1000, or set it to -1 to revert to using the system default statistics target.

Setting the statistics target on a parent partition table affects the child partitions. If you set statistics to 0 on some columns on the parent table, the statistics for the same columns are set to 0 for all children partitions. However, if you later add or exchange another child partition, the new child partition will use either the default statistics target or, in the case of an exchange, the previous statistics target. Therefore, if you add or exchange child partitions, you should set the statistics targets on the new child table.

Automatic Statistics Collection

Greenplum Database can be set to automatically run `ANALYZE` on a table that either has no statistics or has changed significantly when certain operations are performed on the table. For partitioned tables, automatic statistics collection is only triggered when the operation is run directly on a leaf table, and then only the leaf table is analyzed.

Automatic statistics collection is governed by a server configuration parameter, and has three modes:

- `none` disables automatic statistics collection.
- `on_no_stats` triggers an analyze operation for a table with no existing statistics when any of the commands `CREATE TABLE AS SELECT`, `INSERT`, or `COPY` are run on the table by the table owner.
- `on_change` triggers an analyze operation when any of the commands `CREATE TABLE AS SELECT`, `UPDATE`, `DELETE`, `INSERT`, or `COPY` are run on the table by the table owner, and the number of rows affected exceeds the threshold defined by the `gp_autostats_on_change_threshold` configuration parameter.

The automatic statistics collection mode is set separately for commands that occur within a procedural language function and commands that run outside of a function:

- The `gp_autostats_mode` configuration parameter controls automatic statistics collection behavior outside of functions and is set to `on_no_stats` by default.
- The `gp_autostats_mode_in_functions` parameter controls the behavior when table operations are performed within a procedural language function and is set to `none` by default.

With the `on_change` mode, `ANALYZE` is triggered only if the number of rows affected exceeds the threshold defined by the `gp_autostats_on_change_threshold` configuration parameter. The default value for this parameter is a very high value, 2147483647, which effectively disables automatic statistics collection; you must set the threshold to a lower number to enable it. The `on_change` mode could trigger large, unexpected analyze operations that could disrupt the system, so it is not recommended to set it globally. It could be useful in a session, for example to automatically analyze a table following a load.

Setting the `gp_autostats_allow_nonowner` server configuration parameter to `true` also instructs Greenplum Database to trigger automatic statistics collection on a table when:

- `gp_autostats_mode=on_change` and the table is modified by a non-owner.
- `gp_autostats_mode=on_no_stats` and the first user to `INSERT` or `COPY` into the table is a non-owner.

To disable automatic statistics collection outside of functions, set the `gp_autostats_mode` parameter to `none`:

```
gpconfigure -c gp_autostats_mode -v none
```

To enable automatic statistics collection in functions for tables that have no statistics, change `gp_autostats_mode_in_functions` to `on_no_stats`:

```
gpconfigure -c gp_autostats_mode_in_functions -v on_no_stats
```

Set the `log_autostats` system configuration parameter to on if you want to log automatic statistics collection operations.

VMware Tanzu Greenplum on vSphere

Revised: 2022-06-13

This documentation describes how to deploy VMware Tanzu Greenplum on vSphere.

- [Supported Platforms](#)
- [Overview](#)
- [Architecture](#)
- [Planning VMware vSphere with Greenplum](#)
- [Prerequisites](#)
- [Setting Up VMware vSphere Network](#)
- [Setting Up VMware vSphere DRS and HA](#)
- [Setting Up VMware vSphere Storage](#)
- [Setting Up VMware vSphere Encryption](#)
- [Validating Dell EMC VxRail Setup Performance](#)
- [Creating the Jumpbox Virtual Machine](#)
- [Choosing your Deployment Option](#)
- [Validating the Greenplum Installation](#)
- [Managing Single Host Failures in Dell EMC VxRail](#)
- [Planning Downtime for Maintenance](#)

Supported Platforms

VMware Tanzu Greenplum on vSphere is compatible with these operating system and Greenplum Database versions:

OS Version	Greenplum Version
CentOS 7.x ,RHEL 7.x, Oracle Linux 7.x	6.x

VMware Tanzu Greenplum on vSphere is compatible with these VMware vSphere versions:

VMware vSphere component	Version
VMware ESXi	Greater then or equal to 6.7 Update 3
vCenter Server	Greater then or equal to 7.0 GA (7.0.0.10100)

VMware Tanzu Greenplum on vSphere is compatible with these storage systems and versions:

Storage System	Version
VMware vSAN	Less then or equal to 7.0 Update 2
Dell EMC PowerFlex	Greater then or equal to 3.6.0

The following table displays the compatible editions for vSphere, vSAN and vCenter Server based on the supported versions:

Product	Supported Edition and Product Features	References
VMware vSphere	VMware vSphere Enterprise Plus - Distributed Switch - Virtual Machine Encryption - Distributed Resource Scheduler	See more
vSAN	Enterprise - RAID-5/6 Erasure Coding - Data-at-Rest and Data-in-Transit encryption	See more
vCenter Server	vCenter Server Foundation (up to 4 hosts) vCenter Server Standard (more than 4 hosts)	See more

Overview

VMware Tanzu Greenplum on vSphere offers a next generation virtualized platform for bare metal Greenplum users. It provides Greenplum as a Platform, reducing the cost of maintaining a fleet of running Greenplum Database clusters on bare metal.

This documentation explains best practices on the entire stack, from physical configuration all the way up to the Greenplum Database software layer.

In summary, you will go through the following steps:

Visit [Planning VMware vSphere with Greenplum](#), where you explore the requirements and different hardware configurations available in order to size your Dell EMC VxRail with VMware vSphere environment depending on your Greenplum Database needs. There is a relationship between the number of ESXi hosts and the total Greenplum Database capacity of your cluster; this impacts the number and size of the virtual machines that you will deploy. You must ensure that your VMware vSphere environment is able to handle the quantity of resources required, as it will ensure adequate disk storage space, and data processing throughput to meet your end user SLAs.

Follow [Prerequisites](#), [Setting Up VMware vSphere Network](#), [Setting Up VMware vSphere DRS and HA](#), [Setting Up VMware vSphere Storage](#), and [Setting Up VMware vSphere Encryption](#) to configure your Dell EMC VxRail with VMware vSphere environment. Based on the recommended topology of Dell EMC VxRail, you will configure the VMware vSphere network and storage, as well as enable and set up VMware vSphere features such as High Availability or Distributed Resource Scheduler. Optionally, you may enable encryption.

When the VMware vSphere environment is set up, use [HCIBench](#) to verify network connectivity and evaluate the vSAN performance of your environment.

Once the VMware vSphere environment is verified, create a [jumpbox virtual machine](#) and install Terraform in it. Then create a [virtual machine template](#) and configure it based on the system requirements for Greenplum Database.

Using Terraform and the jumpbox virtual machine, [generate a number of virtual machines](#) from the template which will comprise all the components of a Greenplum Database cluster.

Finally, [deploy the Greenplum Database cluster](#).

This documentation also provides information regarding [single host failure scenarios](#) and [host maintenance best practices](#).

Getting Started

Visit the [Architecture](#) page to learn about how VMware Tanzu Greenplum on vSphere works. Then

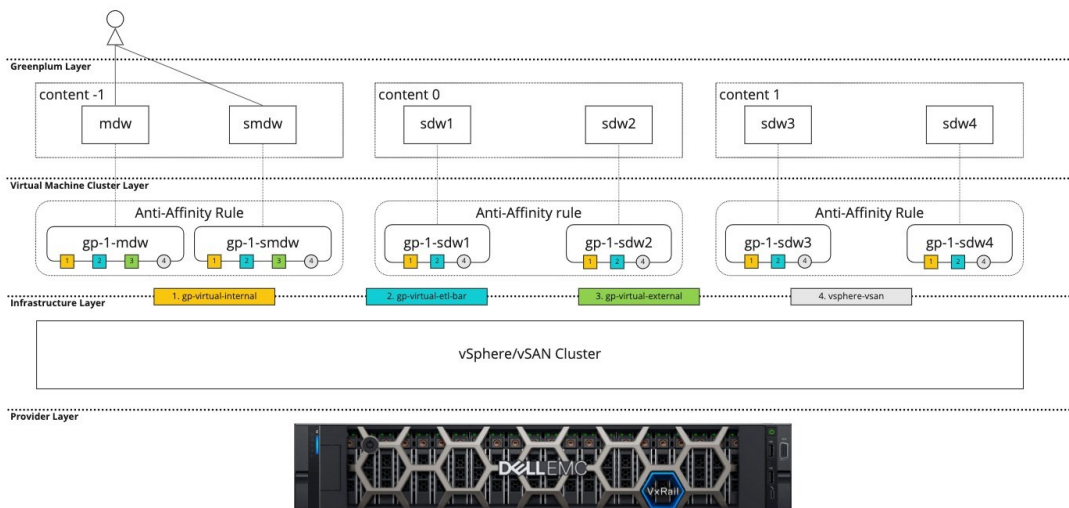

visit [Planning Dell EMC VxRail with Greenplum](#) to start planning and sizing your environment.

VMware Tanzu Greenplum on vSphere Architecture

Layered Architecture

As depicted in the diagram below, VMware Tanzu Greenplum on vSphere architecture is made up of multiple layers between Greenplum Database software and the underlying hardware. The architecture diagram describes the four abstraction layers. Although this topic assumes a Dell EMC VxRail reference architecture (see [Dell EMC VxRail Reference Architecture](#)), conceptually the layers above the infrastructure layer can be leveraged in other VMware vSphere environments, as long as the provider and infrastructure layers can provide similar or better infrastructure.

- [Provider Layer](#)
- [Infrastructure Layer](#)
- [Virtual Machine Cluster Layer](#)
- [Greenplum Database Layer](#)

[Click here to view a larger version of this diagram](#)

Provider Layer

This layer represents the resource provider, which can be based on physical hardware or a cloud provider. For this reference architecture, the resource rule provider is Dell EMC VxRail.

Infrastructure Layer

The infrastructure layer defines the different networks and the data storage that the virtual machines will use on the upper layer. There are three networks defined within this layer: `gp-virtual-external`, `gp-virtual-internal` and `gp-virtual-etl-bar`, and for this reference architecture the underlying data storage uses a vSAN cluster.

In a VMware vSphere cluster environment managed by vCenter, the networks are defined as distributed port groups, and the vSAN cluster communicates through the distributed port group `vsphere-vsan`.

Virtual Machine Cluster Layer

This layer provisions the virtual machines and Anti-Affinity rules to ensure application high availability

on the upper layer. For a Greenplum cluster, there are two types of virtual machines:

- **Master virtual machines** are used to provision the Greenplum master and standby master nodes.
- **Segment virtual machines** are used to provision Greenplum primary and mirror segment nodes.

The vSAN cluster provides reliable storage for all the virtual machines, which store all the Greenplum data files under the data storage mounted on `/gpdata`.

The master virtual machines are connected to the `gp-virtual-internal` network in order to support mirroring and interconnect traffic and to handle management operations via the Greenplum utilities such as `gpstart`, `gpstop`, etcetera. They are also connected to the `gp-virtual-etl-bar` network in order to support Extract, Transform, Load (ETL) and Backup and Restore (BAR) operations. In addition, the master virtual machines are connected to the `gp-virtual-external` network, which routes external traffic into the Greenplum cluster.

The segment virtual machines are connected to the `gp-virtual-internal` network, which is used to handle mirroring and interconnect traffic. They are also connected to the `gp-virtual-etl-bar` network for Extract, Transform, Load (ETL) and Backup and Restore (BAR) operations.

For more information on the different networks and their configuration, see [Setting Up VMware vSphere Network](#).

This layer also defines the **Anti-Affinity** rules between the master and standby nodes, as well as between the primary and mirror pairs. In the diagram, the virtual machines `gp-1-mdw` and `gp-1-smdw` have an Anti-Affinity rule set to ensure that they are not deployed on the same ESXi host. Similar rules apply for the segment pair formed by `gp-1-sdw1` and `gp-1-sdw2`, and the pair made of `gp-1-sdw3` and `gp-1-sdw4`.

Greenplum Layer

This layer is equivalent to what a Greenplum Database Administrator would normally interact with. The **Greenplum node** names match the traditional Greenplum node naming convention:

- `mdw` for the Greenplum master.
- `smdw` for the Greenplum standby master.
- `sdw*` for the Greenplum segments, both primaries and mirrors.

Unlike traditional Greenplum clusters, where a segment host is running multiple segment instances, with VMware Tanzu Greenplum on VMware vSphere there is only one segment instance per Greenplum node.

This design leverages VMware vSphere HA and DRS features in order to provide high availability on the virtual machine cluster layer, so that VMware vSphere can ensure high availability at the application level. Some of the benefits of this configuration are:

- Centralized storage.
- Dynamically balanced load based on the current state of the cluster.
- Virtual machines can be moved among ESXi hosts without affecting Greenplum high availability.
- Simplified mirroring placement.
- Better elasticity to handle ESXi hosts growth, as the virtual machines can be individually moved across hosts by DRS to balance the load if the cluster grows.

In the architecture diagram, every pair of Greenplum nodes works together to provide application

high availability for a given content ID. For example, content ID `-1` is provided by `mdw` and `smdw`, content ID `0` is provided by `sdw1` and `sdw2`, and content ID `1` is provided by `sdw3` and `sdw4`.

Since each pair of Greenplum nodes is mapped to a pair of virtual machines configured with Anti-Affinity rules, the virtual machines serving the same content ID will never be on the same ESXi hosts. This architecture provides Greenplum high availability against a single ESXi host failure.

Planning VMware vSphere with Greenplum

This topic provides guidance on how to size your VMware vSphere environment based on the total size of your Greenplum Database. Criteria such as the RAID type, number of deployed virtual machines, and total amount of available resources required will vary depending on the database size.

NOTE: The information in this topic assumes that you are planning for a Greenplum on VMware vSphere deployment on a Dell EMC VxRail architecture.

The minimum size for the proposed configuration is 4 ESXi nodes, which translates into a Greenplum Database with 64.12 TB of usable storage when no compression is being used. The maximum size is 16 ESXi hosts, which results in 397.32 TB of uncompressed usable storage for the database.

Calculating the Greenplum Database Size and ESXi Hosts

Determine the number of ESXi hosts you need based on your Greenplum database requirements. The table below shows the number of hosts are required based on the size of the Greenplum database.

ESXi Hosts	Usable Storage (TB) (No Compression)	Raw Storage (TB)
4	64.12	512
5	122.04	640
6	147.05	768
7	172.07	896
8	197.09	1024
9	222.11	1152
10	247.13	1280
11	272.15	1408
12	297.18	1536
13	322.20	1664
14	347.22	1792
15	372.25	1920
16	397.32	2048

Usable storage is the total size of user data after applying the associated storage overhead; this is mainly needed by the vSAN storage policy (it requires 30% reservation) and the RAID configuration. It is also used for temporary data reservation, high availability (HA) reservation, and free spaces.

Determining the RAID Type

The following table provides recommendations to consider when choosing between the RAID1 (mirroring) and RAID5 (erasure coding) for the VMware vSphere storage policies that you configure

in a later step. Note that these parameters have been calculated to ensure Greenplum fault tolerance against host failure.

RAID Type	ESXi Hosts	Space Overhead	Performance	Recovery Behavior
RAID1 (mirroring)	4	2x	WRITE 2.2 GiB/s per ESXi host READ 10 GiB/s per ESXi host	In case of disk failure, a 250 GB <code>vmdk</code> requires reading 250 GB of data to rebuild
RAID5 (erasure coding)	5 or more	1.33x	WRITE 2.2 GiB/s per ESXi host READ 10 GiB/s per ESXi host	In case of disk failure, a 250 GB <code>vmdk</code> requires reading 750 GB of data to rebuild

NOTE: The performance numbers captured above are measured performance numbers. Your actual performance numbers may vary.

Determining the Number of Virtual Machines

The number of Greenplum Database virtual machines you deploy depends on the number of hosts in your environment. You must plan for 8 primary segments and 8 mirror segments running on each ESXi host, as well as the Greenplum master and standby master virtual machines.

```
total_number_of_greenplum_vms = 16 * (number_of_hosts) + 2
```

Note that the maximum number of Greenplum virtual machines that can be deployed in a VMware Tanzu Greenplum on vSphere environment is 1000.

For example, in a configuration of four ESXi hosts, you deploy a total of 66 Greenplum virtual machines:

- one master virtual machine
- one master standby virtual machine
- 32 primary segment virtual machines
- 32 mirror segment virtual machines

The following table calculates the number of necessary Greenplum virtual machines depending on the number of ESXi hosts:

Number of ESXi Hosts	Total Number of Greenplum Virtual Machines
4	66
5	82
6	98
7	114
8	130
9	146
10	162
11	178
12	194
13	210

Number of ESXi Hosts	Total Number of Greenplum Virtual Machines
14	226
15	242
16	258 ¹

¹ In order to support 258 Greenplum VMs, you must use CIDR addressing with a network mask of 23 or lower.

Note: you will additionally deploy a [jumpbox virtual machine](#) which you will use to allocate the virtual machines. You must take it into account when allocating IP addresses in the [Prerequisites](#) topic.

Sizing the Greenplum Virtual Machine

The virtual machines running the Greenplum Database software must be correctly sized to handle the database workloads depending on the cluster specifications.

All virtual machines must be configured with the following resources regardless of the environment:

vCPUs	RAM (GB)	Root Volume (GB)
8	30	50

The following table displays the required Data volume size per virtual machine depending on the number of ESXi hosts. The provided values ensure that there is sufficient capacity left in the cluster if a host fails. Note that the storage policies are configured with thick provisioning.

ESXi Hosts	Data Volume (GB)
4	2500
5 or more	4000

Putting It All Together

You must ensure that your VMware Tanzu Greenplum on vSphere environment has enough resources to accommodate the usable space required, the choice of RAID, the number of virtual machines required, the resources needed for each virtual machine, high availability to allow for component failures, and optimal performance.

ESXi Hosts	Usable Storage (TB)	Storage Policy	Virtual Machines	Total Primary Segment vCPUs	Total Primary Segment RAM (GB)
4	64.12	RAID1	66	256	960
5	122.04	RAID5	82	320	1,200
6	147.05	RAID5	98	384	1,440
7	172.07	RAID5	114	448	1,680
8	197.09	RAID5	130	512	1,920
9	222.11	RAID5	146	576	2,160
10	247.13	RAID5	162	640	2,400
11	272.15	RAID5	178	704	2,640
12	297.18	RAID5	194	768	2,880

ESXi Hosts	Usable Storage (TB)	Storage Policy	Virtual Machines	Total Primary Segment vCPUs	Total Primary Segment RAM (GB)
13	322.20	RAID5	210	832	3,120
14	347.22	RAID5	226	896	3,360
15	372.25	RAID5	242	960	3,600
16	397.32	RAID5	250	992	3,720

Dell EMC VxRail Reference Architecture

This reference architecture uses Dell EMC VxRail version 7.0.200. See more details on page 22 of the [Dell EMC VxRail Documentation](#).

Description	Configuration
Model	P570F
CPU	Intel(R) Xeon(R) Gold 6248R CPU @ 3.00 GHz
Logical Cores	96 (HyperThreaded)
NICs	2x PCIe 100 GbE dual port
Physical Cores	48
RAM	768 GB
Cache Storage	4x Dell Express Flash NVMe ColdStream P4800x 750 GB PCIe U.2 SSD
Capacity Storage	20x Dell Express Flash NVMe PM1725B (MU) 6.4 TB PCIe U.2 SSD

There are 4 vSAN disk groups, each of them composed of one cached drive and 5 capacity drives.

Next Steps

Once you have confirmed your version and model of Dell EMC VxRail, the number of ESXi hosts based on your Greenplum Database capacity, and calculated the number of virtual machines and the necessary available resources in your VMware vSphere environment, proceed to [Prerequisites](#) to prepare for the installation.

Prerequisites

You must meet certain prerequisites and collect specific information from your existing VMware vSphere environment in order to proceed with the installation of VMware Tanzu Greenplum. You may need to work with your system and network administrator to gather some of the information.

Greenplum Cluster

- Ensure that you have determined the number and size of virtual machines that you will deploy, based on the Greenplum Database size discussed in the [Planning](#) section.
- You must verify that the free space in the datastore, the free memory in the cluster, and total amount of free processors in the cluster are enough to accommodate the virtual machine [Sizing](#) requirements that match your configuration.

VMware vSphere

- You must have access to VMware vSphere Client through a VMware vSphere administrator level user that belongs to the Administrators group. In this documentation we use `greenplum@vsphere.local` with password `DeleteMe123!`. Refer to the [VMware vSphere documentation](#) for more information.
- There are two possible ways of building your deployment, see [Choosing your Deployment Option](#). If you decide to build your own OVA template, you must have a running CentOS 7 virtual machine in the same datastore and cluster where you will deploy the Greenplum environment. You will need it to create the [virtual machine template](#).
- You must have access to the Internet to download the HCIBench 2.6.0 OVA file for [Validating Dell EMC VxRail Setup Performance](#), the ISO file for [Creating the Jumpbox Virtual Machine](#) and the [Terraform software](#). You may decide to download these files beforehand. If you choose to deploy Greenplum with a pre-built OVA, you will also need to [download the Greenplum Database OVA](#).
- Collect the following information from your VMware vSphere environment, you will need it during the installation and setup stages.
 - ◊ ESXi hosts IP addresses, host names, admin access name and passwords.
 - ◊ VMware vSphere server IP and Fully Qualified Domain Name (FQDN).
 - ◊ VMware vSphere datacenter name.
 - ◊ VMware vSphere vSAN datastore name.
 - ◊ VMware vSphere compute cluster name.

Network

Request the following from your network administrator, you will need it during installation. See [Setting Up vSphere Network](#) for more detailed information.

- 4 routable IP addresses in the same network to be used for the external network `gp-virtual-external`.
- 3 new VLAN IDs. You must also gather information about the existing VLANs in the VMware vSphere environment and how they are interconnected.
- 2 sets of contiguous non-routable IP addresses for the internal networks `gp-virtual-internal` and `gp-virtual-etl-bar`. The number of IP addresses per set must be your number of [calculated virtual machines](#) plus one for the jumpbox virtual machine. For example, for a four host setup, you will need two sets of 67 IP addresses each: 66 for Greenplum and one for the jumpbox.
- NTP server and DNS server IP address.

Next Steps

You are now ready to start with the installation and configuration of VMware Tanzu Greenplum on vSphere. Proceed to [Setting Up vSphere Network](#) to start configuring Greenplum on VMware vSphere.

Setting Up VMware vSphere Network

VMware Tanzu Greenplum on VMware Vsphere uses the three networks described below.

1. Internal network

The internal network is identified by the port group `gp-virtual-internal`. It is used by

Greenplum for internal communications. It requires a new VLAN ID and a number of non-routable contiguous static IP addresses that will be used for: - Greenplum Database virtual machines - Jumpbox virtual machine

Determine the number of required IP addresses based on the number of virtual machines in your environment. For example, for a four ESXi host configuration, it requires 67 non-routable contiguous static IP addresses.

2. External network

The external network is identified by the port group `gp-virtual-external`. It is used by Greenplum for external traffic through the master and standby master nodes. It requires a new VLAN ID and 4 routable static IP addresses that will be used for: - Greenplum Master - Greenplum Standby - Jumpbox Virtual Machine - Greenplum Virtual Machine template

3. Load Backup and Restore network

The load backup and restore network is identified by the port group `gp-virtual-etl-bar`. It is used by Greenplum for ETL traffic and for backup and restore traffic. It requires a new VLAN ID and a number of non-routable contiguous static IP addresses that will be used for: - Greenplum Database Virtual Machines - Jumpbox Virtual Machine

Determine the number of required IP addresses based on the number of virtual machines in your environment. For example, for a four ESXi host configuration, it requires 67 non-routable contiguous static IP addresses.

Note that ETL or backup traffic must take place within the internal network `gp-virtual-etl-bar` which is non-routable.

Verifying the Distributed Virtual Switch Settings

Check the Distributed Virtual Switch settings to make sure that the Maximum Transmission Unit (MTU) is set to 9000 Bytes:

1. On the VMware Vsphere Client Home page, click **Networking** and navigate to your distributed switch.
2. Navigate to **Configure -> Properties -> Advanced**.
3. Verify that **MTU** is set to **9000 Bytes**. If it is set to any other value, edit the value and set it to **9000 Bytes**, and click **OK**.

Creating the Distributed Port Groups

The table below summarizes the distributed port groups that the Virtual Distributed Switch must have configured. Some of them might already be present in your VMware Vsphere environment.

Port Group Name	Description
gp- virtual- internal	Used for Greenplum cluster internal communications, including interconnect, dispatch and mirroring. This network is usually air-gapped, and does not have internet connection. All IP addresses are statically assigned.
gp- virtual- external	Used for Greenplum cluster user connections from outside the cluster. The Greenplum master virtual machine exposes <code>\$PGPORT</code> on this network. It is also used to connect to the master and standby virtual machines for DBA or troubleshooting purposes. This network usually has DHCP enabled.
gp- virtual- etl- bar	Used for ETL and backup/restore operations for the Greenplum cluster.

Port Group Name	Description
VMware Vsphere- management	Used by vCenter to manage the ESXi hosts. It supports the VMkernel port of management.
VMware Vsphere- vmotion	Used for VMware Vsphere HA and DRS. It supports the VMkernel port of vMotion.
vsphere- vsan	Used for vSAN connections. It supports the VMkernel port of vSAN.
vsphere- vcenter	Dedicated management network, including vCenter, DHCP, DNS, and NTP services. Usually the IP addresses are statically assigned.
vsphere- vm	Used by non Greenplum virtual machines to connect to the company network. It usually has internet connectivity. This network usually has DHCP enabled.

Create the above port groups in your VMware Vsphere environment:

1. On the VMware Vsphere Client Home page, click **Networking** and navigate to the distributed switch for this environment.
2. Click on the arrow next to your distributed switch to view the list of existing port groups. Skip the creation of any port groups listed above that already exist.
3. Right-click the distributed switch and select **Distributed port group > New distributed port group**.
4. Specify the name of the new distributed port group (use the table above), then click **Next**.
5. On the **Configure settings** page, make sure you select **VLAN** as the VLAN type, then select the appropriate VLAN ID for each port group. You should have this information provided by your network administrator.
6. Click **Next**, confirm your settings and click **Finish**.

Configuring the Distributed Port Groups

Principles of VMware Vsphere Distributed Switch to Uplink Assignment

When creating and configuring the distributed port groups listed above, you must adhere to the following principles:

- Always use active/standby uplinks to optimize the performance by avoiding a single point of failure.
- Always separate the active/standby uplinks across two different NICs and two different switches to ensure high availability.
- The two uplinks of the active/standby pair must connect to two physical switches which must be interlinked to ensure high availability.
- The port group `vsphere-vsan` must be always on its own active uplink.
- The port group `gp-virtual-internal` must be always on its own active uplink.
- The port group `gp-virtual-etl-bar` must be always on its own active uplink.
- Multiple standby uplinks can be overlapped with the dedicate active uplink. However, there is a risk of degraded performance if the active link goes offline.

Based on the principles above, and depending on your Dell EMC VxRail topology, the configuration of the port groups may vary. The next section describes the recommended topology of Dell EMC VxRail and documents how the port groups must be configured for this particular topology.

Using Four 100GbE Links

This Dell EMC VxRail topology consists of Dell EMC VxRail nodes with two 100GbE Network Cards each with two 100GbE ports. Two ports are connected to two TOR switches, and one optional connection to management switch for Integrated Dell Remote Access Controller (iDRAC). You can find more information about this topology on page 109 of the [Dell EMC VxRail Network Planning Guide](#) (Figure 53).

Configure the port groups in your VMware Vsphere environment:

1. On the VMware Vsphere Client Home page, click **Networking** and navigate to your distributed switch.
2. Right-click the distributed port and select **Edit settings**.
3. On the **Teaming and failover** page, under **Failover order**, add the corresponding uplink.
4. Click **OK**.

You must configure the following port groups on the Virtual Distributed Switch to match the following table:

Port Group Name	uplink1 (vmnic0)	uplink2 (vmnic1)	uplink3 (vmnic2)	uplink4 (vmnic3)
vsphere-management	Active	Unused	Unused	Standby
vsphere-vmotion	Standby	Unused	Unused	Active
vsphere-vm	Standby	Unused	Unused	Active
vsphere-vcenter	Standby	Unused	Unused	Active
vsphere-vsan	Unused	Active	Standby	Unused
gp-virtual-internal	Unused	Standby	Active	Unused
gp-virtual-external	Active	Unused	Unused	Standby
gp-virtual-etl-bar	Standby	Unused	Unused	Active

For example, the **Failover order** configuration for port group `gp-virtual-internal` should look like this:

Failover order ⓘ

Active uplinks

☐ uplink4

Standby uplinks

☐ uplink2

Unused uplinks

☐ uplink1

☐ uplink3

Enabling VMware Vsphere Distributed Switch (vDS) Health Check

Since the distributed switch and the physical switches are configured separately, settings such as the MTU, VLAN, and teaming settings might present configuration discrepancies. To help narrow down any network configuration issues, VMware Vsphere provides a vDS Health Check to detect network

configuration inconsistencies between the distributed switch and physical switches. Please refer to the [VMware Vsphere Documentation](#) for more details.

To enable the VMware Vsphere Distributed Switch Health Check from vCenter:

- Click **Menu** -> **Networking**.
- Select your distributed switch.
- Click **Configure** -> **Settings** -> **Health Check**.
- Click the **Edit** button on the right pane.
- For **VLAN and MTU**, select **Enabled** and leave **Interval** as default (1 minute).
- For **Teaming and Failover**, select **Enabled** and leave **Interval** as default (1 minute).
- Click **OK**.

There are some known limitations of Health Check:

- It does not check the LAG ports.
- It could cause network performance degradation if you have many uplinks, VLANs and hosts.

You may want to enable vDS Health Check only during deployment and testing phases, and turn it back off once you have verified that there are no configuration inconsistencies.

Next Steps

Continue configuring Dell EMC VxRail with VMware Vsphere by [Setting Up vSphere DRS and HA](#).

Setting Up VMware vSphere DRS and HA

Distributed Resource Scheduler (DRS) is responsible for moving virtual machines across ESXi hosts using VMware vSphere vMotion and following a given policy, based on [VMware vSphere Anti-Affinity rules](#). The VMware vSphere Anti-Affinity rules for this reference architecture are configured as part of the script in [Allocating the Virtual Machines with Terraform](#) to make sure that the Greenplum Database primary and mirror segments for the same content ID are never running on the same ESXi hosts. The same rules will apply for the Greenplum master and standby master.

High Availability (HA) is responsible for restarting virtual machines on other VMware vSphere hosts in the cluster without manual intervention when a host outage is detected.

Combined, the two features ensure that the Greenplum Database cluster keeps running in case of an ESXi host outage. See [Managing Single Host Failures in Dell EMC VxRail](#) for more information.

Enabling DRS

On the VMware vSphere Client Home page, navigate to **vCenter** -> Select your Cluster -> **Configure** -> **Services** -> **vSphere DRS**.

Click the **Edit** button and enable VMware vSphere DRS, then configure the following settings:

- Automation
 - ◊ Automation Level: **Fully Automated**
 - ◊ Migration Threshold: **Default**
 - ◊ Predictive DRS: **Disabled**
 - ◊ Virtual Machine Automation: **Enabled**

- Additional Options
 - ◊ VM Distribution: **Disabled**
 - ◊ CPU Over-Commitment: not configured
 - ◊ Scalable Shares: **Disabled**
- Power Management
 - ◊ DPM : **Off**
 - ◊ Automation Level: **Off**
 - ◊ DPM Threshold: **Disabled**
- Advanced Options:
 - ◊ None

Edit Cluster Settings | Cluster

vSphere DRS ☒

Automation | Additional Options | Power Management | Advanced Options

Automation Level

Fully Automated

DRS automatically places virtual machines onto hosts at VM power-on, and virtual machines are automatically migrated from one host to another to optimize resource utilization.

Migration Threshold

Conservative (Less Frequent vMotions) Aggressive (More Frequent vMotions)

DRS provides recommendations when workloads are moderately imbalanced. This threshold is suggested for environments with stable workloads. (Default)

Enabling HA

On the VMware vSphere Client Home page, navigate to **vCenter** -> Select your Cluster -> **Configure** -> **Services** -> **vSphere Availability**.

Click the **Edit** button and enable VMware vSphere HA, then configure the following settings:

- Failures and Responses
 - ◊ Enable Host Monitoring: **On**
 - ◊ Host Failure Response:
 - Failure Response: **Restart VMs**
 - Default VM restart priority: **Medium**
 - VM dependency restart condition: **Resources allocated**
 - Additional delay: **0 seconds**
 - VM restart priority condition timeout: **600 seconds**
 - ◊ Response for Host Isolation: **Power off and restart VMs**

- ◊ Datastore with PDL: **Power off and restart VMs**
- ◊ Datastore with APD: **Power off and restart VMs - Aggressive restart policy**
 - Response recovery: **Reset VMs**
 - Response delay: **3 minutes**
- ◊ VM Monitoring: **VM Monitoring Only**
 - VM monitoring sensitivity: **Custom**
 - Failure interval: **30 seconds**
 - Minimum uptime: **120 seconds**
 - Maximum per-VM resets: **3**
 - Maximum resets time window: **No window**

Edit Cluster Settings | Cluster

vSphere HA 

Failures and responses | Admission Control | Heartbeat Datastores | Advanced Options

You can configure how vSphere HA responds to the failure conditions on this cluster. The following failure conditions are supported: host, host isolation, VM component protection (datastore with PDL and APD), VM and application.

Enable Host Monitoring 

> Host Failure Response	Restart VMs ▾
> Response for Host Isolation	Power off and restart VMs ▾
> Datastore with PDL	Power off and restart VMs ▾
> Datastore with APD	Power off and restart VMs - Aggressive restart policy ▾
> VM Monitoring	VM Monitoring Only ▾

CANCEL

OK

- Admission Control

Next Steps

- If you are not planning on using encryption for your VMware Tanzu Greenplum on vSphere environment, proceed to [Setting Up VMware vSphere Storage](#) to configure the VMware

vSphere storage policies.

- Visit [Setting Up VMware vSphere Encryption](#) in order to explore the different encryption options and set up the chosen type of encryption and its corresponding storage policies.

Setting Up VMware Vsphere Storage

VMware Vsphere storage is policy based storage. We chose vSAN as the storage provider. In this section we specify the vSAN configurations and also how to set the specific storage policies.

Configuring vSAN

We need to set the reservations for vSAN so that in case of a single host failure, we have enough reserved space in order to keep vSAN operational. There are two reservations that we need to enable, namely the `operations reserve` and `host rebuild reserve`. You can find more details [here](#).

Reservations and Alerts | Cluster-W1 ×

Enabling operations reserve for vSAN helps ensure that there will be enough space in the cluster for internal operations to complete successfully. Enabling host rebuild reserve allows vSAN to tolerate one host failure. When reservation is enabled and capacity usage reaches the limit, new workloads fail to deploy. [Learn more](#) 

The reserved capacity is displayed in the capacity overview:

 Actually written 72.89 TB (62.6%)

☒ Operations reserve

☒ Host rebuild reserve

The default health alerts are system recommendations based on your reservation configuration.

☐ Customize alerts 

CANCEL
APPLY

We also need to set the space efficiency. We want to make sure that the space efficiency is `None`. The reason is that Greenplum database already stores the data in columnar format and applies compression. There is no need for vSAN to compress it again. Also vSAN compression introduces higher latency for writes which will cause performance issues for data loading and query spilling.

Creating the Storage Policies

VMware Vsphere storage policies define storage requirements for the virtual machines. These policies determine how the virtual machine storage objects are provisioned and allocated within the datastore to guarantee the required level of service.

This section provides instructions for creating a VMware Vsphere storage policy in a VMware Vsphere environment where no level of encryption is required. To configure storage policies when encryption is used, see [Setting Up VMware Vsphere Encryption](#).

The following steps set up a VMware Vsphere storage policy with no encryption for a four-host configuration using RAID1.

1. Select **Home -> Policies and Profiles -> VM Storage Policies**.
2. Click **Create**.
3. Enter a Storage Policy name and optional description and click **Next**. This example uses **vSAN Greenplum FTT1 RAID1 Stripe4 Thick No Encryption** as the policy name.
4. Under **Policy structure**, check the **Enable rules for vSAN storage** box.

Create VM Storage Policy

Next Steps

You have completed setting up Dell EMC VxRail with VMware Vsphere. Proceed to [Validating Dell EMC VxRail Setup Performance](#) in order to verify network connectivity and test vSAN performance with HCIBench.

Setting Up VMware vSphere Encryption

VMware Tanzu Greenplum on vSphere supports two encryption options: Virtual Machine (VM) encryption and vSAN encryption. This topic compares the two methods and provides the prerequisites and instructions to set up an end-to-end encrypted Greenplum cluster.

VMware recommends [enabling AES-NI](#) in the host BIOS to improve encryption performance.

Enabling encryption has 2% CPU overhead and 0.5% memory overhead, and it causes no impact on IOPS and throughput.

Virtual Machine Encryption versus vSAN Encryption

vSAN datastore encryption and VM encryption vary in several key areas. You can find more details in the [VMware Knowledge Base](#).

A key consideration is data-in transit encryption across hosts in your vSAN cluster, and data-at-rest encryption in your vSAN datastore. Data-in-transit encryption protects data and metadata as they move around the vSAN cluster, while Data-at-rest encryption protects data on storage devices, in case a device is removed from the cluster. You can read more about encryption types [here](#).

The following table shows a quick feature comparison:

Feature/Function	vSAN Encryption	VM Encryption
Uses an external key-management server (KMS)	✓	✓
Per-VM Encryption	X	✓
Whole-datastore encryption	✓	X
Data-at-Rest encryption	✓	✓
End-to-end encryption	X	✓
VMs encrypted by	Placement on datastore	Storage Policy
Encryption occurs	After deduplication	Before deduplication

Based on the above:

- If your objective is end-to-end encryption, use VM encryption.
- If you prefer to have policy-controlled encryption (a mix of encrypted and unencrypted clusters), use VM encryption.
- If your objective is data-at-rest encryption, use vSAN encryption.
- If you prefer to enforce having all the virtual machines within a given vSAN datastore with data-at-rest encryption, use vSAN encryption.

Enabling Encryption on Greenplum

VMware recommends using [virtual machine encryption](#) to avoid the associated overhead when encrypting and unencrypting the vSAN. However, you may choose to use [vSAN encryption](#) instead, based on your environment requirements.

Note: Never use both encryption methods together as it will result in a double encryption with no additional benefits on data protection, but with double the overhead caused by encryption.

Prerequisites

Regardless of the encryption method, these prerequisites must be met:

- Set up and enable the Native Key Provider (NKP) in vCenter. VMware vSphere 7.0U2 introduces the Native Key Provider (NKP) which simplifies the key creation process. Use NKP unless there is already an existing Standard Key Provider in the environment. You can read more about key providers [here](#). For configuration details, see [Configure a VMware vSphere Native Key Provider](#)

Also ensure the NKP is backed up. For details, see [Back Up a VMware vSphere Native Key](#)

Provider.

- Enable Host Encryption Mode. For more details see [Enable Host Encryption Mode Explicitly](#). To verify the results, on each ESXi host, view the Security Profile.

Option 1: Enabling Virtual Machine Encryption

Enable encryption at the virtual machine level by creating a VMware vSphere storage policy using the steps below:

1. Select **Home** -> **Policies and Profiles** -> **VM Storage Policies**.
2. Click **Create**.
3. Enter a Storage Policy name and optional description and click **Next**. This example uses **vSAN Greenplum FTT1 RAID1 Stripe4 Thick VM Encryption** as the policy name.
4. Under **Policy structure**, check the **Enable host based rules** box and the **Enable rules for vSAN storage** box.

5. Under **Host based services**, select **Default encryption properties** to enable VM encryption.

Storage policy component	Default encryption properties
Description	Storage policy component for VM and virtual disk encryption
Provider	VMware VM Encryption
Allow I/O filters before encryption	False

6. Under **vSAN - Availability**, select the **RAID-1 mirroring** vSAN policy. If you are using a different configuration, adjust this parameter accordingly.

Option 2: Enabling vSAN Encryption

In order to enable encryption at the vSAN level, you must first enable vSAN encryption and then create the VMware vSphere storage policy.

Step 1: Enabling vSAN encryption

1. Navigate to your cluster and click the **Configure** tab.
2. Under **vSAN**, select **Services**.
3. Click the vSAN Services **Edit** button.

vSAN Services
Cluster

These settings require all disks to be reformatted. Moving large amount of stored data might be slow and temporarily decrease the performance of the cluster.

CANCEL
APPLY

4. Ensure that space efficiency is set to **None**.
5. Ensure that **Data-At-Rest** encryption is enabled.

Note: There is a **Data-in-Transit encryption** option, which is for the vSAN to ensure that the data is encrypted when transferring data between hosts. However, if you are looking for that level of encryption, we recommend that you use VM encryption instead, which will provide the entire end-to-end encryption, including the encryption-in-transit and encryption-at-rest.

6. Select a key provider and click **Apply**.

From this point, the vSAN will start to provision the disk groups with a new encryption format. Note that this could take several hours, depending on the size of your vSAN storage.

Step 2: Creating the VMware vSphere storage policy

1. Select **Home**, click **Policies and Profiles**, and click **VM Storage Policies**.
2. Click **Create**.
3. Enter a Storage Policy name and optional description and click **Next**. This example uses **vSAN Greenplum FTT1 RAID1 Stripe4 Thick vSAN Encryption** as the policy name.
4. Under **Policy structure**, check the **Enable rules for vSAN storage** box.

Next Steps

You have completed setting up Dell EMC VxRail with VMware vSphere. Proceed to [Validating Dell EMC VxRail Setup Performance](#) in order to verify network connectivity and test vSAN performance with HCI Bench.

Validating VMware vSphere Setup Performance with HCI Bench

HCI Bench stands for Hyper-converged Infrastructure Benchmark. It is an automation wrapper around open source benchmark tools that automates proof-of-concept performance testing across a cluster. The tool fully automates the end-to-end process of deploying test virtual machines, coordinating workload runs, aggregating test results, performance analysis, and collecting necessary data for troubleshooting purposes.

The HCI Bench 2.6.0 OVA file can be downloaded from VMware Fling. You can find more information about it on the [VMware Fling site](#).

For the purpose of this installation, you download and configure HCI Bench 2.6.0 in order to verify network connectivity and test vSAN performance. You will be able to estimate whether your platform is performing within the expected range of parameters. Running this tool can also help you identify configuration issues.

Note: HCI Bench requires that you turn off VMware vSphere DRS while testing is running as it can cause virtual machine distribution imbalance. Once you have finished with this section, enable DRS again.

Deploying the HCI Bench Virtual Machine

1. In vCenter select your cluster and right click to choose **Deploy OVF Template**.
2. Under **Select an OVF Template**, select **URL**, enter the following and click **Next**. If you have already downloaded the OVA, select **Local file** instead and point to your downloaded OVA file.

```
https://download3.vmware.com/software/vmw-tools/hcibench/HCI Bench_2.6.0.ova
```

3. Accept the source verification.
4. Select the datacenter, choose a name for the virtual machine, and click **Next**.
5. Select the cluster and click **Next**. The template will start downloading.
6. Review the details and click **Next**.
7. Read and accept the license agreements and click **Next**.
8. Select the vSAN datastore and click **Next**.
9. Choose the `gp-virtual-external` port group for **Management Network**, and `gp-virtual-internal` for **VM Network**.

FINISH

13. The HCIBench virtual machine will be deployed. You can check its progress under the **Recent Tasks** tab on the VMware vSphere client.

Using HCIBench

1. Once deployment is complete, power on the virtual machine. When the IP address has appeared in vCenter, open the HCIBench UI in your browser by accessing `https://IPADDRESS:8443`.
2. Enter the `root` username and password you configured earlier and start configuring HCIBench.
 - ◆ Enter vCenter hostname or IP address.
 - ◆ Enter vCenter username as **greenplum@vsphere.local**.
 - ◆ Enter vCenter Password as the password you configured for **greenplum@vsphere.local**.
 - ◆ Enter the datacenter name.
 - ◆ Enter the cluster name.
 - ◆ The Resource Pool name field can remain blank. If using one, make sure that the resource pool exists.
 - ◆ Leave the VM Folder Name as **OPTIONAL**.
 - ◆ Enter the network name as `gp-virtual-internal`.
 - ◆ Enable **You Don't Have DHCP?**, then select **Customize** from the drop-down menu.
 - ◆ Enter the datastore name.
 - ◆ Enter the storage policy as the one you configured in [Setting Up VMware vSphere Storage](#).
 - ◆ Set Starting IP Address/Subnet Size to **192.168.10.1/24**.

- ◆ Enable **Clear Read/Write Cache Before Each Test Case**.
- ◆ Enter the ESXi host user name and password. This needs to be the same for all hosts.
- ◆ Disable **Easy Run**.
- ◆ Enable **Reuse VMs If Possible**.

The screenshot shows the 'Configuration' tab of the HCI Bench application. The 'vSphere Environment Information' section includes fields for vCenter Hostname/IP, vCenter Username, vCenter Password, Datacenter Name, Cluster Name, Resource Pool Name, VM Folder Name, Network Name, You Don't Have DHCP?, Datastore(s) Name, Storage Policy, Starting IP Address/Subnet Size, Specify Hosts to Deploy, Easy Run, and Reuse VMs If Possible. The 'Clear Read/Write Cache Before Each Test Case' and 'vSAN Debug Mode' are also visible as toggle switches.

3. Scroll down the page and configure the following:
 - ◆ Select **FIO** for Benchmarking Tool.
 - ◆ Set Number of VMs to the number of primary segments **planned** for your environment.
 - ◆ Set Number of CPUs to **4**.
 - ◆ Set Number of Data Disk to **8**.
 - ◆ Set the Size of RAM in GBs to **8**.
 - ◆ Set Size of Data Disk in GiB to **100**.
4. Under **Testing Configuration**, you create and run three different tests: **Write**, **Long Write** and **Read**. Note that these must be created and run one at a time, and then deleted before creating a new one.
 1. Enter a Test Name that is meaningful.
 2. Under **Select a Workload Parameter File**, click **Add** and use the corresponding values for each test type:

	Write	Long Write	Read
Number of Disks to Test	8	8	8

	Write	Long Write	Read
Working-Set Percentage	100	100	100
Number of Threads Per Disk	4	4	4
Block Size	256K	256K	256K
Read Percentage	0	0	100
Random Percentage	0	0	0
I/O Rate	OPTIONAL	OPTIONAL	OPTIONAL
Test Time	600	3600	600
Warmup Time	60	1800	60
Worker CPU Usage Percentage	OPTIONAL	OPTIONAL	OPTIONAL

- Click **Submit** and **OK**.
- Click the **Refresh** button next to **Select a Workload Parameter File** and select the one you just created from the dropdown menu.
- For **Prepare Virtual Disk Before Testing** set to **ZERO** for the first run to initialize storage. Consecutive runs can be set to **NONE** as it will shorten the test duration.
- Leave **Testing Duration (Seconds)** as **OPTIONAL**.
- Disable **Delete VM After Testing**.

SAVE CONFIG VALIDATE CONFIG START TEST REVIEW RESULT SAVE RESULT DELETE GUEST VMS

- Click **Save Config**.
- Click **Validate Config**.
 - If the tests fail, amend the highlighted errors, save, and validate your configuration again.
 - If your configuration is correct, the tests will pass and you can begin the test.
- Click **Start Test**.
- Once the test is complete you can [review the results](#).
- In order to run a different test, you should first remove the current parameter file:
 - Next to **Select a Workload Parameter File**, select the current file and click **Delete**.

2. Go back to Step 4 and use the table above to create another test with the corresponding settings.

Reviewing the Results

Once the test completes, click on **Review Result**, access the directory with the test name and open the provided PDF report file to display a breakdown of the different parameters that the test has measured.

Next Steps

You are now ready to start setting up and deploying a Greenplum Database cluster in your VMware vSphere environment. Make sure that you have enabled VMware vSphere DRS again and proceed to [Creating the Jumpbox Virtual Machine](#) to install a jumpbox virtual machine which you will use to run Terraform to provision the Greenplum Database virtual machines.

Creating the Jumpbox Virtual Machine

The jumpbox virtual machine is required to provision the cluster virtual machines for the Greenplum deployment. You must run the Terraform code provided in the next sections from this jumpbox virtual machine.

Uploading the ISO Image to vCenter

1. Download the ISO file. The recommended version is `CentOS-7-x86_64-Minimal-2009.iso`. You can download it [here](#). For example:

```
$ curl -JLO http://mirrors.ocf.berkeley.edu/centos/7.9.2009/isos/x86_64/CentOS-7-x86_64-Minimal-2009.iso
```

2. Ensure that the `sha256sum` output of the downloaded ISO is correct:

```
$ sha256sum CentOS-7-x86_64-Minimal-2009.iso
```

The result should match the one provided with the download.

3. Rename the ISO file to `centos7.iso`:

```
$ mv CentOS-7-x86_64-Minimal-2009.iso centos7.iso
```

4. Log in to vCenter using the VMware vSphere client.
5. Right-click the datastore where you want to upload the ISO and select **Browse Files**.
6. Click **New Folder** and create a new folder named `gp-jumpbox`.
7. Upload `centos7.iso` into the `gp-jumpbox` directory.

Deploying the Jumpbox Virtual Machine

1. Navigate to the **Cluster** tab.
2. Right click the **Cluster** to select the **New Virtual Machine** option.
3. Select **Create new virtual machine**, then click **Next**.
4. Name the virtual machine `gp-jumpbox`.

5. Select your datacenter, then click **Next**.
6. Select your cluster, then click **Next**.
7. Select the vSAN datastore, then click **Next**.
8. Select ESXi version **ESXi 7.0 U2 and later**, then click **Next**.
9. Select **Guest OS**.
 1. **Guest OS Family** should be **Linux**.
 2. **Guest OS Version** should be **CentOS 7 (64-bit)**, then click **Next**.
10. Under **Customize Hardware**:
 1. Edit the existing network adapter **New Network** so that it connects to the `gp-virtual-external` port group.
 2. Select **Add New Device -> Network Adapter**, and connect to the `gp-virtual-internal` port group.
 3. Prepare to use the ISO as a source disk for installing CentOS.
 1. Select **Add New Device -> CD/DVD Drive**.
 2. Select **Datastore ISO File** from the drop-down menu.
 3. Navigate to the correct location of the uploaded CentOS ISO, then click **OK**.
 4. Ensure that **Status: Connect At Power On** is enabled.
 4. Leave the default settings for CPU, Memory and Disk and click **Next**.
11. Review your configuration and then click **Finish**.

Initializing the Jumpbox Virtual Machine

1. Power on the newly created virtual machine and launch the web console.
2. Select **Install CentOS 7** and press Enter.
3. Select the preferred language and locale, then click **Continue**.
4. Click on **Installation Destination** under **System**.
 1. Under **Device Selection -> Local Standard Disk** select the desired disk, then click **Done**.
5. Click **Network & Host Name** under **System**.
 1. Enable the first network that connects to the `gp-virtual-external` port group.
 1. If you are using DHCP, an IP address will be automatically assigned.
 2. If you are using static IP assignment, click **Configure -> IPv4 Settings** and assign the corresponding IP address for the external network.
 3. Click **Save**.
 2. Select the second network, which connects to the `gp-virtual-internal` port group.
 1. Click **Configure -> IPv4 Settings** and assign the corresponding IP address for the internal network.
 2. Click **Save** and enable the network. You should see that an internal IP address being assigned to this interface.
 3. Change the hostname to `gp-jumpbox` and then click **Apply**.
 4. Click **Done**.
6. Click **Begin Installation**.

7. Set the `root` password, then click **Done**. Clicking **Done** a second time may be necessary.
8. After setup is complete, click **Reboot**.
9. Before continuing to the next section, verify that the virtual machine has external network access. Log in to the newly created virtual machine and run the following command:

```
$ ping 8.8.8.8
```

Note that you might need to manually install additional packages or tools that are not part of the minimal CentOS ISO image.

Installing VMware Tools

You can find more detailed instructions on the [VMware Knowledge Base](#).

1. On the VMware vSphere client, right click your virtual machine. Select **Guest OS -> Install VMware Tools...**.
2. Select **Mount**. This mounts an ISO file as a virtual CD-ROM.
3. Retrieve the IP address of the adapter connected to the `gp-virtual-external` port group.
4. Log in to gp-jumpbox.
5. Install `perl`:

```
$ yum install -y perl
```

6. Mount the ISO containing the VMware Tools binary.

```
$ mkdir -p /mnt/cdrom
$ mount /dev/cdrom /mnt/cdrom
```

7. Extract the installation file.

```
$ cd /tmp
$ tar -xzf /mnt/cdrom/VMwareTools*.tar.gz
```

8. Unmount the ISO.

```
$ umount /mnt/cdrom
```

9. Install VMware Tools, choose **yes** for the first prompt, and use defaults for the remaining prompts.

```
$ cd /tmp/vmware-tools-distrib
$ ./vmware-install.pl --force-install --default
```

10. Validate that VMware Tools is installed.

```
$ systemctl status vmware-tools
● vmware-tools.service - SYSV: Manages the services needed to run VMware software
   Loaded: loaded (/etc/rc.d/init.d/vmware-tools; bad; vendor preset: disabled)
   Active: active (running) since Wed 2021-06-02 18:14:34 EDT; 2min 59s ago
     Docs: man:systemd-sysv-generator(8)
   Process: 8636 ExecStart=/etc/rc.d/init.d/vmware-tools start (code=exited, status=0/SUCCESS)
  CGroup: /system.slice/vmware-tools.service
          └─8739 /usr/sbin/vmtoolsd
```

```
└─8775 /usr/lib/vmware-vgauth/VGAuthService -s
```

Installing Terraform

You must install Terraform on the jumpbox virtual machine. The minimum version required is **v0.14.3**. You can find more detailed instructions on the [Terraform website](#).

1. Download and install the software.

```
$ cd /tmp
$ yum install -y wget unzip
$ wget https://releases.hashicorp.com/terraform/0.15.5/terraform_0.15.5_linux_a
md64.zip
$ unzip terraform_0.15.5_linux_amd64.zip
$ mv terraform /usr/local/bin/
```

2. Validate the installation.

```
$ terraform --version
Terraform v0.15.5
on linux_amd64
```

Next Steps

The jumpbox virtual machine is now ready for use. Continue to [Choosing your Deployment Option](#) to decide which deployment option will best fit your needs.

Choosing your Deployment Option

There are two available options to deploy the Greenplum Database:

- [Option 1: Deploying Greenplum Using a Pre-built OVA](#)
- [Option 2: Deploying Greenplum Using Your Own Template](#)

With the first option you download a pre-configured Greenplum Database OVA, while the second option requires building your own template. The following table highlights the differences between the two options:

Option 1	Option 2
Photon OS 3.0	CentOS 7
Automated process	Manual process
Deployment time around 30 minutes	Deployment time around 2 hours
Limited support for security & compliance customization	Fully customizable based on security & compliance requirements

Option 1: Deploying Greenplum Using a Pre-built OVA

In this section, you download the Photon OS 3.0 Greenplum Database OVA template from VMware Marketplace, deploy the OVA in VMware vSphere, perform a series of configuration changes to the virtual machine, and create a template from it. Finally, you verify that the virtual machine is in configured correctly by running the `/etc/gpv/validate` utility.

Downloading the Greenplum Database to a local machine

The Greenplum Database OVA template is available on [VMware Marketplace](#).

Log in and download the preferred version. Make note of the directory where the file was saved.

Deploying the Greenplum Database Template OVA

1. Log in to vCenter and navigate to **Hosts and Clusters**.
2. Right click your cluster, then click **Deploy OVF Template**.
3. Choose **Local file**, select the OVA file from your local machine, then click **Next**.
4. Set **Virtual machine name** as `greenplum-db-template`. Select the desired Datacenter, then click **Next**.
5. Select the desired compute resource, then click **Next**. Wait while vCenter queries the OVA advanced configuration options.
6. Verify that the **Review details** section is correct, then click **Next**.
7. Select your vSAN storage, then click **Next**.
8. Select `gp-virtual-external` as the **Destination Network**, then click **Next**.
9. Configure the **Customize Template** section:
 1. Set **Number of Segments** to the number of Greenplum segments you plan to deploy.
 2. Choose between a **Mirrored or Mirrorless** deployment.
 3. Set **Internal Network**:
 - **Internal Network MTU Size** with the desired MTU size. The recommended size is 9000.
 - **Internal Network IP Prefix** with the leading octets for the `gp-virtual-internal` network IP range, for example 192.168.1.
 4. Set **Routable Networking**:
 - **Hostname** as `greenplum-db-template`.
 - **NTP Server** with a routable NTP server to sync with `mdw` and `smdw`.
 5. Click **Next**.
10. Review the configuration, then click **Finish**.
11. Do not power on the template until you have updated memory and CPU resources.

Modifying Resources

Based on your underlying hardware, you may need to change the default settings for CPU, memory and data disk size, which are preset to 8 vCPU, 30 GB and 16 GB respectively.

1. Right click the `greenplum-db-template` virtual machine, then click **Edit Settings**.
2. If you want to change the memory size, click on the number on the right of **Memory** and enter the desired allocated memory.
3. If you want to change the number of CPUs, click on the number on the right of **CPU** and select the desired number of CPUs.
4. If you want to change the size of Data disk as per the [VM Sizing](#), click on the number on the right of **Hard disk 2** and enter the desired size.

OK

- Click **OK**.
- Power on the `greenplum-db-template` virtual machine.

Validating the Virtual Machine Template

- Launch the web console and log in as `gpadmin` with the password `changeme`.
- Follow the prompt to reset the password of `gpadmin`.
- Use Ctrl+D to log out, then try login as `root` with password `changeme`.
- Follow the prompt to reset the password of `root`.
- As root, run `/etc/gpv/validate` and ensure there are no errors.
- If there are no errors, power off the virtual machine.

Provisioning the Virtual Machines

Use the Terraform software you installed in [Creating the Jumpbox Virtual Machine](#) to generate copies of the template virtual machine you just created. The following steps will guide you to configure them based on the number of virtual machines in your environment, IP address ranges, and other settings you specify in the installation script.

- Create a file named `main.tf` and copy the contents described in [OVA Script](#).
- Log in to the jumpbox virtual machine as `root`.
- Use `scp` to copy the `main.tf` file to the jumpbox, under the `root` user home directory.
- Update the following variables under the **Terraform variables** section of the `main.tf` script

with the correct values for your environment. You collected the required information in the [Prerequisites](#) section.

Variable	Description
vsphere_user	Name of the VMware vSphere administrator level user.
vsphere_password	Password of the VMware vSphere administrator level user.
vsphere_server	The IP address or, preferably, the Fully-Qualified Domain Name (FQDN) of your vCenter server.
vsphere_datacenter	The name of the data center for Greenplum in your vCenter environment.
vsphere_compute_cluster	The name of the compute cluster for Greenplum in your data center.
vsphere_datastore	The name of the vSAN datastore which will contain your Greenplum data.
vsphere_storage_policy	The name of the storage policy defined during Setting Up VMware vSphere Storage or Setting Up VMware vSphere Encryption .
gp_virtual_external_ipv4_addresses	The routable IP addresses for mdw and smdw, in that order; for example: ["10.0.0.111", "10.0.0.112"].
gp_virtual_external_ipv4_netmask	The number of bits in the netmask for <code>gp-virtual-external</code> ; for example: 24.
gp_virtual_external_gateway	The gateway IP address for the <code>gp-virtual-external</code> network.
dns_servers	The DNS servers for the <code>gp-virtual-external</code> network, listed as an array; for example: ["8.8.8.8", "8.8.4.4"].
gp_virtual_etl_bar_ipv4_cidr	The leading octets for the internal, non-routable network <code>gp-virtual-etl-bar</code> ; for example: '192.168.2.0/24'.

5. Initialize Terraform:

```
$ terraform init
```

The output would be similar to:

```
Terraform has been successfully initialized!

You may now begin working with Terraform. Try running "terraform plan" to see
any changes that are required for your infrastructure. All Terraform commands
should now work.

If you ever set or change modules or backend configuration for Terraform,
re-run this command to reinitialize your working directory. If you forget, other
commands will detect it and remind you to do so if necessary.
```

6. Verify that your Terraform configuration is correct by running:

```
terraform plan
```

7. Deploy the cluster:

```
terraform apply
```

Answer Yes to the following prompt:

```
Do you want to perform these actions?
Terraform will perform the actions described above.
Only 'yes' will be accepted to approve.

Enter a value: yes
```

You can check the progress of the virtual machines creation under the Recent Tasks panel on your VMware vSphere client.

Once Terraform has completed, it generates a file named `terraform.tfstate`.

This file **must not be deleted**, as it keeps a record of all the virtual machines and their states.

Terraform also uses this file when modifying any virtual machines.

VMware recommends retaining a snapshot of the jumpbox virtual machine.

Monitoring the Greenplum Deployment

The initialization of the Greenplum is fully automated in the `mdw` virtual machine. Once the `mdw` virtual machine is created by the Terraform script, you can log in to `mdw` as `root`, and monitor the deployment process by running:

```
$ journalctl -fu gpv-mdw
```

When the Greenplum cluster is initialized, you should see the following message:

```
Dec 02 20:30:32 mdw bash[2228]: 2021-12-02 20:30:32 Starting the gpcc agents and webserver...
Dec 02 20:30:35 mdw bash[2228]: 2021-12-02 20:30:35 Agent successfully started on 6/6 hosts
Dec 02 20:30:35 mdw bash[2228]: 2021-12-02 20:30:35 View Greenplum Command Center at https://mdw:28080
Dec 02 20:30:35 mdw bash[2228]: Greenplum Initialization Complete!
```

Setting Up the GPCC Login User

After the initialization, the **GPCC** (Greenplum Command Center) web service will be available at:

```
https://mdw_public_ip:28080
```

Note: `https` will be enabled by default.

There are two default login users for GPCC: `gpmon` and `gpcc_user`. The GPCC login user `gpmon` is reserved for the service to function and should not be used, while the GPCC login user `gpcc_user` will be used to login to the GPCC web page.

In order to login to the web page, the password for the GPCC login user `gpcc_user` needs to be reset. Run `/etc/gpv/reset-gpcc-password` as the `gpadmin` Linux user on the `mdw` machine to reset the password. There will be a prompt to type and retype the new password.

Now you can login to the web page with username `gpcc_user` and the new password you just set.

Note: if you want to create a new login user for GPCC, refer to the [GPCC documentation](#).

Next Steps

Now that the Greenplum Database has been deployed, follow the steps provided in [Validating the Greenplum Installation](#) to verify that Greenplum is installed correctly.

Option 2: Deploying Greenplum Using Your Own Template

With this option you create a virtual machine template from an existing CentOS 7 virtual machine, use Terraform from the jumpbox virtual machine to generate copies of the template which will comprise the Greenplum database cluster, and deploy a Greenplum Database cluster.

- [Creating the Virtual Machine Template](#)
- [Allocating the Virtual Machines with Terraform](#)
- [Deploying Greenplum](#)

Creating the Virtual Machine Template

In this section, you clone a virtual machine from an existing CentOS 7 virtual machine, perform a series of configuration changes, and create a template from it. Finally, you verify that it was configured correctly by deploying a test virtual machine from the newly created template and checking its configuration.

Preparing the Virtual Machine

Create a template from an existing virtual machine. You must have a running CentOS 7 virtual machine in the datastore and cluster where you deploy the Greenplum environment.

1. Log in to vCenter and navigate to **Hosts and Clusters**.
2. Right click your existing CentOS 7 virtual machine.
3. Select **Clone -> Clone to Virtual Machine**.
4. Enter `greenplum-db-template-vm` as the virtual machine name, then click **Next**.
5. Select your cluster, then click **Next**.
6. Select the vSAN datastore and select **Keep existing VM storage policies** for **VM Storage Policy**, then click **Next**.
7. Under **Select clone options**, check the boxes **Power on virtual machine after creation** and **Customize this virtual machine's hardware** and click **Next**.
8. Under **Customize hardware**, check the number of hard disks configured for this virtual machine. If there is only one, add a second one by clicking **Add new device -> Hard Disk**.
9. Edit the existing network adapter **New Network** so it connects to the `gp-virtual-external` port group.
 1. If you are using DHCP, a new IP address will be assigned to this interface. If you are using static IP assignment, you must manually set up the IP address in a later step.
10. Review your configuration, then click **Finish**.
11. Once the virtual machine is powered on, launch the Web Console and log in as `root`. Check the virtual machine IP address by running `ip a`. If you are using static IP assignment, you must manually set it up:
 1. Edit the file `/etc/sysconfig/network-scripts/ifcfg-<interface-name>`.
 2. Enter the network information provided by your network administrator for the `gp-virtual-external` network. For example:

```
BOOTPROTO=none
IPADDR=10.202.89.10
NETMASK=255.255.255.0
GATEWAY=10.202.89.1
```

```
DNS1=1.0.0.1
DNS2=1.1.1.1
```

Performing System Configuration

Configure the newly cloned virtual machine in order to support a Greenplum Database system.

1. Log in to the cloned virtual machine `greenplum-db-template-vm` as user `root`.
2. Verify that VMware Tools is installed. Refer to [Installing VMware Tools](#) for instructions.
3. Disable the following services:
 1. Disable SELinux by editing the `/etc/selinux/config` file. Change the value of the `SELINUX` parameter in the configuration file as follows:

```
SELINUX=disabled
```

2. Check that the System Security Services Daemon (SSSD) is installed:

```
$ yum list sssd | grep -i "Installed Packages"
```

If the SSSD is installed, edit the SSSD configuration file and set the `selinux_provider` parameter to `none` to prevent SELinux related SSH authentication denials which could occur even if SELinux is disabled. Edit `/etc/sss/sss.conf` and add the following line. If SSSD is not installed, skip this step.

```
selinux_provider=none
```

3. Disable the Firewall service:

```
$ systemctl stop firewalld
$ systemctl disable firewalld
$ systemctl mask --now firewalld
```

4. Disable the Tuned daemon:

```
$ systemctl stop tuned
$ systemctl disable tuned
$ systemctl mask --now tuned
```

5. Disable Chrony:

```
$ systemctl stop chronyd
$ systemctl disable chronyd
$ systemctl mask --now chronyd
```

4. Back up the boot files:

```
$ cp /etc/default/grub /etc/default/grub-backup
$ cp /boot/grub2/grub.cfg /boot/grub2/grub.cfg-backup
```

5. Add the following boot parameters:

1. Disable Transparent Huge Page (THP):

```
$ grubby --update-kernel=ALL --args="transparent_hugepage=never"
```

2. Add the parameter `elevator=deadline`:

```
$ grubby --update-kernel=ALL --args="elevator=deadline"
```

6. Install and enable the `ntp` daemon:

```
$ yum install -y ntp
$ systemctl enable ntpd
```

7. Configure the NTP servers:

1. Remove all unwanted servers from `/etc/ntp.conf`. For example:

```
...
# Use public servers from the pool.ntp.org project.
# Please consider joining the pool (http://www.pool.ntp.org/join.html).
server 0.centos.pool.ntp.org iburst
...
```

2. Add an entry for each server to `/etc/ntp.conf`:

```
server <data center's NTP time server 1>
server <data center's NTP time server 2>
...
server <data center's NTP time server N>
```

3. Add the master and standby to the list of servers after datacenter NTP servers in `/etc/ntp.conf`:

```
server <data center's NTP time server N>
...
server mdw
server smdw
```

8. Configure kernel settings so the system is optimized for Greenplum Database.

1. Create the configuration file `/etc/sysctl.d/10-gpdb.conf` and paste the following kernel optimization parameters:

```
kernel.msgmax = 65536
kernel.msgmnb = 65536
kernel.msgmni = 2048
kernel.sem = 500 2048000 200 40960
kernel.shmmni = 1024
kernel.sysrq = 1
net.core.netdev_max_backlog = 2000
net.core.rmem_max = 4194304
net.core.wmem_max = 4194304
net.core.rmem_default = 4194304
net.core.wmem_default = 4194304
net.ipv4.tcp_rmem = 4096 4224000 16777216
net.ipv4.tcp_wmem = 4096 4224000 16777216
net.core.optmem_max = 4194304
net.core.somaxconn = 10000
net.ipv4.ip_forward = 0
net.ipv4.tcp_congestion_control = cubic
net.ipv4.tcp_tw_recycle = 0
net.core.default_qdisc = fq_codel
net.ipv4.tcp_mtu_probing = 0
net.ipv4.conf.all.arp_filter = 1
net.ipv4.conf.default.accept_source_route = 0
net.ipv4.ip_local_port_range = 10000 65535
net.ipv4.tcp_max_syn_backlog = 4096
net.ipv4.tcp_syncookies = 1
```

```
vm.overcommit_memory = 2
vm.overcommit_ratio = 95
vm.swappiness = 10
vm.dirty_expire_centisecs = 500
vm.dirty_writeback_centisecs = 100
vm.zone_reclaim_mode = 0
```

2. Add the following parameters, some of the values will depend on the virtual machine settings calculated on the [Sizing section](#).

1. Determine the value of the RAM in bytes by creating the variable `$RAM_IN_BYTES`. For example, for a 30GB RAM virtual machine, run the following:

```
$ RAM_IN_BYTES=$((30 * 1024 * 1024 * 1024))
```

2. Define the following parameters that depend on the variable `$RAM_IN_BYTES` that you just created, and append them to the file `/etc/sysctl.d/10-gpdb.conf` by running the following commands:

```
$ echo "vm.min_free_kbytes = $((($RAM_IN_BYTES * 3 / 100 / 1024))" >> /etc/sysctl.d/10-gpdb.conf
$ echo "kernel.shmall = $((($RAM_IN_BYTES / 2 / 4096))" >> /etc/sysctl.d/10-gpdb.conf
$ echo "kernel.shmmax = $((($RAM_IN_BYTES / 2))" >> /etc/sysctl.d/10-gpdb.conf
```

3. If your virtual machine RAM is less than or equal to 64 GB, run the following commands:

```
$ echo "vm.dirty_background_ratio = 3" >> /etc/sysctl.d/10-gpdb.conf
$ echo "vm.dirty_ratio = 10" >> /etc/sysctl.d/10-gpdb.conf
```

4. If your virtual machine RAM is greater than 64 GB, run the following commands:

```
$ echo "vm.dirty_background_ratio = 0" >> /etc/sysctl.d/10-gpdb.conf
$ echo "vm.dirty_ratio = 0" >> /etc/sysctl.d/10-gpdb.conf
$ echo "vm.dirty_background_bytes = 1610612736 # 1.5GB" >> /etc/sysctl.d/10-gpdb.conf
$ echo "vm.dirty_bytes = 4294967296 # 4GB" >> /etc/sysctl.d/10-gpdb.conf
```

9. Configure `ssh` to allow password-less login.

1. Edit `/etc/ssh/sshd_config` file and update following options:

```
PasswordAuthentication yes
ChallengeResponseAuthentication yes
UsePAM yes
MaxStartups 100
MaxSessions 100
```

2. Create `ssh` keys to allow passwordless login with `root` by running the following commands:

```
# make sure to generate ssh keys without password. Press Enter for defaults
```

```
$ ssh-keygen
$ chmod 700 /root/.ssh
# copy public key to authorized_keys
$ cd /root/.ssh/
$ cat id_rsa.pub > authorized_keys
$ chmod 600 authorized_keys
# it will add host signature to known_hosts
$ ssh-keyscan -t rsa localhost > known_hosts
# duplicate host signature for all hosts in the cluster
$ key=$(cat known_hosts)
$ for i in mdw smdw $(seq -f "sdw%g" 1 64); do
    echo ${key}| sed -e "s/localhost/${i}/" >> known_hosts
done
$ chmod 644 known_hosts
```

10. Configure the system resource limits to control the amount of resources used by Greenplum by creating the file `/etc/security/limits.d/20-nproc.conf`.

1. Ensure that the directory exists before creating the file:

```
$ mkdir -p /etc/security/limits.d
```

2. Append the following contents to the end of `/etc/security/limits.d/20-nproc.conf`:

```
* soft nofile 524288
* hard nofile 524288
* soft nproc 131072
* hard nproc 131072
```

11. Create the base mount point `/gpdata` for the virtual machine data drive:

```
$ mkdir -p /gpdata
$ mkfs.xfs /dev/sdb
$ mount -t xfs -o rw,noatime,nodev,inode64 /dev/sdb /gpdata/
$ df -kh
$ echo /dev/sdb /gpdata/ xfs rw,nodev,noatime,inode64 0 0 >> /etc/fstab
$ mkdir -p /gpdata/primary
$ mkdir -p /gpdata/mirror
$ mkdir -p /gpdata/master
```

12. Configure the file `/etc/rc.local` to make the following settings persistent.

1. Update the file content:

```
# Configure readahead for the `/dev/sdb` to 16384 512-byte sectors, i.e.
8MiB
/sbin/blockdev --setra 16384 /dev/sdb
# Configure gp-virtual-internal network settings with MTU 9000
/sbin/ip link set ens192 mtu 9000
# Configure jumbo frame RX ring buffer to 4096
/sbin/ethtool --set-ring ens192 rx-jumbo 4096
```

2. Make the file executable:

```
$ chmod +x /etc/rc.d/rc.local
```

13. Create the group and user `gpadmin:gpadmin` required by the Greenplum Database.

1. Execute the following steps in order to create the user `gpadmin` in the group `gpadmin`:

```
$ groupadd gpadmin
```

```
$ useradd -g gpadmin -m gpadmin
$ passwd gpadmin
# Enter the desired password at the prompt
```

2. (Optional) Change the root password to a preferred password:

```
$ passwd root
# Enter the desired password at the prompt
```

3. Create the file `/home/gpadmin/.bashrc` for `gpadmin` with the following content:

```
### .bashrc

### Source global definitions
if [ -f /etc/bashrc ]; then
    . /etc/bashrc
fi

### User specific aliases and functions

### If Greenplum has been installed, then add Greenplum-specific commands
to the path
if [ -f /usr/local/greenplum-db/greenplum_path.sh ]; then
    source /usr/local/greenplum-db/greenplum_path.sh
fi
```

4. Change the ownership of `/home/gpadmin/.bashrc` to `gpadmin:gpadmin`:

```
$ chown gpadmin:gpadmin /home/gpadmin/.bashrc
```

5. Change the ownership of the `/gpdata` directory to `gpadmin:gpadmin`:

```
$ chown -R gpadmin:gpadmin /gpdata
```

6. Create `ssh` keys for passwordless login as `gpadmin` user:

```
$ su - gpadmin
# make sure to generate ssh keys without password. Press Enter for default
ts
$ ssh-keygen
$ chmod 700 /home/gpadmin/.ssh
# copy public key to authorized_keys
$ cd /home/gpadmin/.ssh/
$ cat id_rsa.pub > authorized_keys
$ chmod 600 authorized_keys
# it will add host signature to known_hosts
$ ssh-keyscan -t rsa localhost > known_hosts
# duplicate host signature for all hosts in the cluster
$ key=$(cat known_hosts)
$ for i in mdw smdw $(seq -f "sdw%g" 1 64); do
    echo ${key}| sed -e "s/localhost/${i}/" >> known_hosts
done
$ chmod 644 known_hosts
```

7. Log out of `gpadmin` to go back to `root` before you proceed to the next step.

14. Configure `cgroups` for Greenplum.

For security and resource management, Greenplum Database makes use of the Linux `cgroups`.

1. Install the `cgroup` configuration package:

```
$ yum install -y libcgroup-tools
```

2. Verify that the directory `/etc/cgconfig.d` exists:

```
$ mkdir -p /etc/cgconfig.d
```

3. Create the `cgroups` configuration file `/etc/cgconfig.d/10-gpdb.conf` for Greenplum:

```
group gpdb {
    perm {
        task {
            uid = gpadmin;
            gid = gpadmin;
        }
        admin {
            uid = gpadmin;
            gid = gpadmin;
        }
    }
    cpu {
    }
    cpuacct {
    }
    cpuset {
    }
    memory {
    }
}
```

4. Prepare the configuration file and enable `cgconfig` via `systemctl`:

```
$ cgconfigparser -l /etc/cgconfig.d/10-gpdb.conf
$ systemctl enable cgconfig.service
```

15. Update the `/etc/hosts` file with all of the IP addresses and hostnames in the network `gp-virtual-internal`.

1. Verify that you have following parameters defined:

- Total number of segment virtual machines you wish to deploy, the default is 64.
- The starting IP address of the master virtual machine in the `gp-virtual-internal` port group, the default is 250.
- The leading octets for the `gp-virtual-internal` network IP range, the default is 192.168.1..
- The segment IP will start from 192.168.1.2 and the master IP will start from 192.168.1.250

2. Run the following commands, replacing the values based on your environment:

```
$ echo '192.168.1.250 mdw' >> /etc/hosts
$ echo '192.168.1.251 smdw' >> /etc/hosts
$ for i in {1..64}; do
    echo "192.168.1.$((i+1)) sdw${i}" >> /etc/hosts
done
```

16. Create two files `hosts-all` and `hosts-segments` under `/home/gpadmin`. Replace 64 with your number of segment virtual machines if applicable:

```
$ echo mdw > /home/gpadmin/hosts-all
$ echo smdw >> /home/gpadmin/hosts-all
$ > /home/gpadmin/hosts-segments
$ for i in {1..64}; do
    echo "sdw${i}" >> /home/gpadmin/hosts-all
    echo "sdw${i}" >> /home/gpadmin/hosts-segments
done
$ chown gpadmin:gpadmin /home/gpadmin/hosts*
```

Installing the Greenplum Database Software

1. Download the latest version of the Greenplum Database Server 6 for RHEL 7 from [VMware Tanzu Network](#).
2. Move the downloaded binary in to the virtual machine and install Greenplum:

```
$ scp greenplum-db-6.*.rpm root@greenplum-db-template-vm:/tmp
$ ssh root@greenplum-db-template-vm
$ yum install -y /tmp/greenplum-db-6.*.rpm
```

3. Install the following `yum` packages for better supportability:
 - ♦ `dsstat` to monitor system statistics, like network and I/O performance.
 - ♦ `sos` to generate an sosreport, a best practice to collect system information for support purposes.
 - ♦ `tree` to visualize folder structure.
 - ♦ `wget` to easily get artifacts from the Internet.

```
$ yum install -y dsstat
$ yum install -y sos
$ yum install -y tree
$ yum install -y wget
```

4. Power down the virtual machine:

```
$ shutdown now
```

5. Enable vApp options in vCenter:
 - ♦ Select the VM **greenplum-db-template-vm**
 - ♦ In the VM view, click on **Configure** tab at the top of the page
 - ♦ If vApp Option is disabled, then click **EDIT...**
 - click **Enable vApp options**
 - click **OK**
6. Add vApp option **guestinfo.segment_count**:
 - ♦ Select **Settings -> vApp Options**
 - ♦ Under **Properties**, click **ADD**
 - ♦ In the **General** tab, enter the following:
 - For **Category**, enter **Greenplum**
 - For **Label**, enter **Number of Segments**
 - For **Key ID**, enter **guestinfo.segment_count**
 - ♦ In the **Type** tab, enter the following:

- For **Type**, select **Integer**
 - For **Range**, enter range **2-248**
 - ◊ Click on **Save**
 - ◊ Select the new property
 - ◊ Click **Set Value**, and enter an appropriate value, for example: **64**
7. Add vApp option **guestinfo.internal_ip_cidr**:
- ◊ Under **Properties**, click **ADD** again
 - ◊ In the **General** tab, enter the following:
 - For **Category**, enter **Internal Network**
 - For **Label**, enter **Internal Network CIDR (with netmask /24)**
 - For **Key ID**, enter **guestinfo.internal_ip_cidr**
 - ◊ In the **Type** tab, enter the following:
 - For **Type**, select **String**
 - For **Length**, enter range **12-18**
 - ◊ Click on **Save**
 - ◊ Select the new property
 - ◊ Click **Set Value**, and enter an appropriate value: for example: **192.168.10.1/24**

Creating the Greenplum Template

Clone the newly created and configured virtual machine to a template; all the virtual machines in the Greenplum Database cluster will be created from this template.

1. Log in to vCenter and navigate to **Hosts and Clusters**.
2. Right click the **greenplum-db-template-vm** virtual machine.
3. Select **Clone -> Clone to template**.
4. Enter the template name as **greenplum-db-template**, then click **Next**.
5. Select your cluster, then click **Next**.
6. Select the vSAN datastore and the appropriate **VM Storage Policy** that you configured on [Setting Up VMware vSphere Storage](#) or [Setting Up VMware vSphere Encryption](#), then click **Next**.
7. Review your configuration, then click **Finish**.

Validating the Template

Validate that the newly created template is configured correctly by creating a test virtual machine from the template, and verify that all settings are configured correctly.

Creating a Test Virtual Machine

1. Log in to vCenter and navigate to **VMs and Templates**.
2. Right-click the Greenplum template **greenplum-db-template** and select **New VM from this Template**.
3. Enter a name for the virtual machine and click **Next**.
4. Select your cluster, then click **Next**.

5. Select the vSAN datastore and select **Keep existing VM storage policies** for **VM Storage Policy**, then click **Next**.
6. Select **Power on virtual machine after creation**, then click **Next**.
7. Review your configuration, then click **Finish**.

Verifying the Test Virtual Machine Settings

1. Log in to the virtual machine as `root`.
2. Verify that the following services are disabled:

1. SELinux

```
$ sestatus
SELinux status: disabled
```

2. Firewall

```
$ systemctl status firewalld
firewalld.service
Loaded: masked (/dev/null; bad)
Active: inactive (dead)
```

3. Tune

```
$ systemctl status tuned
tuned.service
Loaded: masked (/dev/null; bad)
Active: inactive (dead)
```

4. Chrony

```
$ systemctl status chronyd
chronyd.service
Loaded: masked (/dev/null; bad)
Active: inactive (dead)
```

3. Verify that `ntpd` is installed and enabled:

```
$ systemctl status ntpd
ntpd.service - Network Time Service
Loaded: loaded (/usr/lib/systemd/system/ntpd.service; enabled; vendor prese
t: disabled)
Active: active (running) since Tue 2021-05-04 18:47:25 EDT; 4s ago
```

4. Verify that the NTP servers are configured correctly and the remote servers are ordered properly:

```
$ ntpq -pn

      remote           refid      st t when poll reach   delay   offset  jitt
er
=====
==
-xx.xxx.xxx.xxx    xx.xxx.xxx.xxx      3 u  246  256  377    0.186    2.700    0.9
93
+xx.xxx.xxx.xxx    xx.xxx.xxx.xxx      3 u  223  256  377   26.508    0.247    0.3
97
```

5. Verify that the filesystem configuration is correct:

```
$ lsblk /dev/sdb
NAME MAJ:MIN RM  SIZE RO TYPE MOUNTPOINT
sdb      8:16   0 250G  0 disk /gpdata/

$ grep sdb /etc/fstab
/dev/sdb /gpdata/ xfs rw,nodev,noatime,inode64 0 0

$ df -Th | grep sdb
/dev/sdb                xfs          250G 167M 250G   1% /gpdata

$ ls -l /gpdata
total 0
drwxrwxr-x 2 gpadmin gpadmin 6 Jun 10 15:20 master
drwxrwxr-x 2 gpadmin gpadmin 6 Jun 10 15:20 mirror
drwxrwxr-x 2 gpadmin gpadmin 6 Jun 10 15:20 primary
```

6. Verify that the parameters `transparent_hugepage=never` and `elevator=deadline` exist:

```
$ cat /proc/cmdline
BOOT_IMAGE=/vmlinuz-3.10.0-1160.el7.x86_64 root=/dev/mapper/centos-root ro crashkernel=auto spectre_v2=retpoline rd.lvm.lv=centos/root rd.lvm.lv=centos/swap rhgb quiet LANG=en_US.UTF-8 transparent_hugepage=never elevator=deadline
```

7. Verify that the `ulimit` settings match your specification by running the following command:

```
$ ulimit -a
core file size          (blocks, -c) 0
data seg size           (kbytes, -d) unlimited
scheduling priority     (-e) 0
file size               (blocks, -f) unlimited
pending signals         (-i) 119889
max locked memory       (kbytes, -l) 64
max memory size         (kbytes, -m) unlimited
open files              (-n) 524288
pipe size               (512 bytes, -p) 8
POSIX message queues    (bytes, -q) 819200
real-time priority      (-r) 0
stack size              (kbytes, -s) 8192
cpu time                (seconds, -t) unlimited
max user processes      (-u) 131072
virtual memory          (kbytes, -v) unlimited
file locks              (-x) unlimited
```

8. Verify that the necessary `yum` packages are installed, by running `rpm -qa:`

```
$ rpm -qa | grep apr
$ rpm -qa | grep apr-util
$ rpm -qa | grep dstat
$ rpm -qa | grep greenplum-db-6
$ rpm -qa | grep krb5-devel
$ rpm -qa | grep libcgroup-tools
$ rpm -qa | grep libevent
$ rpm -qa | grep libyaml
$ rpm -qa | grep net-tools
$ rpm -qa | grep ntp
$ rpm -qa | grep perl
$ rpm -qa | grep rsync
$ rpm -qa | grep sos
$ rpm -qa | grep tree
$ rpm -qa | grep wget
$ rpm -qa | grep which
```

```
$ rpm -qa | grep zip
```

9. Verify that you configured the Greenplum Database `cgroups` correctly by running the commands below.

1. Identify the `cgroup` directory mount point:

```
$ grep cgroup /proc/mounts
```

The first line from the above output identifies the `cgroup` mount point. For example, `/sys/fs/cgroup`.

2. Run the following commands, replacing `<cgroup_mount_point>` with the mount point which you identified in the previous step:

```
$ ls -l <cgroup_mount_point>/cpu/gpdb
$ ls -l <cgroup_mount_point>/cpuacct/gpdb
$ ls -l <cgroup_mount_point>/cpuset/gpdb
$ ls -l <cgroup_mount_point>/memory/gpdb
```

The above directories must exist and must be owned by `gpadmin:gpadmin`.

3. Verify that the `cgconfig` service is running by executing the following command:

```
$ systemctl status cgconfig.service
```

10. Verify that the `sysctl` settings have been applied correctly based on your virtual machine settings.

1. First define the variable `$RAM_IN_BYTES` again on this virtual machine. For example, for a 30 GB RAM:

```
$ RAM_IN_BYTES=$((30 * 1024 * 1024 * 1024))
```

2. Retrieve the values listed below by running `sysctl <kernel_setting>` and confirm that the values match the verifier specified for each setting.

Kernel Setting	Value
vm.min_free_kbytes	$\$((\$RAM_IN_BYTES * 3 / 100 / 1024))$
vm.overcommit_memory	2
vm.overcommit_ratio	95
net.ipv4.ip_local_port_range	10000 65535
kernel.shmall	$\$((\$RAM_IN_BYTES / 2 / 4096))$
kernel.shmmax	$\$((\$RAM_IN_BYTES / 2))$

3. For a virtual machine with 64 GB of RAM or less:

Kernel Setting	Value
vm.dirty_background_ratio	3
vm.dirty_ratio	10

4. For a virtual machine with more than 64 GB of RAM:

Kernel Setting	Value
----------------	-------

vm.dirty_background_ratio	0
vm.dirty_ratio	0
vm.dirty_background_bytes	1610612736
vm.dirty_bytes	4294967296

- Verify that `ssh` command allows passwordless login as `gpadmin` user without prompting for a password:

```
$ su - gpadmin
$ ssh localhost
$ exit
$ exit
```

- Verify the readahead value:

```
$ /sbin/blockdev --getra /dev/sdb
16384
```

- Verify the RX Jumbo buffer ring setting:

```
$ /sbin/ethtool -g ens192 | grep Jumbo
RX Jumbo: 4096
RX Jumbo: 4096
```

- Verify the MTU size:

```
$ /sbin/ip a | grep 9000
2: ens192: <BROADCAST,MULTICAST,UP,LOWER_UP> mtu 9000 qdisc mq state UP group d
efault qlen 1000
```

- Power off the VM.

Allocating the Virtual Machines with Terraform

Provisioning the Virtual Machines

Use the Terraform software you installed in [Creating the Jumpbox Virtual Machine](#) to generate copies of the template virtual machine you just created, you will configure them based on the number of virtual machines in your environment, IP address ranges, and other settings you specify in the installation script.

- Create a file named `main.tf` and copy the contents described in the [OVA Script topic](#).
- Log in to the jumpbox virtual machine as `root`.
- Update the following variables under the **Terraform variables** section of the `main.tf` script with the correct values for your environment. You collected the required information in the [Prerequisites](#) section.

Variable	Description
<code>vsphere_user</code>	Name of the VMware vSphere administrator level user.
<code>vsphere_password</code>	Password of the VMware vSphere administrator level user.
<code>vsphere_server</code>	The IP address or, preferably, the Fully-Qualified Domain Name (FQDN) of your vCenter server.

Variable	Description
vsphere_datacenter	The name of the data center for Greenplum in your vCenter environment.
vsphere_compute_cluster	The name of the compute cluster for Greenplum in your data center.
vsphere_datastore	The name of the vSAN datastore which will contain your Greenplum data.
vsphere_storage_policy	The name of the storage policy defined during Setting Up VMware vSphere Storage or Setting Up VMware vSphere Encryption .
gp_virtual_external_ipv4_addresses	The routable IP addresses for mdw and smdw, in that order; for example: ["10.0.0.111", "10.0.0.112"].
gp_virtual_external_ipv4_netmask	The number of bits in the netmask for <code>gp-virtual-external</code> ; for example: 24.
gp_virtual_external_gateway	The gateway IP address for the <code>gp-virtual-external</code> network.
dns_servers	The DNS servers for the <code>gp-virtual-external</code> network, listed as an array; for example: ["8.8.8.8", "8.8.4.4"].
gp_virtual_etl_bar_ipv4_cidr	The leading octets for the ETL, backup and restore network, non-routable network <code>gp-virtual-etl-bar</code> ; for example: '192.168.2.0/24' .

4. Initialize Terraform:

```
$ terraform init
```

You should get the following output:

```
Terraform has been successfully initialized!

You may now begin working with Terraform. Try running "terraform plan" to see
any changes that are required for your infrastructure. All Terraform commands
should now work.

If you ever set or change modules or backend configuration for Terraform,
re-run this command to reinitialize your working directory. If you forget, other
commands will detect it and remind you to do so if necessary.
```

5. Verify that your Terraform configuration is correct by running the following command:

```
$ terraform plan
```

6. Deploy the cluster:

```
$ terraform apply
```

Answer Yes to the following prompt:

```
Do you want to perform these actions?
Terraform will perform the actions described above.
Only 'yes' will be accepted to approve.

Enter a value: yes
```

The virtual machines will be created and configured to deploy your Greenplum cluster. You can

check the progress under the Recent Tasks panel on your VMware vSphere client.

Once Terraform has completed, it generates a file named `terraform.tfstate`. This file **must not be deleted**, as it keeps a record of all the virtual machines and their states. Terraform also uses this file when modifying any virtual machines. We also recommend to retain a snapshot of the jumpbox virtual machine.

Terraform timeout

Occasionally, Terraform may time out when deploying the virtual machines. If a virtual machine cannot be cloned within the timeout value, by default 30 minutes, Terraform will fail and the cluster setup will be incomplete. Terraform will report the following error:

```
error cloning virtual machine: timeout waiting for clone to complete
```

You must review the root cause of the issue which resides within the vCenter environment, check host and storage performance in order to find out why a virtual machine is taking over 30 minutes to be cloned. There are two ways of working around this issue by editing Terraform settings:

1. Reduce the parallelism of Terraform from 10 to 5 and redeploy the cluster by running the following command:

```
terraform apply --parallelism 5
```

2. Increase the Terraform timeout property, set in minutes. See more about this property in the [Terraform documentation](#).

Modify the `main.tf` script in two places, one for the `segment_hosts` and another one for the `master_hosts`, add the property `timeout` under the `clone` section:

```
...
resource "vsphere_virtual_machine" "segment_hosts" {
...

  clone {
...
    timeout = 40
...
  }
}

resource "vsphere_virtual_machine" "master_hosts" {
...
  clone {
...
    timeout = 40
...
  }
}
```

After saving the changes, rerun `terraform apply` to redeploy the cluster.

Validating the Deployment

Once Terraform has provisioned the virtual machines, perform the following validation steps:

1. Validate the Resource Pool for the Greenplum cluster.
 1. Log in to vCenter and navigate to **Hosts and Clusters**.
 2. Select the newly created resource pool and verify that the **Resource Settings** are as below:

The screenshot shows the VMware vSphere interface for a resource pool named 'greenplum-1'. The 'Summary' tab is selected, displaying a circular progress indicator and the following statistics:

This pool / Total	
VMs and Templates:	66 / 66
Powered on VMs:	66 / 66
Child Resource Pools:	0 / 0
Child vApps:	0 / 0

Below the statistics, the 'Resource Settings' section is expanded, showing the following configuration:

Resource Settings	
Scalable Shares	Not scaled (and, descendants' shares not scaled)
CPU	
Shares	Normal (4000)
Reservation	Expandable
Limit	Unlimited
Worst Case Allocation	65,956 MHz
Memory	
Shares	Normal (163840)
Reservation	Expandable
Limit	Unlimited
Worst Case Allocation	65,956 MB

Note that the **Worst Case Allocation** fields will differ depending on what is currently running in your environment.

3. Click the expanding arrow next to the resource pool name, you should see all the newly created virtual machines: `gp-1-mdw`, `gp-1-smdw`, `gp-1-sdw1`, etc.
2. Validate that the `gp-virtual-internal` network is working.
 1. Log in to the master node as `root`.
 2. Switch to `gpadmin` user.

```
$ su - gpadmin
```

3. Make sure that the file `/home/gpadmin/hosts-all` exists.
4. Use the `gpssh` command to verify connectivity to all nodes in the `gp-virtual-internal` network.

```
$ gpssh -f hosts-all -e hostname
```

3. Validate the MTU settings on all virtual machines.
 1. Log in to the master node as `root`.
 2. Use the `gpssh` command to verify the value of the MTU.

```
$ source /usr/local/greenplum-db/greenplum_path.sh
$ gpssh -f /home/gpadmin/hosts-all -e "ifconfig ens192 | grep -i mtu"
```

4. Clean Up the Temporary VMware vSphere Admin Account

If you created a temporary VMware vSphere administrator level user such as `greenplum`, it is safe to remove it now.

Deploying Greenplum

You are now ready to deploy Greenplum Database on the newly deployed cluster. Perform the steps below from the Greenplum master node.

Deploying a Greenplum Database Cluster

1. Initialize the Greenplum cluster.

1. Log in to the Greenplum master node as `gpadmin` user.
2. Create the Greenplum configuration script `create_gpinitssystem_config.sh` and paste the following contents:

```
#!/bin/bash
# setup the gpinitssystem config
primaryArray() {
    numOfSegments=$1
    array=""
    newline=$'\n'
    for i in $(seq 1 ${numOfSegments}); do
        array+="sdw$((i*2-1))~sdw$((i*2-1))~6000~/gpdata/primary/gpseg$((i-1))~$((i*2))~$((i-1))$newline"
    done
    echo "${array}"
}

mirrorArray() {
    numOfSegments=$1
    array=""
    newline=$'\n'
    for i in $(seq 1 ${numOfSegments}); do
        array+="sdw$((i*2))~sdw$((i*2))~7000~/gpdata/mirror/gpseg$((i-1))~$((i*2+1))~$((i-1))$newline"
    done
    echo "${array}"
}

create_gpinitssystem_config() {
    echo "Generate gpinitssystem"
    cat <<EOF> ./gpinitssystem_config
    ARRAY_NAME="Greenplum Data Platform"
    TRUSTED_SHELL=ssh
    CHECK_POINT_SEGMENTS=8
    ENCODING=UNICODE
    SEG_PREFIX=gpseg
    HEAP_CHECKSUM=on
    HBA_HOSTNAMES=0
    QD_PRIMARY_ARRAY=mdw~mdw~5432~/gpdata/master/gpseg-1~1~1
    numTotalSegments=$1
    declare -a PRIMARY_ARRAY=(
    $( primaryArray $(( ${numTotalSegments}/2 )) )
    )
    declare -a MIRROR_ARRAY=(
    $( mirrorArray $(( ${numTotalSegments}/2 )) )
    )
    EOF
}

numTotalSegments=$1
if [ -z "$numTotalSegments" ]; then
    echo "Usage: bash create_gpinitssystem_config.sh <num_total_segments>"
else
    create_gpinitssystem_config $numTotalSegments
fi
```

3. Run the script to generate the configuration file for `gpinitssystem`. Replace `64` with the number of segments in your environment:

```
$ bash create_gpinitssystem_config.sh 64
```

You should now see a file called `gpinitssystem_config`.

4. Run the following command to initialize the Greenplum Database:

```
$ gpinitssystem -a -I gpinitssystem_config -s smdw
```

2. Configure the Greenplum master and standby master environment variables, and load the master variables:

```
$ echo export MASTER_DATA_DIRECTORY=/gpdata/master/gpseg-1 >> ~/.bashrc
$ ssh smdw 'echo export MASTER_DATA_DIRECTORY=/gpdata/master/gpseg-1 >> ~/.bashrc'
$ source ~/.bashrc
```

3. Configure the Greenplum cluster with the commands below. Note that some of the parameter values will vary, depending on your virtual machine RAM size.

```
### Interconnect Settings
$ gpconfig -c gp_interconnect_queue_depth -v 16
$ gpconfig -c gp_interconnect_snd_queue_depth -v 16

# Since you have one segment per VM and less competing workloads per VM,
# you can set the memory limit for resource group higher than the default
$ gpconfig -c gp_resource_group_memory_limit -v 0.85

# This value should be 5% of the total RAM on the VM
$ gpconfig -c statement_mem -v 1536MB

# This value should be set to 25% of the total RAM on the VM
$ gpconfig -c max_statement_mem -v 7680MB

# This value should be set to 85% of the total RAM on the VM
$ gpconfig -c gp_vmem_protect_limit -v 26112

# Since you have less I/O bandwidth, you can turn this parameter on
$ gpconfig -c gp_workfile_compression -v on
```

4. Restart the Greenplum cluster for the newly configured settings to take effect:

```
$ gpstop -r
```

Next Steps

Now that the Greenplum Database has been deployed, follow the steps provided in [Validating the Greenplum Installation](#) to ensure Greenplum Database has been installed correctly.

Validating the Greenplum Installation

Run the commands below from the master node as `gpadmin` user in order to validate basic functionality of the Greenplum cluster.

1. Refresh the environment variables:

```
$ source ~/.bashrc
```

2. Show the state of the Greenplum cluster:

```
$ gpstate
```

3. Connect to the `postgres` database and check segment configuration information:

```
$ psql postgres
postgres=# SELECT * FROM gp_segment_configuration ORDER BY hostname;
```

4. Once connected to the `postgres` database, verify that you can create a table, insert data to it and read it:

```
postgres=# CREATE TABLE t AS SELECT generate_series(1, 1000000);
postgres=# SELECT MIN(cnt), MAX(cnt), COUNT(cnt) FROM (SELECT COUNT(*) cnt FROM
t GROUP BY gp_segment_id) tt;
postgres=# DROP TABLE t;
```

Managing Single Host Failures in VMware vSphere

This section describes the possible scenarios of a single ESXi host failure and how VMware vSphere's DRS and HA features ensure automatic failover of virtual machines to other running ESXi hosts.

How DRS and HA protect a running Greenplum cluster

In a VMware Tanzu Greenplum on vSphere deployment there is a one-to-one mapping between the Greenplum segments and the virtual machines that are hosting the segments. This means that each virtual machine is only hosting one instance of a Greenplum segment: primary or mirror.

Given the virtual machine host name, you can determine which segment is running in it, as well as what virtual machines are in a primary/mirror pair for a given content id.

For a 66 virtual machine deployment, 64 of them are segments named `sdw1` to `sdw64`. There is also the master, `mdw`, and a standby master `smdw`.

Use the formula below to compute the content id for each segment. It uses the host name index from the virtual machines: for example, for `sdw1` the index is 1.

```
content_id = floor((hostname_index - 1) / 2)
```

By applying the formula above, the virtual machines `sdw1` and `sdw2` map to content ID 0, while `sdw3` and `sdw4` map to content ID 1, and so on.

The index number lets you determine whether a virtual machine hosts the primary or the mirror for that content: an odd index is created as a primary, and an even index is created as a mirror. Note that the roles may change when a failover happens (see [Best Practices](#) for more details).

During deployment, Terraform created DRS Anti-Affinity rules to ensure that two virtual machines with the same content id never run on the same ESXi host.

When an ESXi host hosting a primary virtual machines fails, Greenplum always fails over to its corresponding mirror that is safely running on another host.

In the section [Setting Up VMware vSphere HA and DRS](#), you enabled VMware vSphere HA with the following options:

- Host Failure Response/Failure Resource: **Restart VMs**
- Admission Control/Host failures cluster tolerates: **1**

As a result, VMware vSphere HA is configured to tolerate the failure of a single host. This configuration signals the VMware vSphere cluster to reserve the necessary resources, such as CPU and memory, in order to accommodate all the virtual machines that were running on the failed host.

For example, for a VMware vSphere cluster with 4 hosts, 25% of resources are reserved.

Single Host Failure Scenarios

When an ESXi host goes down, VMware vSphere HA will restart the virtual machines that were running on it on other ESXi hosts. There are 4 different scenarios:

- [Mirror Segment Failure](#)
- [Primary Segment Failure](#)
- [Standby Master Failure](#)
- [Master Failure](#)

Note that since multiple virtual machines run on the same ESXi host, you will encounter more than one of these scenarios during a single host outage. However, you will never experience standby master and master failure for the same host.

Mirror Segment Failure

In this scenario, you will not notice when a mirror segment goes down. It is still possible to perform database operations such as query a table, load data into a table, or create more tables. The detection of a mirror going down can take up to 2 minutes (see [Grace Period](#) for details).

However, Greenplum high availability is affected because the mirror cannot replicate the work of the primary.

You can query the `gp_segment_configuration` table and obtain similar information:

```
gpadmin=# SELECT * FROM gp_segment_configuration WHERE status = 'd' AND role = 'm';
 dbid | content | role | preferred_role | mode | status | port | hostname | address |
 datadir
-----+-----+-----+-----+-----+-----+-----+-----+-----+-----+
 3 | 0 | m | m | n | d | 7000 | sdw2 | sdw2 |
 /gpdata/primary/gpseg0
```

The failed mirror virtual machine will be automatically restarted on another host by VMware vSphere HA. You may run `gprecoverseg` from the Greenplum master and the mirror segment will be brought back up.

Primary Segment Failure

In this scenario, when a primary segment goes down, all queries running on that segment will be cancelled. You will observe the following error message when trying to run a query:

```
gpadmin=# SELECT COUNT(DISTINCT c) FROM t t1;
ERROR:  FTS detected connection lost during dispatch to seg0 slice1 192.168.11.1:6000
pid=3259:
```

The Greenplum Fault Tolerance Server (FTS) process will detect the primary segment failing and the failover to its mirror will commence. You will see the role switch on `gp_segment_configuration` table:

```
gpadmin=# SELECT * FROM gp_segment_configuration WHERE content = 0;
 dbid | content | role | preferred_role | mode | status | port | hostname | address |
 datadir
-----+-----+-----+-----+-----+-----+-----+-----+-----+-----+
 2 | 0 | m | p | n | d | 6000 | sdw1 | sdw1 |
 /gpdata
```

```

3 |      0 | p | m | n | u | 7000 | sdw2 | sdw2 |
/gpdata
(2 rows)

```

The original primary segment will be marked as a mirror and its status will be marked as down.

The original mirror segment will be promoted to be the new primary and, when retrying the failed query above, it will finish successfully:

```

gpadmin=# SELECT count(DISTINCT c) FROM t t1;
count
-----
101
(1 row)

```

The failed primary virtual machine will be automatically restarted by VMware vSphere HA on another host. You may now log in to the Greenplum master virtual machine and run `gprecoverseg`, similar to the step above, to bring back the downed mirror.

Standby Master Failure

When the standby master goes down, the only feature affected by this failure is the reduced availability of the master. Once the standby master has been recovered, it will catch up with the catalog changes on the master.

Before the standby master failure, the `gp_segment_configuration` table would show the following:

```

gpadmin=# SELECT * FROM gp_segment_configuration WHERE content = -1;
dbid | content | role | preferred_role | mode | status | port | hostname | address |
-----+-----+-----+-----+-----+-----+-----+-----+-----+
1 | -1 | p | p | n | u | 5432 | mdw | mdw |
/gpdata
66 | -1 | m | m | s | u | 5432 | smdw | smdw |
/gpdata
(2 rows)

```

The above table does not reflect state of the standby master. You must query the `pg_stat_replication` table in order to check the status of the standby master. If the replication process `gp_walreceiver` is running, it means that the standby master is up.

```

gpadmin=# SELECT username, application_name, client_addr FROM pg_stat_replication;
username | application_name | client_addr
-----+-----+-----
gpadmin | gp_walreceiver | 192.168.11.251
(1 row)

```

When the standby master is down, the output of `gpstate` will return output similar to the following:

```

[gpadmin@mdw ~]$ gpstate
<Date-Time> gpstate:mdw:gpadmin-[INFO]:-Greenplum instance status summary
<Date-Time> gpstate:mdw:gpadmin-[INFO]:-----
-----
<Date-Time> gpstate:mdw:gpadmin-[INFO]:- Master instance
= Active
<Date-Time> gpstate:mdw:gpadmin-[INFO]:- Master standby
= smdw
<Date-Time> gpstate:mdw:gpadmin-[WARNING]:-Standby master state
= Standby host DOWN <<<<<<<
<Date-Time> gpstate:mdw:gpadmin-[INFO]:- Total segment instance count from metadata

```

```

= 64
<Date-Time> gpstate:mdw:gpadmin-[INFO]:-----
-----

```

If the standby master virtual machine goes down, VMware vSphere HA will automatically restart it on another host.

You must run `gpinitstandby -n` from the Greenplum master to bring the standby master back up.

```

[gpadmin@mdw ~]$ gpinitstandby -n
<Date-Time> gpinitstandby:mdw:gpadmin-[INFO]:-Starting standby master
<Date-Time> gpinitstandby:mdw:gpadmin-[INFO]:-Checking if standby master is running o
n host: smdw in directory: /gpdata
<Date-Time> gpinitstandby:mdw:gpadmin-[INFO]:-Successfully started standby master

```

You may verify that the standby master is up and running by running `gpstate`:

```

[gpadmin@mdw ~]$ gpstate
<Date-Time> gpstate:mdw:gpadmin-[INFO]:-Greenplum instance status summary
<Date-Time> gpstate:mdw:gpadmin-[INFO]:-----
-----
<Date-Time> gpstate:mdw:gpadmin-[INFO]:- Master instance
= Active
<Date-Time> gpstate:mdw:gpadmin-[INFO]:- Master standby
= smdw
<Date-Time> gpstate:mdw:gpadmin-[INFO]:- Standby master state
= Standby host passive
<Date-Time> gpstate:mdw:gpadmin-[INFO]:- Total segment instance count from metadata
= 64
<Date-Time> gpstate:mdw:gpadmin-[INFO]:-----
-----

```

Master Failure

If the Greenplum master goes down, you will lose connection to the entire Greenplum cluster. This is a highly disruptive experience because all client connections will be dropped.

VMware vSphere HA will automatically restart the failed master virtual machine on another host.

Once the virtual machine has been restarted, you must run `gpstart` to restart the cluster.

Note that this scenario assumes that Greenplum master virtual machine comes back up without issues when starting it on a different host. In the event of Greenplum master corruption, see [Recovering a Failed Master](#) in order to activate the standby master.

After Host Recovery

When a failed ESXi host comes back up, because the failed virtual machines have already been restarted on other running hosts by VMware vSphere HA, VMware vSphere DRS will rearrange the virtual machines, not necessarily the ones that went down, to balance the load of all the ESXi hosts. This operation is done through VMware vSphere vMotion, which is transparent to the running virtual machines.

There is no need for an explicit rebalancing operation because the virtual machines are all identical by design, primaries and mirrors. Service disruption occurs only once during host failure, and only in the case of a primary or master failure.

Best Practices for Greenplum HA

In most cases, running `gprecoverseg` will recover the failed segments with no issues when the

affected virtual machine is restarted by VMware vSphere HA on a different ESXi host. VMware recommends you monitor the status of the cluster in order to run `gprecoverseg` when required. Refer to [Monitoring tasks](#) from the Greenplum Administrator Guide. Alternatively, you may use [Greenplum Command Center](#) to set up alerts.

After a segment recovery, segment instances may not be returned to the preferred role that they were given at system initialization time. This will have no effect on the performance for a Greenplum on VMware vSphere configuration.

However, you may want to maintain consistency between the virtual machine host names and their preferred role (odd numbers for primaries, even numbers for mirrors) for monitoring purposes. Consider running `gprecoverseg -r` periodically to rebalance segment roles after segment failures. Note that queries in progress will be canceled and rolled back, so you may want to schedule this operation during a maintenance window.

Appendix: Grace Period for a Downed Segment

There are two Greenplum configuration parameters that control the detection of a downed mirror:

- `gp_fts_mark_mirror_down_grace_period` controls the waiting time between primary and its mirror. The default value is 30 seconds.
- `gp_fts_probe_interval` controls the FTS probe interval from the master to the primaries. The default value is 60 seconds.

Combining the values of both parameters, it will take up to two minutes to detect a mirror segment going down.

Note: If both the primary and mirror virtual machines with the same content id are restarted during that period, Greenplum database will hit a double fault, during which it is no longer able to process queries. In this case, the only way to bring the cluster back online is to restart the entire Greenplum cluster using `gpstop -r`.

Planning Downtime for Maintenance

Once the Greenplum cluster is up and running, the ESXi hosts will need maintenance from time to time. VMware vSphere features a maintenance mode supported by the ESXi hosts for such planned downtime.

In order to ensure that the Greenplum cluster service is not interrupted during the planned maintenance time, and that the maintenance window can fit into your SLA requirements, there are some settings you must specify when putting a host into maintenance mode:

- The Data Evacuation mode, or vSAN Data Migration mode, must be set to **Ensure accessibility**. This is the default mode and it ensures that all accessible virtual machines running on the host that is going down for maintenance remain accessible.
- The checkbox **Move powered-off and suspended virtual machines to other hosts in the cluster** must be enabled, so any powered-off virtual machines can still be available during the maintenance window if needed.

Bringing the ESXi Host Down

1. In the VMware vSphere Client home page, navigate to **Home > Hosts and Clusters** and select your host.
2. Right-click the host and select **Maintenance Mode > Enter Maintenance Mode**.
3. By default, the check box **Move powered-off and suspended virtual machines to other**

hosts will be enabled. Make sure it stays enabled.

- Click the drop down menu next to **vSAN Data Migration** and select **Ensure Accessibility**.

Enter Maintenance Mode

This host is in a vSAN cluster. Once the host is in maintenance mode, it cannot access the vSAN datastore and the state of any virtual machines on the datastore. No virtual machines can be provisioned on this host while in maintenance mode. You must either power off or migrate the virtual machines from the host manually.

☒ Move powered-off and suspended virtual machines to other hosts in the cluster

vSAN data migration

Ensure accessibility 

 VMware recommends to run a data migration pre-check before entering maintenance mode. Pre-check determines if the operation will be successful, and reports the state of the cluster once the host enters maintenance mode.

Put the selected hosts in maintenance mode?

[GO TO PRE-CHECK](#)

[CANCEL](#)

[OK](#)

- In the confirmation dialog box, click **OK**.

The above steps ensure that the entire maintenance process is transparent to the Greenplum workloads.

Bringing the ESXi Host Back Up

In order to bring the host back from maintenance mode, simply right click on the host, select **Maintenance Mode**, then **Exit maintenance mode**.

Performance Impact of Host Maintenance

The impact will depend on the overall load on the VMware vSphere cluster. Assuming that you have followed the High Availability guidelines, and N being the number of ESXi hosts:

- There will be a bandwidth reduction of $1/N$ for the Greenplum internal networks `gp-virtual-internal`, and `gp-virtual-etl-bar`.
- The vSAN storage capacity will be reduced by $1/N$, however this will not impact Greenplum storage capacity, as the virtual machines disks are thick provisioned.
- Since VMware vSphere HA reserved $1/N$ of the compute resources, the cluster will not be affected by compute resource degradation. For example, for a 4 node cluster with 96 vcores on each host, each host reserves 24 vcores and uses 72 vcores. When a single ESXi host goes down, the 72 reserved vcores will replace the capacity of the downed host.
- Since you configured your environment with Failures To Tolerate (FTT) set to 1, if you bring one host down on maintenance mode, the FTT will be 0, so if another host goes down this will result in service interruption.

Installing and Upgrading Greenplum

Information about installing, configuring, and upgrading Greenplum Database software and configuring Greenplum Database host machines.

- **Platform Requirements**
This topic describes the Greenplum Database 6 platform and operating system software requirements.
- **Estimating Storage Capacity**
To estimate how much data your Greenplum Database system can accommodate, use these measurements as guidelines. Also keep in mind that you may want to have extra space for landing backup files and data load files on each segment host.
- **Configuring Your Systems**
Describes how to prepare your operating system environment for Greenplum Database software installation.
- **Installing the Greenplum Database Software**
Describes how to install the Greenplum Database software binaries on all of the hosts that will comprise your Greenplum Database system, how to enable passwordless SSH for the `gpadmin` user, and how to verify the installation.
- **Creating the Data Storage Areas**
Describes how to create the directory locations where Greenplum Database data is stored for each master, standby, and segment instance.
- **Validating Your Systems**
Validate your hardware and network performance.
- **Initializing a Greenplum Database System**
Describes how to initialize a Greenplum Database database system.
- **Installing Optional Extensions (Tanzu Greenplum)**
Information about installing optional Tanzu Greenplum Database extensions and packages, such as the Procedural Language extensions and the Python and R Data Science Packages.
- **Installing Additional Supplied Modules**
The Greenplum Database distribution includes several PostgreSQL- and Greenplum-sourced `contrib` modules that you have the option to install.
- **Configuring Timezone and Localization Settings**
Describes the available timezone and localization features of Greenplum Database.
- **Upgrading to Greenplum 6**
This topic identifies the upgrade paths for upgrading a Greenplum Database 6.x release to a newer 6.x release. The topic also describes the migration paths for migrating Tanzu Greenplum Database 4.x or 5.x data to Greenplum Database 6.x.
- **Enabling iptables (Optional)**
On Linux systems, you can configure and enable the `iptables` firewall to work with Greenplum Database.
- **Installation Management Utilities**

References for the command-line management utilities used to install and initialize a Greenplum Database system.

- **Greenplum Environment Variables**
Reference of the environment variables to set for Greenplum Database.
- **Example Ansible Playbook**
A sample Ansible playbook to install a Greenplum Database software release onto the hosts that will comprise a Greenplum Database system.

Estimating Storage Capacity

To estimate how much data your Greenplum Database system can accommodate, use these measurements as guidelines. Also keep in mind that you may want to have extra space for landing backup files and data load files on each segment host.

- **Calculating Usable Disk Capacity**
- **Calculating User Data Size**
- **Calculating Space Requirements for Metadata and Logs**

Parent topic: [Installing and Upgrading Greenplum](#)

Calculating Usable Disk Capacity

To calculate how much data a Greenplum Database system can hold, you have to calculate the usable disk capacity per segment host and then multiply that by the number of segment hosts in your Greenplum Database array. Start with the raw capacity of the physical disks on a segment host that are available for data storage (raw_capacity), which is:

```
disk_size * number_of_disks
```

Account for file system formatting overhead (roughly 10 percent) and the RAID level you are using. For example, if using RAID-10, the calculation would be:

```
(raw_capacity * 0.9) / 2 = formatted_disk_space
```

For optimal performance, do not completely fill your disks to capacity, but run at 70% or lower. So with this in mind, calculate the usable disk space as follows:

```
formatted_disk_space * 0.7 = usable_disk_space
```

Using only 70% of your disk space allows Greenplum Database to use the other 30% for temporary and transaction files on the same disks. If your host systems have a separate disk system that can be used for temporary and transaction files, you can specify a tablespace that Greenplum Database uses for the files. Moving the location of the files might improve performance depending on the performance of the disk system.

Once you have formatted RAID disk arrays and accounted for the maximum recommended capacity (usable_disk_space), you will need to calculate how much storage is actually available for user data (U). If using Greenplum Database mirrors for data redundancy, this would then double the size of your user data ($2 * U$). Greenplum Database also requires some space be reserved as a working area for active queries. The work space should be approximately one third the size of your user data (work space = $U/3$):

```
With mirrors: (2 * U) + U/3 = usable_disk_space
```

```
Without mirrors: U + U/3 = usable_disk_space
```

Guidelines for temporary file space and user data space assume a typical analytic workload. Highly concurrent workloads or workloads with queries that require very large amounts of temporary space can benefit from reserving a larger working area. Typically, overall system throughput can be increased while decreasing work area usage through proper workload management. Additionally, temporary space and user space can be isolated from each other by specifying that they reside on different tablespaces.

In the *Greenplum Database Administrator Guide*, see these topics:

- [Managing Performance](#) for information about workload management
- [Creating and Managing Tablespaces](#) for information about moving the location of temporary and transaction files
- [Monitoring System State](#) for information about monitoring Greenplum Database disk space usage

Parent topic: [Estimating Storage Capacity](#)

Calculating User Data Size

As with all databases, the size of your raw data will be slightly larger once it is loaded into the database. On average, raw data will be about 1.4 times larger on disk after it is loaded into the database, but could be smaller or larger depending on the data types you are using, table storage type, in-database compression, and so on.

- **Page Overhead** - When your data is loaded into Greenplum Database, it is divided into pages of 32KB each. Each page has 20 bytes of page overhead.
- **Row Overhead** - In a regular 'heap' storage table, each row of data has 24 bytes of row overhead. An 'append-optimized' storage table has only 4 bytes of row overhead.
- **Attribute Overhead** - For the data values itself, the size associated with each attribute value is dependent upon the data type chosen. As a general rule, you want to use the smallest data type possible to store your data (assuming you know the possible values a column will have).
- **Indexes** - In Greenplum Database, indexes are distributed across the segment hosts as is table data. The default index type in Greenplum Database is B-tree. Because index size depends on the number of unique values in the index and the data to be inserted, precalculating the exact size of an index is impossible. However, you can roughly estimate the size of an index using these formulas.

```
B-tree: unique_values * (data_type_size + 24 bytes)
```

```
Bitmap: (unique_values * number_of_rows * 1 bit * compression_ratio / 8) + (unique_values * 32)
```

Parent topic: [Estimating Storage Capacity](#)

Calculating Space Requirements for Metadata and Logs

On each segment host, you will also want to account for space for Greenplum Database log files and metadata:

- **System Metadata** — For each Greenplum Database segment instance (primary or mirror) or master instance running on a host, estimate approximately 20 MB for the system catalogs and metadata.

- **Write Ahead Log** — For each Greenplum Database segment (primary or mirror) or master instance running on a host, allocate space for the write ahead log (WAL). The WAL is divided into segment files of 64 MB each. At most, the number of WAL files will be:

```
2 * checkpoint_segments + 1
```

You can use this to estimate space requirements for WAL. The default `checkpoint_segments` setting for a Greenplum Database instance is 8, meaning 1088 MB WAL space allocated for each segment or master instance on a host.

- **Greenplum Database Log Files** — Each segment instance and the master instance generates database log files, which will grow over time. Sufficient space should be allocated for these log files, and some type of log rotation facility should be used to ensure that log files do not grow too large.
- **Command Center Data** — The data collection agents utilized by Command Center run on the same set of hosts as your Greenplum Database instance and utilize the system resources of those hosts. The resource consumption of the data collection agent processes on these hosts is minimal and should not significantly impact database performance. Historical data collected by the collection agents is stored in its own Command Center database within your Greenplum Database system. Collected data is distributed just like regular database data, so you will need to account for disk space in the data directory locations of your Greenplum segment instances. The amount of space required depends on the amount of historical data you would like to keep. Historical data is not automatically truncated. Database administrators must set up a truncation policy to maintain the size of the Command Center database.

Parent topic: [Estimating Storage Capacity](#)

Configuring Your Systems

Describes how to prepare your operating system environment for Greenplum Database software installation.

Perform the following tasks in order:

1. Make sure your host systems meet the requirements described in [Platform Requirements](#).
2. [Disable or configure SELinux](#).
3. [Disable or configure firewall software](#).
4. [Set the required operating system parameters](#).
5. [Synchronize system clocks](#).
6. [Create the gpadmin account](#).

Unless noted, these tasks should be performed for *all* hosts in your Greenplum Database array (master, standby master, and segment hosts).

The Greenplum Database host naming convention for the master host is `mdw` and for the standby master host is `smdw`.

The segment host naming convention is `sdwN` where `sdw` is a prefix and `N` is an integer. For example, segment host names would be `sdw1`, `sdw2` and so on. NIC bonding is recommended for hosts with multiple interfaces, but when the interfaces are not bonded, the convention is to append a dash (-) and number to the host name. For example, `sdw1-1` and `sdw1-2` are the two interface names for host `sdw1`.

For information about running Tanzu Greenplum Database in the cloud see *Cloud Services* in the [Tanzu Greenplum Partner Marketplace](#).

Important: When data loss is not acceptable for a Greenplum Database cluster, Greenplum master and segment mirroring is recommended. If mirroring is not enabled then Greenplum stores only one copy of the data, so the underlying storage media provides the only guarantee for data availability and correctness in the event of a hardware failure.

The VMware Tanzu Greenplum on vSphere virtualized environment ensures the enforcement of anti-affinity rules required for Greenplum mirroring solutions and fully supports mirrorless deployments. Other virtualized or containerized deployment environments are generally not supported for production use unless both Greenplum master and segment mirroring are enabled.

Note: For information about upgrading Tanzu Greenplum from a previous version, see the *Tanzu Greenplum Database Release Notes* for the release that you are installing.

Note: Automating the configuration steps described in this topic and [Installing the Greenplum Database Software](#) with a system provisioning tool, such as Ansible, Chef, or Puppet, can save time and ensure a reliable and repeatable Greenplum Database installation.

Parent topic: [Installing and Upgrading Greenplum](#)

Disable or Configure SELinux

For all Greenplum Database host systems running RHEL or CentOS, SELinux must either be **Disabled** or configured to allow unconfined access to Greenplum processes, directories, and the gpadmin user.

If you choose to disable SELinux:

1. As the root user, check the status of SELinux:

```
# sestatus
SELinuxstatus: disabled
```

2. If SELinux is not disabled, disable it by editing the `/etc/selinux/config` file. As root, change the value of the `SELINUX` parameter in the `config` file as follows:

```
SELINUX=disabled
```

3. If the System Security Services Daemon (SSSD) is installed on your systems, edit the SSSD configuration file and set the `selinux_provider` parameter to `none` to prevent SELinux-related SSH authentication denials that could occur even with SELinux disabled. As root, edit `/etc/sss/sss.conf` and add this parameter:

```
selinux_provider=none
```

4. Reboot the system to apply any changes that you made and verify that SELinux is disabled.

If you choose to enable SELinux in **Enforcing** mode, then Greenplum processes and users can operate successfully in the default **Unconfined** context. If you require increased SELinux confinement for Greenplum processes and users, you must test your configuration to ensure that there are no functionality or performance impacts to Greenplum Database. See the [SELinux User's and Administrator's Guide](#) for detailed information about configuring SELinux and SELinux users.

Disable or Configure Firewall Software

You should also disable firewall software such as `iptables` (on systems such as RHEL 6.x and CentOS 6.x), `firewalld` (on systems such as RHEL 7.x and CentOS 7.x), or `ufw` (on Ubuntu systems, disabled by default). If firewall software is not disabled, you must instead configure your software to

allow required communication between Greenplum hosts.

To disable `iptables`:

1. As the root user, check the status of `iptables`:

```
# /sbin/chkconfig --list iptables
```

If `iptables` is disabled, the command output is:

```
iptables 0:off 1:off 2:off 3:off 4:off 5:off 6:off
```

2. If necessary, run this command as root to disable `iptables`:

```
/sbin/chkconfig iptables off
```

You will need to reboot your system after applying the change.

3. For systems with `firewalld`, check the status of `firewalld` with the command:

```
# systemctl status firewalld
```

If `firewalld` is disabled, the command output is:

```
* firewalld.service - firewalld - dynamic firewall daemon
   Loaded: loaded (/usr/lib/systemd/system/firewalld.service; disabled; vendor
   preset: enabled)
   Active: inactive (dead)
```

4. If necessary, run these commands as root to disable `firewalld`:

```
# systemctl stop firewalld.service
# systemctl disable firewalld.service
```

If you decide to enable `iptables` with Greenplum Database for security purposes, see [Enabling iptables \(Optional\)](#) for important considerations and example configurations.

See the documentation for the firewall or your operating system for additional information.

Recommended OS Parameters Settings

Greenplum requires that certain Linux operating system (OS) parameters be set on all hosts in your Greenplum Database system (masters and segments).

In general, the following categories of system parameters need to be altered:

- **Shared Memory** - A Greenplum Database instance will not work unless the shared memory segment for your kernel is properly sized. Most default OS installations have the shared memory values set too low for Greenplum Database. On Linux systems, you must also disable the OOM (out of memory) killer. For information about Greenplum Database shared memory requirements, see the Greenplum Database server configuration parameter `shared_buffers` in the *Greenplum Database Reference Guide*.
- **Network** - On high-volume Greenplum Database systems, certain network-related tuning parameters must be set to optimize network connections made by the Greenplum interconnect.
- **User Limits** - User limits control the resources available to processes started by a user's shell. Greenplum Database requires a higher limit on the allowed number of file descriptors that a single process can have open. The default settings may cause some Greenplum

Database queries to fail because they will run out of file descriptors needed to process the query.

More specifically, you need to edit the following Linux configuration settings:

- [The hosts File](#)
- [The sysctl.conf File](#)
- [System Resources Limits](#)
- [Core Dump](#)
- [XFS Mount Options](#)
- [Disk I/O Settings](#)
 - ◊ [Read ahead values](#)
 - ◊ [Disk I/O scheduler disk access](#)
- [Networking](#)
- [Transparent Huge Pages \(THP\)](#)
- [IPC Object Removal](#)
- [SSH Connection Threshold](#)

The hosts File

Edit the `/etc/hosts` file and make sure that it includes the host names and all interface address names for every machine participating in your Greenplum Database system.

The sysctl.conf File

The `sysctl.conf` parameters listed in this topic are for performance, optimization, and consistency in a wide variety of environments. Change these settings according to your specific situation and setup.

Set the parameters in the `/etc/sysctl.conf` file and reload with `sysctl -p`:

```
# kernel.shmall = _PHYS_PAGES / 2 # See Shared Memory Pages
kernel.shmall = 197951838
# kernel.shmmax = kernel.shmall * PAGE_SIZE
kernel.shmmax = 810810728448
kernel.shmmni = 4096
vm.overcommit_memory = 2 # See Segment Host Memory
vm.overcommit_ratio = 95 # See Segment Host Memory

net.ipv4.ip_local_port_range = 10000 65535 # See Port Settings
kernel.sem = 250 2048000 200 8192
kernel.sysrq = 1
kernel.core_uses_pid = 1
kernel.msgmnb = 65536
kernel.msgmax = 65536
kernel.msgmni = 2048
net.ipv4.tcp_syncookies = 1
net.ipv4.conf.default.accept_source_route = 0
net.ipv4.tcp_max_syn_backlog = 4096
net.ipv4.conf.all.arp_filter = 1
net.core.netdev_max_backlog = 10000
net.core.rmem_max = 2097152
net.core.wmem_max = 2097152
vm.swappiness = 10
vm.zone_reclaim_mode = 0
vm.dirty_expire_centisecs = 500
```

```
vm.dirty_writeback_centisecs = 100
vm.dirty_background_ratio = 0 # See System Memory
vm.dirty_ratio = 0
vm.dirty_background_bytes = 1610612736
vm.dirty_bytes = 4294967296
```

Shared Memory Pages

Greenplum Database uses shared memory to communicate between `postgres` processes that are part of the same `postgres` instance. `kernel.shmall` sets the total amount of shared memory, in pages, that can be used system wide. `kernel.shmmax` sets the maximum size of a single shared memory segment in bytes.

Set `kernel.shmall` and `kernel.shmmax` values based on your system's physical memory and page size. In general, the value for both parameters should be one half of the system physical memory.

Use the operating system variables `_PHYS_PAGES` and `PAGE_SIZE` to set the parameters.

```
kernel.shmall = ( _PHYS_PAGES / 2 )
kernel.shmmax = ( _PHYS_PAGES / 2 ) * PAGE_SIZE
```

To calculate the values for `kernel.shmall` and `kernel.shmmax`, run the following commands using the `getconf` command, which returns the value of an operating system variable.

```
$ echo $(expr $(getconf _PHYS_PAGES) / 2)
$ echo $(expr $(getconf _PHYS_PAGES) / 2 \* $(getconf PAGE_SIZE))
```

As best practice, we recommend you set the following values in the `/etc/sysctl.conf` file using calculated values. For example, a host system has 1583 GB of memory installed and returns these values: `_PHYS_PAGES = 395903676` and `PAGE_SIZE = 4096`. These would be the `kernel.shmall` and `kernel.shmmax` values:

```
kernel.shmall = 197951838
kernel.shmmax = 810810728448
```

If the Greenplum Database master has a different shared memory configuration than the segment hosts, the `_PHYS_PAGES` and `PAGE_SIZE` values might differ, and the `kernel.shmall` and `kernel.shmmax` values on the master host will differ from those on the segment hosts.

Segment Host Memory

The `vm.overcommit_memory` Linux kernel parameter is used by the OS to determine how much memory can be allocated to processes. For Greenplum Database, this parameter should always be set to 2.

`vm.overcommit_ratio` is the percent of RAM that is used for application processes and the remainder is reserved for the operating system. The default is 50 on Red Hat Enterprise Linux.

For `vm.overcommit_ratio` tuning and calculation recommendations with resource group-based resource management or resource queue-based resource management, refer to [Options for Configuring Segment Host Memory](#) in the *Greenplum Database Administrator Guide*.

Port Settings

To avoid port conflicts between Greenplum Database and other applications during Greenplum initialization, make a note of the port range specified by the operating system parameter `net.ipv4.ip_local_port_range`. When initializing Greenplum using the `gpinitssystem` cluster configuration file, do not specify Greenplum Database ports in that range. For example, if `net.ipv4.ip_local_port_range = 10000 65535`, set the Greenplum Database base port numbers to these values.

```
PORT_BASE = 6000
MIRROR_PORT_BASE = 7000
```

For information about the `gpinitssystem` cluster configuration file, see [Initializing a Greenplum Database System](#).

For Azure deployments with Greenplum Database avoid using port 65330; add the following line to `sysctl.conf`:

```
net.ipv4.ip_local_reserved_ports=65330
```

For additional requirements and recommendations for cloud deployments, see [Greenplum Database Cloud Technical Recommendations](#).

System Memory

For host systems with more than 64GB of memory, these settings are recommended:

```
vm.dirty_background_ratio = 0
vm.dirty_ratio = 0
vm.dirty_background_bytes = 1610612736 # 1.5GB
vm.dirty_bytes = 4294967296 # 4GB
```

For host systems with 64GB of memory or less, remove `vm.dirty_background_bytes` and `vm.dirty_bytes` and set the two `ratio` parameters to these values:

```
vm.dirty_background_ratio = 3
vm.dirty_ratio = 10
```

Increase `vm.min_free_kbytes` to ensure `PF_MEMALLOC` requests from network and storage drivers are easily satisfied. This is especially critical on systems with large amounts of system memory. The default value is often far too low on these systems. Use this `awk` command to set `vm.min_free_kbytes` to a recommended 3% of system physical memory:

```
awk 'BEGIN {OFMT = "%.0f";} /MemTotal/ {print "vm.min_free_kbytes =", $2 * .03;}'
/proc/meminfo >> /etc/sysctl.conf
```

Do not set `vm.min_free_kbytes` to higher than 5% of system memory as doing so might cause out of memory conditions.

System Resources Limits

Set the following parameters in the `/etc/security/limits.conf` file:

```
* soft nfile 524288
* hard nfile 524288
* soft nproc 131072
* hard nproc 131072
```

For Red Hat Enterprise Linux (RHEL) and CentOS systems, parameter values in the `/etc/security/limits.d/90-nproc.conf` file (RHEL/CentOS 6) or `/etc/security/limits.d/20-nproc.conf` file (RHEL/CentOS 7) override the values in the `limits.conf` file. Ensure that any parameters in the override file are set to the required value. The Linux module `pam_limits` sets user limits by reading the values from the `limits.conf` file and then from the override file. For information about PAM and user limits, see the documentation on PAM and `pam_limits`.

Run the `ulimit -u` command on each segment host to display the maximum number of processes that are available to each user. Validate that the return value is 131072.

Core Dump

Enable core file generation to a known location by adding the following line to `/etc/sysctl.conf`:

```
kernel.core_pattern=/var/core/core.%h.%t
```

Add the following line to `/etc/security/limits.conf`:

```
* soft core unlimited
```

To apply the changes to the live kernel, run the following command:

```
# sysctl -p
```

XFS Mount Options

XFS is the preferred data storage file system on Linux platforms. Use the `mount` command with the following recommended XFS mount options for RHEL 7 and CentOS systems:

```
rw,nodev,noatime,nobarrier,inode64
```

The `nobarrier` option is not supported on RHEL 8 or Ubuntu systems. Use only the options:

```
rw,nodev,noatime,inode64
```

See the `mount` manual page (`man mount` opens the man page) for more information about using this command.

The XFS options can also be set in the `/etc/fstab` file. This example entry from an `fstab` file specifies the XFS options.

```
/dev/data /data xfs nodev,noatime,inode64 0 0
```

Note: You must have root permission to edit the `/etc/fstab` file.

Disk I/O Settings

- Read-ahead value

Each disk device file should have a read-ahead (`blockdev`) value of 16384. To verify the read-ahead value of a disk device:

```
# sudo /sbin/blockdev --getra <devname>
```

For example:

```
# sudo /sbin/blockdev --getra /dev/sdb
```

To set `blockdev` (read-ahead) on a device:

```
# sudo /sbin/blockdev --setra <bytes> <devname>
```

For example:

```
# sudo /sbin/blockdev --setra 16384 /dev/sdb
```

See the manual page (man) for the `blockdev` command for more information about using that command (`man blockdev` opens the man page).

Note: The `blockdev --setra` command is not persistent. You must ensure the read-ahead value is set whenever the system restarts. How to set the value will vary based on your system.

One method to set the `blockdev` value at system startup is by adding the `/sbin/blockdev --setra` command in the `rc.local` file. For example, add this line to the `rc.local` file to set the read-ahead value for the disk `sdb`.

```
/sbin/blockdev --setra 16384 /dev/sdb
```

On systems that use `systemd`, you must also set the execute permissions on the `rc.local` file to enable it to run at startup. For example, on a RHEL/CentOS 7 system, this command sets execute permissions on the file.

```
# chmod +x /etc/rc.d/rc.local
```

Restart the system to have the setting take effect.

- Disk I/O scheduler

The Linux disk scheduler orders the I/O requests submitted to a storage device, controlling the way the kernel commits reads and writes to disk.

A typical Linux disk I/O scheduler supports multiple access policies. The optimal policy selection depends on the underlying storage infrastructure. The recommended scheduler policy settings for Greenplum Database systems for specific OSs and storage device types follow:

Storage Device Type	OS	Recommended Scheduler Policy
Non-Volatile Memory Express (NVMe)	RHEL 7	<code>none</code>
	RHEL 8	
	Ubuntu	
Solid-State Drives (SSD)	RHEL 7	<code>noop</code>
	RHEL 8	<code>none</code>
	Ubuntu	
Other	RHEL 7	<code>deadline</code>
	RHEL 8	<code>mq-deadline</code>
	Ubuntu	

To specify a scheduler until the next system reboot, run the following:

```
# echo schedulername > /sys/block/<devname>/queue/scheduler
```

For example:

```
# echo deadline > /sys/block/sdb/queue/scheduler
```

Note: Using the `echo` command to set the disk I/O scheduler policy is not persistent; you must ensure that you run the command whenever the system reboots. How to run the command will vary based on your system.

To specify the I/O scheduler at boot time on systems that use `grub2` such as RHEL 7.x or CentOS 7.x, use the system utility `grubby`. This command adds the parameter when run as

root:

```
# grubby --update-kernel=ALL --args="elevator=deadline"
```

After adding the parameter, reboot the system.

This `grubby` command displays kernel parameter settings:

```
# grubby --info=ALL
```

Refer to your operating system documentation for more information about the `grubby` utility. If you used the `grubby` command to configure the disk scheduler on a RHEL or CentOS 7.x system and it does not update the kernels, see the [Note](#) at the end of the section.

For additional information about configuring the disk scheduler, refer to the RedHat Enterprise Linux documentation for [RHEL 7](#) or [RHEL 8](#). The Ubuntu wiki [IOSchedulers](#) topic describes the I/O schedulers available on Ubuntu systems.

Networking

The maximum transmission unit (MTU) of a network specifies the size (in bytes) of the largest data packet/frame accepted by a network-connected device. A jumbo frame is a frame that contains more than the standard MTU of 1500 bytes.

Greenplum Database utilizes 3 distinct MTU settings:

- The Greenplum Database `gp_max_packet_size` server configuration parameter. The default max packet size is 8192. This default assumes a jumbo frame MTU.
- The operating system MTU setting.
- The rack switch MTU setting.

These settings are connected, in that they should always be either the same, or close to the same, value, or otherwise in the order of Greenplum < OS < switch for MTU size.

9000 is a common supported setting for switches, and is the recommended OS and rack switch MTU setting for your Greenplum Database hosts.

Transparent Huge Pages (THP)

Disable Transparent Huge Pages (THP) as it degrades Greenplum Database performance. RHEL 6.0 or higher enables THP by default. One way to disable THP on RHEL 6.x is by adding the parameter `transparent_hugepage=never` to the kernel command in the file `/boot/grub/grub.conf`, the GRUB boot loader configuration file. This is an example kernel command from a `grub.conf` file. The command is on multiple lines for readability:

```
kernel /vmlinuz-2.6.18-274.3.1.el5 ro root=LABEL=/
        elevator=deadline crashkernel=128M@16M quiet console=tty1
        console=ttyS1,115200 panic=30 transparent_hugepage=never
        initrd /initrd-2.6.18-274.3.1.el5.img
```

On systems that use `grub2` such as RHEL 7.x or CentOS 7.x, use the system utility `grubby`. This command adds the parameter when run as root.

```
# grubby --update-kernel=ALL --args="transparent_hugepage=never"
```

After adding the parameter, reboot the system.

For Ubuntu systems, install the `hugepages` package and run this command as root:

```
# hugeadm --thp-never
```

This cat command checks the state of THP. The output indicates that THP is disabled.

```
$ cat /sys/kernel/mm/*transparent_hugepage/enabled
always [never]
```

For more information about Transparent Huge Pages or the `grubby` utility, see your operating system documentation. If the `grubby` command does not update the kernels, see the [Note](#) at the end of the section.

IPC Object Removal

Disable IPC object removal for RHEL 7.2 or CentOS 7.2, or Ubuntu. The default `systemd` setting `RemoveIPC=yes` removes IPC connections when non-system user accounts log out. This causes the Greenplum Database utility `gpinitssystem` to fail with semaphore errors. Perform one of the following to avoid this issue.

- When you add the `gpadmin` operating system user account to the master node in [Creating the Greenplum Administrative User](#), create the user as a system account.
- Disable `RemoveIPC`. Set this parameter in `/etc/systemd/logind.conf` on the Greenplum Database host systems.

```
RemoveIPC=no
```

The setting takes effect after restarting the `systemd-login` service or rebooting the system. To restart the service, run this command as the root user.

```
service systemd-logind restart
```

SSH Connection Threshold

Certain Greenplum Database management utilities including `gpexpand`, `gpinitssystem`, and `gpaddmirrors`, use secure shell (SSH) connections between systems to perform their tasks. In large Greenplum Database deployments, cloud deployments, or deployments with a large number of segments per host, these utilities may exceed the host's maximum threshold for unauthenticated connections. When this occurs, you receive errors such as: `ssh_exchange_identification: Connection closed by remote host`.

To increase this connection threshold for your Greenplum Database system, update the SSH `MaxStartups` and `MaxSessions` configuration parameters in one of the `/etc/ssh/sshd_config` or `/etc/ssh_config` SSH daemon configuration files.

Note: You must have root permission to edit these two files.

If you specify `MaxStartups` and `MaxSessions` using a single integer value, you identify the maximum number of concurrent unauthenticated connections (`MaxStartups`) and maximum number of open shell, login, or subsystem sessions permitted per network connection (`MaxSessions`). For example:

```
MaxStartups 200
MaxSessions 200
```

If you specify `MaxStartups` using the “start:rate:full” syntax, you enable random early connection drop by the SSH daemon. `start` identifies the maximum number of unauthenticated SSH connection attempts allowed. Once start number of unauthenticated connection attempts is reached, the SSH daemon refuses rate percent of subsequent connection attempts. `full` identifies the maximum

number of unauthenticated connection attempts after which all attempts are refused. For example:

```
Max Startups 10:30:200
MaxSessions 200
```

Restart the SSH daemon after you update `MaxStartups` and `MaxSessions`. For example, on a CentOS 6 system, run the following command as the `root` user:

```
# service sshd restart
```

For detailed information about SSH configuration options, refer to the SSH documentation for your Linux distribution.

Note: If the `grubby` command does not update the kernels of a RHEL 7.x or CentOS 7.x system, you can manually update all kernels on the system. For example, to add the parameter `transparent_hugepage=never` to all kernels on a system.

1. Add the parameter to the `GRUB_CMDLINE_LINUX` line in the file parameter in `/etc/default/grub`.

```
GRUB_TIMEOUT=5
GRUB_DISTRIBUTOR="$(sed 's, release .*$,g' /etc/system-release)"
GRUB_DEFAULT=saved
GRUB_DISABLE_SUBMENU=true
GRUB_TERMINAL_OUTPUT="console"
GRUB_CMDLINE_LINUX="crashkernel=auto rd.lvm.lv=cl/root rd.lvm.lv=cl/swap rhgb q
uiet transparent_hugepage=never"
GRUB_DISABLE_RECOVERY="true"
```

Note: You must have root permission to edit the `/etc/default/grub` file.

2. As root, run the `grub2-mkconfig` command to update the kernels.

```
# grub2-mkconfig -o /boot/grub2/grub.cfg
```

3. Reboot the system.

Synchronizing System Clocks

You should use NTP (Network Time Protocol) to synchronize the system clocks on all hosts that comprise your Greenplum Database system. See www.ntp.org for more information about NTP.

NTP on the segment hosts should be configured to use the master host as the primary time source, and the standby master as the secondary time source. On the master and standby master hosts, configure NTP to point to your preferred time server.

To configure NTP

1. On the master host, log in as root and edit the `/etc/ntp.conf` file. Set the `server` parameter to point to your data center's NTP time server. For example (if `10.6.220.20` was the IP address of your data center's NTP server):

```
server 10.6.220.20
```

2. On each segment host, log in as root and edit the `/etc/ntp.conf` file. Set the first `server` parameter to point to the master host, and the second `server` parameter to point to the standby master host. For example:

```
server mdw prefer
server smdw
```

3. On the standby master host, log in as root and edit the `/etc/ntp.conf` file. Set the first `server` parameter to point to the primary master host, and the second server parameter to point to your data center's NTP time server. For example:

```
server mdw prefer
server 10.6.220.20
```

4. On the master host, use the NTP daemon synchronize the system clocks on all Greenplum hosts. For example, using `gpssh`:

```
# gpssh -f hostfile_gpssh_allhosts -v -e 'ntpd'
```

Creating the Greenplum Administrative User

Create a dedicated operating system user account on each node to run and administer Greenplum Database. This user account is named `gpadmin` by convention.

Important: You cannot run the Greenplum Database server as `root`.

The `gpadmin` user must have permission to access the services and directories required to install and run Greenplum Database.

The `gpadmin` user on each Greenplum host must have an SSH key pair installed and be able to SSH from any host in the cluster to any other host in the cluster without entering a password or passphrase (called “passwordless SSH”). If you enable passwordless SSH from the master host to every other host in the cluster (“1-*n* passwordless SSH”), you can use the Greenplum Database `gpssh-exkeys` command-line utility later to enable passwordless SSH from every host to every other host (“*n-n* passwordless SSH”).

You can optionally give the `gpadmin` user sudo privilege, so that you can easily administer all hosts in the Greenplum Database cluster as `gpadmin` using the `sudo`, `ssh/scp`, and `gpssh/gpscp` commands.

The following steps show how to set up the `gpadmin` user on a host, set a password, create an SSH key pair, and (optionally) enable sudo capability. These steps must be performed as root on every Greenplum Database cluster host. (For a large Greenplum Database cluster you will want to automate these steps using your system provisioning tools.)

Note: See [Example Ansible Playbook](#) for an example that shows how to automate the tasks of creating the `gpadmin` user and installing the Greenplum Database software on all hosts in the cluster.

1. Create the `gpadmin` group and user.

Note: If you are installing Greenplum Database on RHEL 7.2 or CentOS 7.2 and want to disable IPC object removal by creating the `gpadmin` user as a system account, provide both the `-r` option (create the user as a system account) and the `-m` option (create a home directory) to the `useradd` command. On Ubuntu systems, you must use the `-m` option with the `useradd` command to create a home directory for a user.

This example creates the `gpadmin` group, creates the `gpadmin` user as a system account with a home directory and as a member of the `gpadmin` group, and creates a password for the user.

```
# groupadd gpadmin
# useradd gpadmin -r -m -g gpadmin
# passwd gpadmin
```

```
New password: <changeme>
Retype new password: <changeme>
```

Note: You must have root permission to create the `gpadmin` group and user.

Note: Make sure the `gpadmin` user has the same user id (uid) and group id (gid) numbers on each host to prevent problems with scripts or services that use them for identity or permissions. For example, backing up Greenplum databases to some networked filesystems or storage appliances could fail if the `gpadmin` user has different uid or gid numbers on different segment hosts. When you create the `gpadmin` group and user, you can use the `groupadd -g` option to specify a gid number and the `useradd -u` option to specify the uid number. Use the command `id gpadmin` to see the uid and gid for the `gpadmin` user on the current host.

2. Switch to the `gpadmin` user and generate an SSH key pair for the `gpadmin` user.

```
$ su gpadmin
$ ssh-keygen -t rsa -b 4096
Generating public/private rsa key pair.
Enter file in which to save the key (/home/gpadmin/.ssh/id_rsa):
Created directory '/home/gpadmin/.ssh'.
Enter passphrase (empty for no passphrase):
Enter same passphrase again:
```

At the passphrase prompts, press Enter so that SSH connections will not require entry of a passphrase.

3. Grant sudo access to the `gpadmin` user.

On Red Hat or CentOS, run `visudo` and uncomment the `%wheel` group entry.

```
%wheel          ALL=(ALL)          NOPASSWD: ALL
```

Make sure you uncomment the line that has the `NOPASSWD` keyword.

Add the `gpadmin` user to the `wheel` group with this command.

```
# usermod -aG wheel gpadmin
```

Installing the Greenplum Database Software

Describes how to install the Greenplum Database software binaries on all of the hosts that will comprise your Greenplum Database system, how to enable passwordless SSH for the `gpadmin` user, and how to verify the installation.

Perform the following tasks in order:

1. [Install Greenplum Database:](#)
 - [Download the Greenplum Database Server Software](#) (VMware Tanzu Greenplum)
 - [Verify the Greenplum Database Software](#) (VMware Tanzu Greenplum)

- ◊ [Install the Greenplum Database Software](#)
 - ◊ [\(Optional\) Install to a Non-Default Directory](#)
2. [Enabling Passwordless SSH](#)
 3. [Confirm the software installation.](#)
 4. [Next Steps](#)

Parent topic: [Installing and Upgrading Greenplum](#)

Installing Greenplum Database

You must install Greenplum Database on each host machine of the Greenplum Database system.

VMware distributes the Greenplum Database software as a downloadable package that you install on each host system with the operating system's package management system.

Open source Greenplum Database releases are available as: source code tarballs, RPM installers for CentOS, and DEB packages for Debian and Ubuntu. See <https://greenplum.org/download/> for links to source code and instructions to compile Greenplum Database from source, and for links to download pre-built binaries in RPM and DEB format. For the Ubuntu operating system, Greenplum also offers a binary that can be installed via the `apt-get` command with the Ubuntu Personal Package Archive system.

Downloading the Greenplum Database Server Software (VMware Tanzu Greenplum)

You can download the *Greenplum Database Server* software package from [VMware Tanzu Network](#).

Be sure to note the name and the file system location of the downloaded file.

Verifying the Greenplum Database Software (VMware Tanzu Greenplum)

VMware generates a SHA256 fingerprint for each Greenplum Database software download available from Tanzu Network. This fingerprint enables you to verify that your downloaded file is unaltered from the original.

Follow the instructions in [Verifying the VMware Tanzu Greenplum Software Download](#) to verify the integrity of the *Greenplum Database Server* software.

Installing the Greenplum Database Software

Before you begin installing Greenplum Database, be sure you have completed the steps in [Configuring Your Systems](#) to configure each of the master, standby master, and segment host machines for Greenplum Database.

Important: After installing Greenplum Database, you must set Greenplum Database environment variables. See [Setting Greenplum Environment Variables](#).

See [Example Ansible Playbook](#) for an example script that shows how you can automate creating the `gpadmin` user and installing the Greenplum Database.

Follow these instructions to install Greenplum Database from a pre-built binary.

Important: You require sudo or root user access to install from a pre-built RPM or DEB file.

1. Download and copy the Greenplum Database package to the `gpadmin` user's home directory on the master, standby master, and every segment host machine. The distribution file name has the format `greenplum-db-<version>-<platform>.rpm` for RHEL, CentOS, and

Oracle Linux systems, or `greenplum-db-<version>-<platform>.deb` for Ubuntu systems, where `<platform>` is similar to `rhel7-x86_64` (Red Hat 7 64-bit).

Note: For Oracle Linux installations, download and install the `rhel7-x86_64` distribution files.

2. With `sudo` (or as root), install the Greenplum Database package on each host machine using your system's package manager software.

- For RHEL/CentOS systems, run the `yum` command:

```
$ sudo yum install ./greenplum-db-<version>-<platform>.rpm
```

- For Ubuntu systems, run the `apt` command:

```
$ sudo apt install ./greenplum-db-<version>-<platform>.deb
```

The `yum` or `apt` command automatically installs software dependencies, copies the Greenplum Database software files into a version-specific directory under `/usr/local`, `/usr/local/greenplum-db-<version>`, and creates the symbolic link `/usr/local/greenplum-db` to the installation directory.

3. Change the owner and group of the installed files to `gpadmin`:

```
$ sudo chown -R gpadmin:gpadmin /usr/local/greenplum*
$ sudo chgrp -R gpadmin /usr/local/greenplum*
```

(Optional) Installing to a Non-Default Directory

On RHEL/CentOS systems, you can use the `rpm` command with the `--prefix` option to install Greenplum Database to a non-default directory (instead of under `/usr/local`). Note, however, that using `rpm` does not automatically install Greenplum Database dependencies; you must manually install dependencies to each host system.

Follow these instructions to install Greenplum Database to a specific directory.

Important: You require `sudo` or root user access to install from a pre-built RPM file.

1. Download and copy the Greenplum Database package to the `gpadmin` user's home directory on the master, standby master, and every segment host machine. The distribution file name has the format `greenplum-db-<version>-<platform>.rpm` for RHEL and CentOS systems, or `greenplum-db-<version>-<platform>.deb` for Ubuntu systems, where `<platform>` is similar to `rhel7-x86_64` (Red Hat 7 64-bit).
2. Manually install the Greenplum Database dependencies to each host system:

```
$ sudo yum install apr apr-util bash bzip2 curl krb5 libcurl libevent \
libxml2 libyaml zlib openldap openssl openssl-libs perl readline rsync
R sed tar zip
```

3. Use `rpm` with the `--prefix` option to install the Greenplum Database package to your chosen installation directory on each host machine:

```
$ sudo rpm --install ./greenplum-db-<version>-<platform>.rpm --prefix=<directory>
```

The `rpm` command copies the Greenplum Database software files into a version-specific directory under your chosen `<directory>`, `<directory>/greenplum-db-<version>`, and creates the symbolic link `<directory>/greenplum-db` to the versioned directory.

4. Change the owner and group of the installed files to `gpadmin`:

```
$ sudo chown -R gpadmin:gpadmin <directory>/greenplum*
```

Note: All example procedures in the Greenplum Database documentation assume that you installed to the default directory, which is `/usr/local`. If you install to a non-default directory, substitute that directory for `/usr/local`.

If you install to a non-default directory using `rpm`, you will need to continue using `rpm` (and of `yum`) to perform minor version upgrades; these changes are covered in the upgrade documentation.

Enabling Passwordless SSH

The `gpadmin` user on each Greenplum host must be able to SSH from any host in the cluster to any other host in the cluster without entering a password or passphrase (called “passwordless SSH”). If you enable passwordless SSH from the master host to every other host in the cluster (“1-*n* passwordless SSH”), you can use the Greenplum Database `gpssh-exkeys` command-line utility to enable passwordless SSH from every host to every other host (“*n-n* passwordless SSH”).

1. Log in to the master host as the `gpadmin` user.
2. Source the `path` file in the Greenplum Database installation directory.

```
$ source /usr/local/greenplum-db-<version>/greenplum_path.sh
```

Note: Add the above `source` command to the `gpadmin` user’s `.bashrc` or other shell startup file so that the Greenplum Database path and environment variables are set whenever you log in as `gpadmin`.

3. Use the `ssh-copy-id` command to add the `gpadmin` user’s public key to the `authorized_hosts` SSH file on every other host in the cluster.

```
$ ssh-copy-id smdw
$ ssh-copy-id sdw1
$ ssh-copy-id sdw2
$ ssh-copy-id sdw3
. . .
```

This enables 1-*n* passwordless SSH. You will be prompted to enter the `gpadmin` user’s password for each host. If you have the `sshpass` command on your system, you can use a command like the following to avoid the prompt.

```
$ SSHPASS=<password> sshpass -e ssh-copy-id smdw
```

4. In the `gpadmin` home directory, create a file named `hostfile_exkeys` that has the machine configured host names and host addresses (interface names) for each host in your Greenplum system (master, standby master, and segment hosts). Make sure there are no blank lines or extra spaces. Check the `/etc/hosts` file on your systems for the correct host names to use for your environment. For example, if you have a master, standby master, and three segment hosts with two unbonded network interfaces per host, your file would look something like this:

```
mdw
mdw-1
mdw-2
smdw
smdw-1
```

```
smdw-2
sdw1
sdw1-1
sdw1-2
sdw2
sdw2-1
sdw2-2
sdw3
sdw3-1
sdw3-2
```

5. Run the `gpssh-exkeys` utility with your `hostfile_exkeys` file to enable *n-n* passwordless SSH for the `gpadmin` user.

```
$ gpssh-exkeys -f hostfile_exkeys
```

Confirming Your Installation

To make sure the Greenplum software was installed and configured correctly, run the following confirmation steps from your Greenplum master host. If necessary, correct any problems before continuing on to the next task.

1. Log in to the master host as `gpadmin`:

```
$ su - gpadmin
```

2. Use the `gpssh` utility to see if you can log in to all hosts without a password prompt, and to confirm that the Greenplum software was installed on all hosts. Use the `hostfile_exkeys` file you used to set up passwordless SSH. For example:

```
$ gpssh -f hostfile_exkeys -e 'ls -l /usr/local/greenplum-db-<version>'
```

If the installation was successful, you should be able to log in to all hosts without a password prompt. All hosts should show that they have the same contents in their installation directories, and that the directories are owned by the `gpadmin` user.

If you are prompted for a password, run the following command to redo the ssh key exchange:

```
$ gpssh-exkeys -f hostfile_exkeys
```

About Your Greenplum Database Installation

- `greenplum_path.sh` — This file contains the environment variables for Greenplum Database. See [Setting Greenplum Environment Variables](#).
- `bin` — This directory contains the Greenplum Database management utilities. This directory also contains the PostgreSQL client and server programs, most of which are also used in Greenplum Database.
- `docs/cli_help` — This directory contains help files for Greenplum Database command-line utilities.
- `docs/cli_help/gpconfigs` — This directory contains sample `gpinitssystem` configuration files and host files that can be modified and used when installing and initializing a Greenplum Database system.
- `ext` — Bundled programs (such as Python) used by some Greenplum Database utilities.

- **include** — The C header files for Greenplum Database.
- **lib** — Greenplum Database and PostgreSQL library files.
- **sbin** — Supporting/Internal scripts and programs.
- **share** — Shared files for Greenplum Database.

- [Validating Your Systems](#)
- [Initializing a Greenplum Database System](#)

Verifying the VMware Tanzu Greenplum Software Download

Describes how to verify Greenplum Database software that you download from VMware Tanzu Network.

VMware generates a SHA256 fingerprint for each Greenplum Database software download available from [VMware Tanzu Network](#). This fingerprint enables you to verify that your downloaded file is unaltered from the original.

After you download a Greenplum Database server or component software package, you can verify the integrity of the software as follows:

1. On VMware Tanzu Network, navigate to the Greenplum Database version and package that you downloaded.
2. On the VMware Tanzu Greenplum *Release Download Files* page, click the **i** icon to the right of the Greenplum Database software package that you downloaded.

This action displays a dialog that contains information about the package file, including the **File** name and the **SHA256** fingerprint.

3. Copy/paste the **SHA256** to a local file, or keep the Tanzu Network browser tab open.
4. On your local host, open a terminal window, navigate to the download directory, and locate the Greenplum package file that you downloaded from Tanzu Network.
5. Compare the downloaded file name with the **File** name specified in the Tanzu Network package information, and verify that they are the same.
6. Identify an OS utility that you can use to locally calculate a file checksum. On CentOS, this utility command is named `sha256sum`.
7. Run the utility to display the checksum of the package file that you downloaded from Tanzu Network. For example, if you downloaded the **Greenplum Database Server** package on CentOS:

```
$ sha256sum greenplum-db-6.18.0-rhel17-x86_64.rpm
```

8. If the command checksum output matches the **SHA256** fingerprint specified in the Tanzu Network package information, the file was downloaded intact. You can safely proceed to install the software.

Creating the Data Storage Areas

Describes how to create the directory locations where Greenplum Database data is stored for each master, standby, and segment instance.

Parent topic: [Installing and Upgrading Greenplum](#)

Creating Data Storage Areas on the Master and Standby Master Hosts

A data storage area is required on the Greenplum Database master and standby master hosts to store Greenplum Database system data such as catalog data and other system metadata.

To create the data directory location on the master

The data directory location on the master is different than those on the segments. The master does not store any user data, only the system catalog tables and system metadata are stored on the master instance, therefore you do not need to designate as much storage space as on the segments.

1. Create or choose a directory that will serve as your master data storage area. This directory should have sufficient disk space for your data and be owned by the `gpadmin` user and group. For example, run the following commands as `root`:

```
# mkdir -p /data/master
```

2. Change ownership of this directory to the `gpadmin` user. For example:

```
# chown gpadmin:gpadmin /data/master
```

3. Using `gpssh`, create the master data directory location on your standby master as well. For example:

```
# source /usr/local/greenplum-db/greenplum_path.sh
# gpssh -h smdw -e 'mkdir -p /data/master'
# gpssh -h smdw -e 'chown gpadmin:gpadmin /data/master'
```

Creating Data Storage Areas on Segment Hosts

Data storage areas are required on the Greenplum Database segment hosts for primary segments. Separate storage areas are required for mirror segments.

To create the data directory locations on all segment hosts

1. On the master host, log in as `root`:

```
# su
```

2. Create a file called `hostfile_gpssh_segonly`. This file should have only one machine configured host name for each segment host. For example, if you have three segment hosts:

```
sdw1
sdw2
sdw3
```

3. Using `gpssh`, create the primary and mirror data directory locations on all segment hosts at once using the `hostfile_gpssh_segonly` file you just created. For example:

```
# source /usr/local/greenplum-db/greenplum_path.sh
# gpssh -f hostfile_gpssh_segonly -e 'mkdir -p /data/primary'
# gpssh -f hostfile_gpssh_segonly -e 'mkdir -p /data/mirror'
# gpssh -f hostfile_gpssh_segonly -e 'chown -R gpadmin /data/*'
```

Next Steps

- [Validating Your Systems](#)
- [Initializing a Greenplum Database System](#)

Validating Your Systems

Validate your hardware and network performance.

Greenplum provides a management utility called `gpcheckperf`, which can be used to identify hardware and system-level issues on the machines in your Greenplum Database array. `gpcheckperf` starts a session on the specified hosts and runs the following performance tests:

- Network Performance (`gpnetbench*`)
- Disk I/O Performance (`dd` test)
- Memory Bandwidth (`stream` test)

Before using `gpcheckperf`, you must have a trusted host setup between the hosts involved in the performance test. You can use the utility `gpssh-exkeys` to update the known host files and exchange public keys between hosts if you have not done so already. Note that `gpcheckperf` calls to `gpssh` and `gpscp`, so these Greenplum utilities must be in your `$PATH`.

- [Validating Network Performance](#)
- [Validating Disk I/O and Memory Bandwidth](#)

Parent topic: [Installing and Upgrading Greenplum](#)

Validating Network Performance

To test network performance, run `gpcheckperf` with one of the network test run options: parallel pair test (`-r N`), serial pair test (`-r n`), or full matrix test (`-r M`). The utility runs a network benchmark program that transfers a 5 second stream of data from the current host to each remote host included in the test. By default, the data is transferred in parallel to each remote host and the minimum, maximum, average and median network transfer rates are reported in megabytes (MB) per second. If the summary transfer rate is slower than expected (less than 100 MB/s), you can run the network test serially using the `-r n` option to obtain per-host results. To run a full-matrix bandwidth test, you can specify `-r M` which will cause every host to send and receive data from every other host specified. This test is best used to validate if the switch fabric can tolerate a full-matrix workload.

Most systems in a Greenplum Database array are configured with multiple network interface cards (NICs), each NIC on its own subnet. When testing network performance, it is important to test each subnet individually. For example, considering the following network configuration of two NICs per host:

Greenplum Host	Subnet1 NICs	Subnet2 NICs
Segment 1	sdw1-1	sdw1-2
Segment 2	sdw2-1	sdw2-2
Segment 3	sdw3-1	sdw3-2

You would create four distinct host files for use with the `gpcheckperf` network test:

hostfile_gpchecknet_ic1	hostfile_gpchecknet_ic2
-------------------------	-------------------------

sdw1-1	sdw1-2
sdw2-1	sdw2-2
sdw3-1	sdw3-2

You would then run [gpcheckperf](#) once per subnet. For example (if testing an *even* number of hosts, run in parallel pairs test mode):

```
$ gpcheckperf -f hostfile_gpchecknet_ic1 -r N -d /tmp > subnet1.out
$ gpcheckperf -f hostfile_gpchecknet_ic2 -r N -d /tmp > subnet2.out
```

If you have an *odd* number of hosts to test, you can run in serial test mode (`-r n`).

Parent topic: [Validating Your Systems](#)

Validating Disk I/O and Memory Bandwidth

To test disk and memory bandwidth performance, run [gpcheckperf](#) with the disk and stream test run options (`-r ds`). The disk test uses the `dd` command (a standard UNIX utility) to test the sequential throughput performance of a logical disk or file system. The memory test uses the STREAM benchmark program to measure sustainable memory bandwidth. Results are reported in MB per second (MB/s).

To run the disk and stream tests

1. Log in on the master host as the `gpadmin` user.
2. Source the `greenplum_path.sh` path file from your Greenplum installation. For example:

```
$ source /usr/local/greenplum-db/greenplum_path.sh
```

3. Create a host file named `hostfile_gpcheckperf` that has one host name per segment host. Do not include the master host. For example:

```
sdw1
sdw2
sdw3
sdw4
```

4. Run the `gpcheckperf` utility using the `hostfile_gpcheckperf` file you just created. Use the `-d` option to specify the file systems you want to test on each host (you must have write access to these directories). You will want to test all primary and mirror segment data directory locations. For example:

```
$ gpcheckperf -f hostfile_gpcheckperf -r ds -D \
-d /data1/primary -d /data2/primary \
-d /data1/mirror -d /data2/mirror
```

5. The utility may take a while to perform the tests as it is copying very large files between the hosts. When it is finished you will see the summary results for the Disk Write, Disk Read, and Stream tests.

Parent topic: [Validating Your Systems](#)

Initializing a Greenplum Database System

Describes how to initialize a Greenplum Database database system.

The instructions in this chapter assume you have already prepared your hosts as described in [Configuring Your Systems](#) and installed the Greenplum Database software on all of the hosts in the system according to the instructions in [Installing the Greenplum Database Software](#).

This chapter contains the following topics:

- [Overview](#)
- [Initializing Greenplum Database](#)
- [Setting Greenplum Environment Variables](#)
- [Next Steps](#)

Parent topic: [Installing and Upgrading Greenplum](#)

Overview

Because Greenplum Database is distributed, the process for initializing a Greenplum Database management system (DBMS) involves initializing several individual PostgreSQL database instances (called *segment instances* in Greenplum).

Each database instance (the master and all segments) must be initialized across all of the hosts in the system in such a way that they can all work together as a unified DBMS. Greenplum provides its own version of `initdb` called `gpinitssystem`, which takes care of initializing the database on the master and on each segment instance, and starting each instance in the correct order.

After the Greenplum Database database system has been initialized and started, you can then create and manage databases as you would in a regular PostgreSQL DBMS by connecting to the Greenplum master.

Initializing Greenplum Database

These are the high-level tasks for initializing Greenplum Database:

1. Make sure you have completed all of the installation tasks described in [Configuring Your Systems](#) and [Installing the Greenplum Database Software](#).
2. Create a host file that contains the host addresses of your segments. See [Creating the Initialization Host File](#).
3. Create your Greenplum Database system configuration file. See [Creating the Greenplum Database Configuration File](#).
4. By default, Greenplum Database will be initialized using the locale of the master host system. Make sure this is the correct locale you want to use, as some locale options cannot be changed after initialization. See [Configuring Timezone and Localization Settings](#) for more information.
5. Run the Greenplum Database initialization utility on the master host. See [Running the Initialization Utility](#).
6. Set the Greenplum Database timezone. See [Setting the Greenplum Database Timezone](#).
7. Set environment variables for the Greenplum Database user. See [Setting Greenplum Environment Variables](#).

When performing the following initialization tasks, you must be logged into the master host as the `gpadmin` user, and to run Greenplum Database utilities, you must source the `greenplum_path.sh` file to set Greenplum Database environment variables. For example, if you are logged into the master, run these commands.

```
$ su - gpadmin
$ source /usr/local/greenplum-db/greenplum_path.sh
```

Creating the Initialization Host File

The `gpinitssystem` utility requires a host file that contains the list of addresses for each segment host. The initialization utility determines the number of segment instances per host by the number host addresses listed per host times the number of data directory locations specified in the `gpinitssystem_config` file.

This file should only contain segment host addresses (not the master or standby master). For segment machines with multiple, unbonded network interfaces, this file should list the host address names for each interface — one per line.

Note: The Greenplum Database segment host naming convention is `sdwN` where `sdw` is a prefix and `N` is an integer. For example, `sdw2` and so on. If hosts have multiple unbonded NICs, the convention is to append a dash (-) and number to the host name. For example, `sdw1-1` and `sdw1-2` are the two interface names for host `sdw1`. However, NIC bonding is recommended to create a load-balanced, fault-tolerant network.

To create the initialization host file

1. Create a file named `hostfile_gpinitssystem`. In this file add the host address name(s) of your *segment* host interfaces, one name per line, no extra lines or spaces. For example, if you have four segment hosts with two unbonded network interfaces each:

```
sdw1-1
sdw1-2
sdw2-1
sdw2-2
sdw3-1
sdw3-2
sdw4-1
sdw4-2
```

2. Save and close the file.

Note: If you are not sure of the host names and/or interface address names used by your machines, look in the `/etc/hosts` file.

Creating the Greenplum Database Configuration File

Your Greenplum Database configuration file tells the `gpinitssystem` utility how you want to configure your Greenplum Database system. An example configuration file can be found in `$GPHOME/docs/cli_help/gpconfigs/gpinitssystem_config`.

To create a gpinitssystem_config file

1. Make a copy of the `gpinitssystem_config` file to use as a starting point. For example:

```
$ cp $GPHOME/docs/cli_help/gpconfigs/gpinitssystem_config \
/home/gpadmin/gpconfigs/gpinitssystem_config
```

2. Open the file you just copied in a text editor.

Set all of the required parameters according to your environment. See `gpinitssystem` for more information. A Greenplum Database system must contain a master instance and at *least two* segment instances (even if setting up a single node system).

The `DATA_DIRECTORY` parameter is what determines how many segments per host will be created. If your segment hosts have multiple network interfaces, and you used their interface address names in your host file, the number of segments will be evenly spread over the number of available interfaces.

To specify `PORT_BASE`, review the port range specified in the `net.ipv4.ip_local_port_range` parameter in the `/etc/sysctl.conf` file. See [Recommended OS Parameters Settings](#).

Here is an example of the *required* parameters in the `gpinitssystem_config` file:

```
SEG_PREFIX=gpseg
PORT_BASE=6000
declare -a DATA_DIRECTORY=(/data1/primary /data1/primary /data1/primary /data2/primary /data2/primary /data2/primary)
MASTER_HOSTNAME=mdw
MASTER_DIRECTORY=/data/master
MASTER_PORT=5432
TRUSTED_SHELL=ssh
CHECK_POINT_SEGMENTS=8
ENCODING=UNICODE
```

3. (Optional) If you want to deploy mirror segments, uncomment and set the mirroring parameters according to your environment. To specify `MIRROR_PORT_BASE`, review the port range specified under the `net.ipv4.ip_local_port_range` parameter in the `/etc/sysctl.conf` file. Here is an example of the *optional* mirror parameters in the `gpinitssystem_config` file:

```
MIRROR_PORT_BASE=7000
declare -a MIRROR_DATA_DIRECTORY=(/data1/mirror /data1/mirror /data1/mirror /data2/mirror /data2/mirror /data2/mirror)
```

Note: You can initialize your Greenplum system with primary segments only and deploy mirrors later using the `gpaddmirrors` utility.

4. Save and close the file.

Running the Initialization Utility

The `gpinitssystem` utility will create a Greenplum Database system using the values defined in the configuration file.

These steps assume you are logged in as the `gpadmin` user and have sourced the `greenplum_path.sh` file to set Greenplum Database environment variables.

To run the initialization utility

1. Run the following command referencing the path and file name of your initialization configuration file (`gpinitssystem_config`) and host file (`hostfile_gpinitssystem`). For example:

```
$ cd ~
$ gpinitssystem -c gpconfigs/gpinitssystem_config -h gpconfigs/hostfile_gpinitssystem
```

For a fully redundant system (with a standby master and a *spread* mirror configuration) include the `-s` and `--mirror-mode=spread` options. For example:

```
$ gpinitssystem -c gpconfigs/gpinitssystem_config -h gpconfigs/hostfile_gpinitssystem \
-s <standby_master_hostname> --mirror-mode=spread
```

During a new cluster creation, you may use the `-O output_configuration_file` option to save the cluster configuration details in a file. For example:

```
$ gpinitssystem -c gpconfigs/gpinitssystem_config -O gpconfigs/config_template
```

This output file can be edited and used at a later stage as the input file of the `-I` option, to create a new cluster or to recover from a backup. See [gpinitssystem](#) for further details.

Note: Calling `gpinitssystem` with the `-O` option does not initialize the Greenplum Database system; it merely generates and saves a file with cluster configuration details.

2. The utility will verify your setup information and make sure it can connect to each host and access the data directories specified in your configuration. If all of the pre-checks are successful, the utility will prompt you to confirm your configuration. For example:

```
=> Continue with Greenplum creation? Yy/Nn
```

3. Press `y` to start the initialization.
4. The utility will then begin setup and initialization of the master instance and each segment instance in the system. Each segment instance is set up in parallel. Depending on the number of segments, this process can take a while.
5. At the end of a successful setup, the utility will start your Greenplum Database system. You should see:

```
=> Greenplum Database instance successfully created.
```

Troubleshooting Initialization Problems

If the utility encounters any errors while setting up an instance, the entire process will fail, and could possibly leave you with a partially created system. Refer to the error messages and logs to determine the cause of the failure and where in the process the failure occurred. Log files are created in `~/gpAdminLogs`.

Depending on when the error occurred in the process, you may need to clean up and then try the `gpinitssystem` utility again. For example, if some segment instances were created and some failed, you may need to stop `postgres` processes and remove any utility-created data directories from your data storage area(s). A backout script is created to help with this cleanup if necessary.

Using the Backout Script

If the `gpinitssystem` utility fails, it will create the following backout script if it has left your system in a partially installed state:

```
~/gpAdminLogs/backout_gpinitssystem_<user>_<timestamp>
```

You can use this script to clean up a partially created Greenplum Database system. This backout script will remove any utility-created data directories, `postgres` processes, and log files. After correcting the error that caused `gpinitssystem` to fail and running the backout script, you should be ready to retry initializing your Greenplum Database array.

The following example shows how to run the backout script:

```
$ bash ~/gpAdminLogs/backout_gpinitssystem_gpadmin_20071031_121053
```

Setting the Greenplum Database Timezone

As a best practice, configure Greenplum Database and the host systems to use a known, supported timezone. Greenplum Database uses a timezone from a set of internally stored PostgreSQL timezones. Setting the Greenplum Database timezone prevents Greenplum Database from selecting a timezone each time the cluster is restarted and sets the timezone for the Greenplum Database master and segment instances.

Use the `gpconfig` utility to show and set the Greenplum Database timezone. For example, these commands show the Greenplum Database timezone and set the timezone to `US/Pacific`.

```
$ gpconfig -s TimeZone
$ gpconfig -c TimeZone -v 'US/Pacific'
```

You must restart Greenplum Database after changing the timezone. The command `gpstop -ra` restarts Greenplum Database. The catalog view `pg_timezone_names` provides Greenplum Database timezone information.

For more information about the Greenplum Database timezone, see [Configuring Timezone and Localization Settings](#).

Setting Greenplum Environment Variables

You must set environment variables in the Greenplum Database user (`gpadmin`) environment that runs Greenplum Database on the Greenplum Database master and standby master hosts. A `greenplum_path.sh` file is provided in the Greenplum Database installation directory with environment variable settings for Greenplum Database.

The Greenplum Database management utilities also require that the `MASTER_DATA_DIRECTORY` environment variable be set. This should point to the directory created by the `gpinitssystem` utility in the master data directory location.

Note: The `greenplum_path.sh` script changes the operating environment in order to support running the Greenplum Database-specific utilities. These same changes to the environment can negatively affect the operation of other system-level utilities, such as `ps` or `yum`. Use separate accounts for performing system administration and database administration, instead of attempting to perform both functions as `gpadmin`.

These steps ensure that the environment variables are set for the `gpadmin` user after a system reboot.

To set up the `gpadmin` environment for Greenplum Database

1. Open the `gpadmin` profile file (such as `.bashrc`) in a text editor. For example:

```
$ vi ~/.bashrc
```

2. Add lines to this file to source the `greenplum_path.sh` file and set the `MASTER_DATA_DIRECTORY` environment variable. For example:

```
source /usr/local/greenplum-db/greenplum_path.sh
export MASTER_DATA_DIRECTORY=/data/master/gpseg-1
```

3. (Optional) You may also want to set some client session environment variables such as `PGPORT`, `PGUSER` and `PGDATABASE` for convenience. For example:

```
export PGPORT=5432
export PGUSER=gpadmin
export PGDATABASE=gpadmin
```

4. (Optional) If you use RHEL 7 or CentOS 7, add the following line to the end of the `.bashrc` file to enable using the `ps` command in the `greenplum_path.sh` environment:

```
export LD_PRELOAD=/lib64/libz.so.1 ps
```

5. Save and close the file.
6. After editing the profile file, source it to make the changes active. For example:

```
$ source ~/.bashrc
```

7. If you have a standby master host, copy your environment file to the standby master as well. For example:

```
$ cd ~
$ scp .bashrc <standby_hostname>:~`pwd`
```

Note: The `.bashrc` file should not produce any output. If you wish to have a message display to users upon logging in, use the `.bash_profile` file instead.

Next Steps

After your system is up and running, the next steps are:

- [Allowing Client Connections](#)
- [Creating Databases and Loading Data](#)

Allowing Client Connections

After a Greenplum Database is first initialized it will only allow local connections to the database from the `gpadmin` role (or whatever system user ran `gpinitssystem`). If you would like other users or client machines to be able to connect to Greenplum Database, you must give them access. See the *Greenplum Database Administrator Guide* for more information.

Creating Databases and Loading Data

After verifying your installation, you may want to begin creating databases and loading data. See [Defining Database Objects](#) and [Loading and Unloading Data](#) in the *Greenplum Database Administrator Guide* for more information about creating databases, schemas, tables, and other database objects in Greenplum Database and loading your data.

Installing Optional Extensions (Tanzu Greenplum)

Information about installing optional Tanzu Greenplum Database extensions and packages, such as the Procedural Language extensions and the Python and R Data Science Packages.

- [Procedural Language, Machine Learning, and Geospatial Extensions](#)
- [Python Data Science Module Package](#)
- [R Data Science Library Package](#)
- [Greenplum Platform Extension Framework \(PXF\)](#)

Parent topic: [Installing and Upgrading Greenplum](#)

Procedural Language, Machine Learning, and Geospatial

Extensions

Optional. Use the Greenplum package manager ([gppkg](#)) to install Greenplum Database extensions such as PL/Java, PL/R, PostGIS, and MADlib, along with their dependencies, across an entire cluster. The package manager also integrates with existing scripts so that any packages are automatically installed on any new hosts introduced into the system following cluster expansion or segment host recovery.

See [gppkg](#) for more information, including usage.

Extension packages can be downloaded from the Greenplum Database page on [VMware Tanzu Network](#). The extension documentation in the [Greenplum Database Reference Guide](#) contains information about installing extension packages and using extensions.

- [Greenplum PL/R Language Extension](#)
- [Greenplum PL/Java Language Extension](#)
- [Greenplum MADlib Extension for Analytics](#)
- [Greenplum PostGIS Extension](#)

Important: If you intend to use an extension package with Greenplum Database 6 you must install and use a Greenplum Database extension package (gppkg files and contrib modules) that is built for Greenplum Database 6. Any custom modules that were used with earlier versions must be rebuilt for use with Greenplum Database 6.

Parent topic: [Installing Optional Extensions \(Tanzu Greenplum\)](#)

Python Data Science Module Package

Greenplum Database provides a collection of data science-related Python modules that can be used with the Greenplum Database PL/Python language. You can download these modules in [.gppkg](#) format from [VMware Tanzu Network](#).

This section contains the following information:

- [Python Data Science Modules](#)
- [Installing the Python Data Science Module Package](#)
- [Uninstalling the Python Data Science Module Package](#)

For information about the Greenplum Database PL/Python Language, see [Greenplum PL/Python Language Extension](#).

Parent topic: [Installing Optional Extensions \(Tanzu Greenplum\)](#)

Python Data Science Modules

Modules provided in the Python Data Science package are listed below.

Packages required for Deep Learning features of MADlib are now included. Note that it is not supported for RHEL 6.

Module Name	Description/Used For
atomicwrites	Atomic file writes
attrs	Declarative approach for defining class attributes
Autograd	Gradient-based optimization

Module Name	Description/Used For
backports.functools-lru-cache	Backports <code>functools.lru_cache</code> from Python 3.3
Beautiful Soup	Navigating HTML and XML
Blis	Blis linear algebra routines
Boto	Amazon Web Services library
Boto3	The AWS SDK
botocore	Low-level, data-driven core of boto3
Bottleneck	Fast NumPy array functions
Bz2file	Read and write bzip2-compressed files
Certifi	Provides Mozilla CA bundle
Chardet	Universal encoding detector for Python 2 and 3
ConfigParser	Updated <code>configparser</code> module
contextlib2	Backports and enhancements for the <code>contextlib</code> module
Cycler	Composable style cycles
cymem	Manage calls to calloc/free through Cython
Docutils	Python documentation utilities
enum34	Backport of Python 3.4 Enum
Funcsigs	Python function signatures from PEP362
functools32	Backport of the <code>functools</code> module from Python 3.2.3
functools	Functional tools focused on practicality
future	Compatibility layer between Python 2 and Python 3
futures	Backport of the <code>concurrent.futures</code> package from Python 3
Gensim	Topic modeling and document indexing
GluonTS (Python 3 only)	Probabilistic time series modeling
h5py	Read and write HDF5 files
idna	Internationalized Domain Names in Applications (IDNA)
importlib-metadata	Read metadata from Python packages
Jinja2	Stand-alone template engine
JMESPath	JSON Matching Expressions
Joblib	Python functions as pipeline jobs
jsonschema	JSON Schema validation
Keras (RHEL/CentOS 7 only)	Deep learning
Keras Applications	Reference implementations of popular deep learning models
Keras Preprocessing	Easy data preprocessing and data augmentation for deep learning models
Kiwi	A fast implementation of the Cassowary constraint solver
Lifelines	Survival analysis

Module Name	Description/Used For
lxml	XML and HTML processing
MarkupSafe	Safely add untrusted strings to HTML/XML markup
Matplotlib	Python plotting package
mock	Rolling backport of <code>unittest.mock</code>
more-itertools	More routines for operating on iterables, beyond itertools
MurmurHash	Cython bindings for MurmurHash
NLTK	Natural language toolkit
NumExpr	Fast numerical expression evaluator for NumPy
NumPy	Scientific computing
packaging	Core utilities for Python packages
Pandas	Data analysis
pathlib, pathlib2	Object-oriented filesystem paths
patsy	Package for describing statistical models and for building design matrices
Pattern-en	Part-of-speech tagging
pip	Tool for installing Python packages
plac	Command line arguments parser
pluggy	Plugin and hook calling mechanisms
preshed	Cython hash table that trusts the keys are pre-hashed
protobuf	Protocol buffers
py	Cross-python path, ini-parsing, io, code, log facilities
pyLDavis	Interactive topic model visualization
PyMC3	Statistical modeling and probabilistic machine learning
pparsing	Python parsing
pytest	Testing framework
python-dateutil	Extensions to the standard Python datetime module
pytz	World timezone definitions, modern and historical
PyYAML	YAML parser and emitter
requests	HTTP library
s3transfer	Amazon S3 transfer manager
scandir	Directory iteration function
scikit-learn	Machine learning data mining and analysis
SciPy	Scientific computing
setuptools	Download, build, install, upgrade, and uninstall Python packages
six	Python 2 and 3 compatibility library
smart-open	Utilities for streaming large files (S3, HDFS, gzip, bz2, and so forth)

Module Name	Description/Used For
spaCy	Large scale natural language processing
srsly	Modern high-performance serialization utilities for Python
StatsModels	Statistical modeling
subprocess32	Backport of the subprocess module from Python 3
Tensorflow (RHEL/CentOS 7 only)	Numerical computation using data flow graphs
Theano	Optimizing compiler for evaluating mathematical expressions on CPUs and GPUs
thinc	Practical Machine Learning for NLP
tqdm	Fast, extensible progress meter
urllib3	HTTP library with thread-safe connection pooling, file post, and more
wasabi	Lightweight console printing and formatting toolkit
wcwidth	Measures number of Terminal column cells of wide-character codes
Werkzeug	Comprehensive WSGI web application library
wheel	A built-package format for Python
XGBoost	Gradient boosting, classifying, ranking
zipp	Backport of pathlib-compatible object wrapper for zip files

Installing the Python Data Science Module Package

Before you install the Python Data Science Module package, make sure that your Greenplum Database is running, you have sourced `greenplum_path.sh`, and that the `$MASTER_DATA_DIRECTORY` and `$GPHOME` environment variables are set.

Note: The `PyMC3` module depends on `Tk`. If you want to use `PyMC3`, you must install the `tk` OS package on every node in your cluster. For example:

```
$ sudo yum install tk
```

1. Locate the Python Data Science module package that you built or downloaded.
The file name format of the package is `DataSciencePython-<version>-relhel<N>-x86_64.gppkg`.
2. Copy the package to the Greenplum Database master host.
3. Follow the instructions in [Verifying the Greenplum Database Software Download](#) to verify the integrity of the *Greenplum Procedural Languages Python Data Science Package* software.
4. Use the `gppkg` command to install the package. For example:

```
$ gppkg -i DataSciencePython-<version>-relhel<N>-x86_64.gppkg
```

`gppkg` installs the Python Data Science modules on all nodes in your Greenplum Database cluster. The command also updates the `PYTHONPATH`, `PATH`, and `LD_LIBRARY_PATH` environment variables in your `greenplum_path.sh` file.

5. Restart Greenplum Database. You must re-source `greenplum_path.sh` before restarting your

Greenplum cluster:

```
$ source /usr/local/greenplum-db/greenplum_path.sh
$ gpstop -r
```

The Greenplum Database Python Data Science Modules are installed in the following directory:

```
$GPHOME/ext/DataSciencePython/lib/python2.7/site-packages/
```

Uninstalling the Python Data Science Module Package

Use the `gppkg` utility to uninstall the Python Data Science Module package. You must include the version number in the package name you provide to `gppkg`.

To determine your Python Data Science Module package version number and remove this package:

```
$ gppkg -q --all | grep DataSciencePython
DataSciencePython-<version>
$ gppkg -r DataSciencePython-<version>
```

The command removes the Python Data Science modules from your Greenplum Database cluster. It also updates the `PYTHONPATH`, `PATH`, and `LD_LIBRARY_PATH` environment variables in your `greenplum_path.sh` file to their pre-installation values.

Re-source `greenplum_path.sh` and restart Greenplum Database after you remove the Python Data Science Module package:

```
$ . /usr/local/greenplum-db/greenplum_path.sh
$ gpstop -r
```

Note: When you uninstall the Python Data Science Module package from your Greenplum Database cluster, any UDFs that you have created that import Python modules installed with this package will return an error.

R Data Science Library Package

R packages are modules that contain R functions and data sets. Greenplum Database provides a collection of data science-related R libraries that can be used with the Greenplum Database PL/R language. You can download these libraries in `.gppkg` format from [VMware Tanzu Network](#).

This chapter contains the following information:

- [R Data Science Libraries](#)
- [Installing the R Data Science Library Package](#)
- [Uninstalling the R Data Science Library Package](#)

For information about the Greenplum Database PL/R Language, see [Greenplum PL/R Language Extension](#).

Parent topic: [Installing Optional Extensions \(Tanzu Greenplum\)](#)

R Data Science Libraries

Libraries provided in the R Data Science package include:

abind	gss	R2WinBUGS
adabag	gtable	R6
arm	gtools	randomForest
assertthat	hms	RColorBrewer
backports	hybridHclust	Rcpp
BH	igraph	RcppArmadillo
bitops	ipred	RcppEigen
car	iterators	readr
caret	labeling	recipes
caTools	lattice	reshape2
cli	lava	rjags
clipr	lazyeval	rlang
coda	lme4	RobustRankAggreg
colorspace	lmtree	ROCR
compHclust	lubridate	rpart
crayon	magrittr	RPostgreSQL
curl	MASS	sandwich
data.table	Matrix	scales
DBI	MatrixModels	SparseM
Deriv	mcmc	SQUAREM
dichromat	MCMCpack	stabledist
digest	minqa	stringi
doParallel	ModelMetrics	stringr
dplyr	MTS	survival
e1071	munsell	tibble
ellipsis	mvtnorm	tidyr
fansi	neuralnet	tidyselect
fastICA	nloptr	timeDate
fBasics	nnet	timeSeries
fGarch	numDeriv	tseries
flashClust	pbrktest	TTR
foreach	pillar	urca
forecast	pkgconfig	utf8
foreign	plogr	vctrs
fracdiff	plyr	viridisLite
gdata	proclim	withr
generics	purrr	xts
ggplot2	quadprog	zeallot
glmnet	quantmod	zoo
glue	quantreg	
gower	R2jags	
gplots		

Installing the R Data Science Library Package

Before you install the R Data Science Library package, make sure that your Greenplum Database is running, you have sourced `greenplum_path.sh`, and that the `$MASTER_DATA_DIRECTORY` and `$GPHOME` environment variables are set.

1. Locate the R Data Science library package that you built or downloaded.

The file name format of the package is `DataScienceR-<version>-relhel<N>_x86_64.gppkg`.

2. Copy the package to the Greenplum Database master host.
3. Follow the instructions in [Verifying the Greenplum Database Software Download](#) to verify the integrity of the *Greenplum Procedural Languages R Data Science Package* software.
4. Use the `gppkg` command to install the package. For example:

```
$ gppkg -i DataScienceR-<version>-relhel<N>_x86_64.gppkg
```

`gppkg` installs the R Data Science libraries on all nodes in your Greenplum Database cluster. The command also sets the `R_LIBS_USER` environment variable and updates the `PATH` and `LD_LIBRARY_PATH` environment variables in your `greenplum_path.sh` file.

5. Restart Greenplum Database. You must re-source `greenplum_path.sh` before restarting your Greenplum cluster:

```
$ source /usr/local/greenplum-db/greenplum_path.sh
$ gpstop -r
```

The Greenplum Database R Data Science Modules are installed in the following directory:

```
$GPHOME/ext/DataScienceR/library
```

Note: `rjags` libraries are installed in the `$GPHOME/ext/DataScienceR/extlib/lib` directory. If you want to use `rjags` and your `$GPHOME` is not `/usr/local/greenplum-db`, you must perform additional configuration steps to create a symbolic link from `$GPHOME` to `/usr/local/greenplum-db` on each node in your Greenplum Database cluster. For example:

```
$ gpssh -f all_hosts -e 'ln -s $GPHOME /usr/local/greenplum-db'
$ gpssh -f all_hosts -e 'chown -h gpadmin /usr/local/greenplum-db'
```

Uninstalling the R Data Science Library Package

Use the `gppkg` utility to uninstall the R Data Science Library package. You must include the version number in the package name you provide to `gppkg`.

To determine your R Data Science Library package version number and remove this package:

```
$ gppkg -q --all | grep DataScienceR
DataScienceR-<version>
$ gppkg -r DataScienceR-<version>
```

The command removes the R Data Science libraries from your Greenplum Database cluster. It also removes the `R_LIBS_USER` environment variable and updates the `PATH` and `LD_LIBRARY_PATH` environment variables in your `greenplum_path.sh` file to their pre-installation values.

Re-source `greenplum_path.sh` and restart Greenplum Database after you remove the R Data Science Library package:

```
$ . /usr/local/greenplum-db/greenplum_path.sh
$ gpstop -r
```

Note: When you uninstall the R Data Science Library package from your Greenplum Database cluster, any UDFs that you have created that use R libraries installed with this package will return an error.

Greenplum Platform Extension Framework (PXF)

Optional. If you do not plan to use PXF, no action is necessary.

If you plan to use PXF, refer to [Accessing External Data with PXF](#) for introductory PXF information. The [Installing PXF](#) and [Configuring PXF](#) topics in the PXF documentation provide installation and configuration instructions.

Parent topic: [Installing Optional Extensions \(Tanzu Greenplum\)](#)

Installing Additional Supplied Modules

The Greenplum Database distribution includes several PostgreSQL- and Greenplum-sourced `contrib` modules that you have the option to install.

Each module is typically packaged as a Greenplum Database extension. You must register these modules in each database in which you want to use it. For example, to register the `dblink` module in the database named `testdb`, use the command:

```
$ psql -d testdb -c 'CREATE EXTENSION dblink;'
```

To remove a module from a database, drop the associated extension. For example, to remove the `dblink` module from the `testdb` database:

```
$ psql -d testdb -c 'DROP EXTENSION dblink;'
```

Note: When you drop a module extension from a database, any user-defined function that you created in the database that references functions defined in the module will no longer work. If you created any database objects that use data types defined in the module, Greenplum Database will notify you of these dependencies when you attempt to drop the module extension.

You can register the following modules in this manner:

- | | |
|--|--|
| <ul style="list-style-type: none"> • <code>btree_gin</code> • <code>citext</code> • <code>dblink</code> • <code>diskquota</code> • <code>fuzzystrmatch</code> • <code>gp_array_agg</code> • <code>gp_parallel_retrieve_cursor</code> • <code>gp_percentile_agg</code> • <code>gp_sparse_vector</code> | <ul style="list-style-type: none"> • <code>greenplum_fdw</code> • <code>hstore</code> • <code>orafce</code> (Tanzu Greenplum only) • <code>pageinspect</code> • <code>pg_trgm</code> • <code>pgcrypto</code> • <code>postgres_fdw</code> • <code>sslinf</code> |
|--|--|

For additional information about the modules supplied with Greenplum Database, refer to [Additional Supplied Modules](#) in the *Greenplum Database Reference Guide*.

Parent topic: [Installing and Upgrading Greenplum](#)

Configuring Timezone and Localization Settings

Describes the available timezone and localization features of Greenplum Database.

Parent topic: [Installing and Upgrading Greenplum](#)

Configuring the Timezone

Greenplum Database selects a timezone to use from a set of internally stored PostgreSQL timezones. The available PostgreSQL timezones are taken from the Internet Assigned Numbers Authority (IANA) Time Zone Database, and Greenplum Database updates its list of available timezones as necessary when the IANA database changes for PostgreSQL.

Greenplum Database selects the timezone by matching a PostgreSQL timezone with the value of the `TimeZone` server configuration parameter, or the host system time zone if `TimeZone` is not set. For example, when selecting a default timezone from the host system time zone, Greenplum Database uses an algorithm to select a PostgreSQL timezone based on the host system timezone files. If the system timezone includes leap second information, Greenplum Database cannot match the system timezone with a PostgreSQL timezone. In this case, Greenplum Database calculates a “best match” with a PostgreSQL timezone based on information from the host system.

As a best practice, configure Greenplum Database and the host systems to use a known, supported timezone. This sets the timezone for the Greenplum Database master and segment instances, and prevents Greenplum Database from selecting a best match timezone each time the cluster is restarted, using the current system timezone and Greenplum Database timezone files (which may have been updated from the IANA database since the last restart). Use the `gpconfig` utility to show and set the Greenplum Database timezone. For example, these commands show the Greenplum Database timezone and set the timezone to `US/Pacific`.

```
# gpconfig -s TimeZone
# gpconfig -c TimeZone -v 'US/Pacific'
```

You must restart Greenplum Database after changing the timezone. The command `gpstop -ra` restarts Greenplum Database. The catalog view `pg_timezone_names` provides Greenplum Database timezone information.

About Locale Support in Greenplum Database

Greenplum Database supports localization with two approaches:

- Using the locale features of the operating system to provide locale-specific collation order, number formatting, and so on.
- Providing a number of different character sets defined in the Greenplum Database server, including multiple-byte character sets, to support storing text in all kinds of languages, and providing character set translation between client and server.

Locale support refers to an application respecting cultural preferences regarding alphabets, sorting, number formatting, etc. Greenplum Database uses the standard ISO C and POSIX locale facilities provided by the server operating system. For additional information refer to the documentation of your operating system.

Locale support is automatically initialized when a Greenplum Database system is initialized. The initialization utility, `gpinit`, will initialize the Greenplum array with the locale setting of its execution environment by default, so if your system is already set to use the locale that you want in your Greenplum Database system then there is nothing else you need to do.

When you are ready to initiate Greenplum Database and you want to use a different locale (or you are not sure which locale your system is set to), you can instruct `gpinitssystem` exactly which locale to use by specifying the `-n locale` option. For example:

```
$ gpinitssystem -c gp_init_config -n sv_SE
```

See [Initializing a Greenplum Database System](#) for information about the database initialization process.

The example above sets the locale to Swedish (sv) as spoken in Sweden (SE). Other possibilities might be `en_US` (U.S. English) and `fr_CA` (French Canadian). If more than one character set can be useful for a locale then the specifications look like this: `cs_CZ.ISO8859-2`. What locales are available under what names on your system depends on what was provided by the operating system vendor and what was installed. On most systems, the command `locale -a` will provide a list of available locales.

Occasionally it is useful to mix rules from several locales, for example use English collation rules but Spanish messages. To support that, a set of locale subcategories exist that control only a certain aspect of the localization rules:

- `LC_COLLATE` — String sort order
- `LC_CTYPE` — Character classification (What is a letter? Its upper-case equivalent?)
- `LC_MESSAGES` — Language of messages
- `LC_MONETARY` — Formatting of currency amounts
- `LC_NUMERIC` — Formatting of numbers
- `LC_TIME` — Formatting of dates and times

If you want the system to behave as if it had no locale support, use the special locale `C` or `POSIX`.

The nature of some locale categories is that their value has to be fixed for the lifetime of a Greenplum Database system. That is, once `gpinitssystem` has run, you cannot change them anymore. `LC_COLLATE` and `LC_CTYPE` are those categories. They affect the sort order of indexes, so they must be kept fixed, or indexes on text columns will become corrupt. Greenplum Database enforces this by recording the values of `LC_COLLATE` and `LC_CTYPE` that are seen by `gpinitssystem`. The server automatically adopts those two values based on the locale that was chosen at initialization time.

The other locale categories can be changed as desired whenever the server is running by setting the server configuration parameters that have the same name as the locale categories (see the *Greenplum Database Reference Guide* for more information on setting server configuration parameters). The defaults that are chosen by `gpinitssystem` are written into the master and segment `postgresql.conf` configuration files to serve as defaults when the Greenplum Database system is started. If you delete these assignments from the master and each segment `postgresql.conf` files then the server will inherit the settings from its execution environment.

Note that the locale behavior of the server is determined by the environment variables seen by the server, not by the environment of any client. Therefore, be careful to configure the correct locale settings on each Greenplum Database host (master and segments) before starting the system. A consequence of this is that if client and server are set up in different locales, messages may appear in different languages depending on where they originated.

Inheriting the locale from the execution environment means the following on most operating systems: For a given locale category, say the collation, the following environment variables are consulted in this order until one is found to be set: `LC_ALL`, `LC_COLLATE` (the variable corresponding to the respective category), `LANG`. If none of these environment variables are set then the locale

defaults to `c`.

Some message localization libraries also look at the environment variable `LANGUAGE` which overrides all other locale settings for the purpose of setting the language of messages. If in doubt, please refer to the documentation for your operating system, in particular the documentation about `gettext`, for more information.

Native language support (NLS), which enables messages to be translated to the user's preferred language, is not enabled in Greenplum Database for languages other than English. This is independent of the other locale support.

Locale Behavior

The locale settings influence the following SQL features:

- Sort order in queries using `ORDER BY` on textual data
- The ability to use indexes with `LIKE` clauses
- The `upper`, `lower`, and `initcap` functions
- The `to_char` family of functions

The drawback of using locales other than `c` or `POSIX` in Greenplum Database is its performance impact. It slows character handling and prevents ordinary indexes from being used by `LIKE`. For this reason use locales only if you actually need them.

Troubleshooting Locales

If locale support does not work as expected, check that the locale support in your operating system is correctly configured. To check what locales are installed on your system, you may use the command `locale -a` if your operating system provides it.

Check that Greenplum Database is actually using the locale that you think it is. `LC_COLLATE` and `LC_CTYPE` settings are determined at initialization time and cannot be changed without redoing `gpinitssystem`. Other locale settings including `LC_MESSAGES` and `LC_MONETARY` are initially determined by the operating system environment of the master and/or segment host, but can be changed after initialization by editing the `postgresql.conf` file of each Greenplum master and segment instance. You can check the active locale settings of the master host using the `SHOW` command. Note that every host in your Greenplum Database array should be using identical locale settings.

Character Set Support

The character set support in Greenplum Database allows you to store text in a variety of character sets, including single-byte character sets such as the ISO 8859 series and multiple-byte character sets such as EUC (Extended Unix Code), UTF-8, and Mule internal code. All supported character sets can be used transparently by clients, but a few are not supported for use within the server (that is, as a server-side encoding). The default character set is selected while initializing your Greenplum Database array using `gpinitssystem`. It can be overridden when you create a database, so you can have multiple databases each with a different character set.

Name	Description	Language	Server?	Bytes/Char	Aliases
BIG5	Big Five	Traditional Chinese	No	1-2	WIN950, Windows950
EUC_CN	Extended UNIX Code-CN	Simplified Chinese	Yes	1-3

WIN874	Windows CP874	Thai	Yes	1	
WIN1250	Windows CP1250	Central European	Yes	1	
WIN1251	Windows CP1251	Cyrillic	Yes	1	WIN
WIN1252	Windows CP1252	Western European	Yes	1	
WIN1253	Windows CP1253	Greek	Yes	1	
WIN1254	Windows CP1254	Turkish	Yes	1	
WIN1255	Windows CP1255	Hebrew	Yes	1	
WIN1256	Windows CP1256	Arabic	Yes	1	
WIN1257	Windows CP1257	Baltic	Yes	1	
WIN1258	Windows CP1258	Vietnamese	Yes	1	ABC, TCVN, TCVN5712, VSCII

Setting the Character Set

gpinitssystem defines the default character set for a Greenplum Database system by reading the setting of the `ENCODING` parameter in the `gp_init_config` file at initialization time. The default character set is `UNICODE` or `UTF8`.

You can create a database with a different character set besides what is used as the system-wide default. For example:

```
=> CREATE DATABASE korean WITH ENCODING 'EUC_KR';
```

Important: Although you can specify any encoding you want for a database, it is unwise to choose an encoding that is not what is expected by the locale you have selected. The `LC_COLLATE` and `LC_CTYPE` settings imply a particular encoding, and locale-dependent operations (such as sorting) are likely to misinterpret data that is in an incompatible encoding.

Since these locale settings are frozen by gpinitssystem, the apparent flexibility to use different encodings in different databases is more theoretical than real.

One way to use multiple encodings safely is to set the locale to `C` or `POSIX` during initialization time, thus disabling any real locale awareness.

Character Set Conversion Between Server and Client

Greenplum Database supports automatic character set conversion between server and client for certain character set combinations. The conversion information is stored in the master `pg_conversion` system catalog table. Greenplum Database comes with some predefined conversions or you can create a new conversion using the SQL command `CREATE CONVERSION`.

Server Character Set	Available Client Character Sets
BIG5	not supported as a server encoding
EUC_CN	EUC_CN, MULE_INTERNAL, UTF8

Server Character Set	Available Client Character Sets
EUC_JP	EUC_JP, MULE_INTERNAL, SJIS, UTF8
EUC_KR	EUC_KR, MULE_INTERNAL, UTF8
EUC_TW	EUC_TW, BIG5, MULE_INTERNAL, UTF8
GB18030	not supported as a server encoding
GBK	not supported as a server encoding
ISO_8859_5	ISO_8859_5, KOI8, MULE_INTERNAL, UTF8, WIN866, WIN1251
ISO_8859_6	ISO_8859_6, UTF8
ISO_8859_7	ISO_8859_7, UTF8
ISO_8859_8	ISO_8859_8, UTF8
JOHAB	JOHAB, UTF8
KOI8	KOI8, ISO_8859_5, MULE_INTERNAL, UTF8, WIN866, WIN1251
LATIN1	LATIN1, MULE_INTERNAL, UTF8
LATIN2	LATIN2, MULE_INTERNAL, UTF8, WIN1250
LATIN3	LATIN3, MULE_INTERNAL, UTF8
LATIN4	LATIN4, MULE_INTERNAL, UTF8
LATIN5	LATIN5, UTF8
LATIN6	LATIN6, UTF8
LATIN7	LATIN7, UTF8
LATIN8	LATIN8, UTF8
LATIN9	LATIN9, UTF8
LATIN10	LATIN10, UTF8
MULE_INTERNAL	MULE_INTERNAL, BIG5, EUC_CN, EUC_JP, EUC_KR, EUC_TW, ISO_8859_5, KOI8, LATIN1 to LATIN4, SJIS, WIN866, WIN1250, WIN1251
SJIS	not supported as a server encoding
SQL_ASCII	not supported as a server encoding
UHC	not supported as a server encoding
UTF8	all supported encodings
WIN866	WIN866
ISO_8859_5	KOI8, MULE_INTERNAL, UTF8, WIN1251
WIN874	WIN874, UTF8
WIN1250	WIN1250, LATIN2, MULE_INTERNAL, UTF8
WIN1251	WIN1251, ISO_8859_5, KOI8, MULE_INTERNAL, UTF8, WIN866
WIN1252	WIN1252, UTF8
WIN1253	WIN1253, UTF8
WIN1254	WIN1254, UTF8

Server Character Set	Available Client Character Sets
WIN1255	WIN1255, UTF8
WIN1256	WIN1256, UTF8
WIN1257	WIN1257, UTF8
WIN1258	WIN1258, UTF8

To enable automatic character set conversion, you have to tell Greenplum Database the character set (encoding) you would like to use in the client. There are several ways to accomplish this:

- Using the `\encoding` command in `psql`, which allows you to change client encoding on the fly.
- Using `SET client_encoding TO`. Setting the client encoding can be done with this SQL command:

```
=> SET CLIENT_ENCODING TO '<value>';
```

To query the current client encoding:

```
=> SHOW client_encoding;
```

To return to the default encoding:

```
=> RESET client_encoding;
```

- Using the `PGCLIENTENCODING` environment variable. When `PGCLIENTENCODING` is defined in the client's environment, that client encoding is automatically selected when a connection to the server is made. (This can subsequently be overridden using any of the other methods mentioned above.)
- Setting the configuration parameter `client_encoding`. If `client_encoding` is set in the master `postgresql.conf` file, that client encoding is automatically selected when a connection to Greenplum Database is made. (This can subsequently be overridden using any of the other methods mentioned above.)

If the conversion of a particular character is not possible — suppose you chose `EUC_JP` for the server and `LATIN1` for the client, then some Japanese characters do not have a representation in `LATIN1` — then an error is reported.

If the client character set is defined as `SQL_ASCII`, encoding conversion is disabled, regardless of the server's character set. The use of `SQL_ASCII` is unwise unless you are working with all-ASCII data. `SQL_ASCII` is not supported as a server encoding.

1 Not all APIs support all the listed character sets. For example, the JDBC driver does not support `MULE_INTERNAL`, `LATIN6`, `LATIN8`, and `LATIN10`. 2 The `SQL_ASCII` setting behaves considerably differently from the other settings. Byte values 0-127 are interpreted according to the ASCII standard, while byte values 128-255 are taken as uninterpreted characters. If you are working with any non-ASCII data, it is unwise to use the `SQL_ASCII` setting as a client encoding. `SQL_ASCII` is not supported as a server encoding.

Upgrading to Greenplum 6

This topic identifies the upgrade paths for upgrading a Greenplum Database 6.x release to a newer 6.x release. The topic also describes the migration paths for migrating Tanzu Greenplum Database

4.x or 5.x data to Greenplum Database 6.x.

Greenplum Database 6 supports upgrading from a Greenplum 6.x release to a newer 6.x release. Direct upgrade from Tanzu Greenplum 5.28 and later to Tanzu Greenplum 6.9 and later is provided via `gpupgrade`; for more information, see the [gpupgrade documentation](#). Direct upgrade from Greenplum Database 4.3, or from Greenplum 5.27 and earlier, to Greenplum 6 is not supported; you must migrate the data to Greenplum 6.

- **Upgrading from an Earlier Greenplum 6 Release**
The upgrade path supported for this release is Greenplum Database 6.x to a newer Greenplum Database 6.x release.
- **PXF Upgrade and Migration**
- **Migrating Data from Greenplum 4.3 or 5 to Greenplum 6**
You can migrate data from Greenplum Database 4.3 or 5 to Greenplum 6 using the standard backup and restore procedures, `gpbackup` and `gprestore`, or by using `gpcopy` for Tanzu Greenplum.

Parent topic: [Installing and Upgrading Greenplum](#)

Upgrading from an Earlier Greenplum 6 Release

The upgrade path supported for this release is Greenplum Database 6.x to a newer Greenplum Database 6.x release.

Important: Set the Greenplum Database timezone to a value that is compatible with your host systems. Setting the Greenplum Database timezone prevents Greenplum Database from selecting a timezone each time the cluster is restarted and sets the timezone for the Greenplum Database master and segment instances. After you upgrade to this release and if you have not set a Greenplum Database timezone value, verify that the selected Greenplum Database timezone is acceptable for your deployment. See [Configuring Timezone and Localization Settings](#) for more information.

Prerequisites

Before starting the upgrade process, perform the following checks.

- Verify the health of the Greenplum Database host hardware, and verify that the hosts meet the requirements for running Greenplum Database. The Greenplum Database `gpcheckperf` utility can assist you in confirming the host requirements.

Note: If you need to run the `gpcheckcat` utility, run it a few weeks before the upgrade during a maintenance period. If necessary, you can resolve any issues found by the utility before the scheduled upgrade.

The utility is in `$GPHOME/bin`. Place Greenplum Database in restricted mode when you run the `gpcheckcat` utility. See the *Greenplum Database Utility Guide* for information about the `gpcheckcat` utility.

If `gpcheckcat` reports catalog inconsistencies, you can run `gpcheckcat` with the `-g` option to generate SQL scripts to fix the inconsistencies.

After you run the SQL scripts, run `gpcheckcat` again. You might need to repeat the process of running `gpcheckcat` and creating SQL scripts to ensure that there are no inconsistencies. Run the SQL scripts generated by `gpcheckcat` on a quiescent system. The utility might report false alerts if there is activity on the system.

Important: VMware customers should contact VMware Support if the `gpcheckcat` utility

reports errors but does not generate a SQL script to fix the errors. Information for contacting VMware Support is at <https://tanzu.vmware.com/support>.

- If you have configured the Greenplum Platform Extension Framework (PXF) in your previous Greenplum Database installation, you must stop the PXF service, and you might need to back up PXF configuration files before upgrading to a new version of Greenplum Database. Refer to [PXF Pre-Upgrade Actions](#) for instructions.

If you have not yet configured PXF, no action is necessary.

- If you have configured and used the Tanzu Greenplum Streaming Server (GPSS) in your previous Tanzu Greenplum Database installation, you must stop any running GPSS jobs and service instances before you upgrade to a new version of Greenplum Database. Refer to [GPSS Pre-Upgrade Actions](#) for instructions.

If you do not plan to use GPSS, or you have not yet configured GPSS, no action is necessary.

Parent topic: [Upgrading to Greenplum 6](#)

Upgrading from 6.x to a Newer 6.x Release

An upgrade from Greenplum Database 6.x to a newer 6.x release involves stopping Greenplum Database, updating the Greenplum Database software binaries, and restarting Greenplum Database. If you are using Greenplum Database extension packages there are additional requirements. See [Prerequisites](#) in the previous section.

1. Log in to your Greenplum Database master host as the Greenplum administrative user:

```
$ su - gpadmin
```

2. Perform a smart shutdown of your Greenplum Database 6.x system (there can be no active connections to the database). This example uses the `-a` option to disable confirmation prompts:

```
$ gpstop -a
```

3. Copy the new Greenplum Database software installation package to the `gpadmin` user's home directory on each master, standby, and segment host.
4. *If you used `yum` or `apt` to install Greenplum Database to the default location*, run these commands on each host to upgrade to the new software release.

For RHEL/CentOS systems:

```
$ sudo yum upgrade ./greenplum-db-<version>-<platform>.rpm
```

For Ubuntu systems:

```
# apt install ./greenplum-db-<version>-<platform>.deb
```

The `yum` or `apt` command installs the new Greenplum Database software files into a version-specific directory under `/usr/local` and updates the symbolic link `/usr/local/greenplum-db` to point to the new installation directory.

5. *If you used `rpm` to install Greenplum Database to a non-default location on RHEL/CentOS systems*, run `rpm` on each host to upgrade to the new software release and specify the same custom installation directory with the `--prefix` option. For example:

```
$ sudo rpm -U ./greenplum-db-<version>-<platform>.rpm --prefix=<directory>
```

The `rpm` command installs the new Greenplum Database software files into a version-specific directory under the `<directory>` you specify, and updates the symbolic link `<directory>/greenplum-db` to point to the new installation directory.

6. Update the permissions for the new installation. For example, run this command as `root` to change the user and group of the installed files to `gpadmin`.

```
$ sudo chown -R gpadmin:gpadmin /usr/local/greenplum*
```

7. If needed, update the `greenplum_path.sh` file on the master and standby master hosts for use with your specific installation. These are some examples.
 - If Greenplum Database uses LDAP authentication, edit the `greenplum_path.sh` file to add the line:

```
export LDAPCONF=/etc/openldap/ldap.conf
```

- If Greenplum Database uses PL/Java, you might need to set or update the environment variables `JAVA_HOME` and `LD_LIBRARY_PATH` in `greenplum_path.sh`. **Note:** When comparing the previous and new `greenplum_path.sh` files, be aware that installing some Greenplum Database extensions also updates the `greenplum_path.sh` file. The `greenplum_path.sh` from the previous release might contain updates that were the result of installing those extensions.
8. Edit the environment of the Greenplum Database superuser (`gpadmin`) and make sure you are sourcing the `greenplum_path.sh` file for the new installation. For example change the following line in the `.bashrc` or your chosen profile file:

```
source /usr/local/greenplum-db-<current_version>/greenplum_path.sh
```

to:

```
source /usr/local/greenplum-db-<new_version>/greenplum_path.sh
```

Or if you are sourcing a symbolic link (`/usr/local/greenplum-db`) in your profile files, update the link to point to the newly installed version. For example:

```
$ sudo rm /usr/local/greenplum-db
$ sudo ln -s /usr/local/greenplum-db-<new_version> /usr/local/greenplum-db
```

9. Source the environment file you just edited. For example:

```
$ source ~/.bashrc
```

10. After all segment hosts have been upgraded, log in as the `gpadmin` user and restart your Greenplum Database system:

```
# su - gpadmin
$ gpstart
```

11. For Tanzu Greenplum Database, use the `gppkg` utility to re-install Tanzu Greenplum Database extensions. If you were previously using any Tanzu Greenplum Database extensions such as `pgcrypto`, `PL/R`, `PL/Java`, or `PostGIS`, download the corresponding packages from [VMware Tanzu Network](#), and install using this utility. See the extension documentation for details.

Also copy any files that are used by the extensions (such as JAR files, shared object files, and libraries) from the previous version installation directory to the new version installation

directory on the master and segment host systems.

12. If you configured PXF in your previous Greenplum Database installation, you may need to install PXF in your new Greenplum installation, and you may be required to re-initialize or register the PXF service after you upgrade Greenplum Database. Refer to the [Step 2 PXF upgrade procedure](#) for instructions.
13. For Tanzu Greenplum Database, if you configured GPSS in your previous installation, you may be required to perform some upgrade actions, and you must re-restart the GPSS service instances and jobs. Refer to [Step 2](#) of the GPSS upgrade procedure for instructions.

After upgrading Greenplum Database, ensure that all features work as expected. For example, test that backup and restore perform as expected, and Greenplum Database features such as user-defined functions, and extensions such as MADlib and PostGIS perform as expected.

Troubleshooting a Failed Upgrade

If you experience issues during the migration process and have active entitlements for Greenplum Database or Tanzu Greenplum Database that were purchased through VMware, contact VMware Support. Information for contacting VMware Support is at <https://tanzu.vmware.com/support>.

Be prepared to provide the following information:

- A completed [Upgrade Procedure](#)
- Log output from `gpcheckcat` (located in `~/gpAdminLogs`)

PXF Upgrade and Migration

When you upgrade your Greenplum Database system, you must perform some additional steps in order to bring your PXF configuration up to date.

There are two possible scenarios:

1. *Greenplum Database 5.x to 6.x upgrade or migration:*
 - If you are using the `gpghdfs` external table protocol to access data stored in Hadoop in your Greenplum Database 5.x installation, you must first [migrate your gpghdfs external tables](#) to use PXF instead, since Greenplum Database version 6 removes support for the `gpghdfs` protocol.
 - PXF actions are required if you choose a `gpupgrade`-based Greenplum Database 5.x to 6.x upgrade.
 - PXF actions are required if you choose to manually [migrate from Greenplum Database 5.x to 6.x](#).
2. *Greenplum Database 6.x to 6.newer upgrade:* You may be required to perform PXF upgrade actions when you [upgrade from a previous Greenplum Database 6.x version](#). Note that different steps are outlined based on your PXF installation source: a manually installed `rpm` or `deb` package downloaded from Tanzu Network, or the PXF version included with the Greenplum Database Server installer in versions 6.18.x and older.

If you are upgrading a PXF `rpm` or `deb` installation independent of a Greenplum Database upgrade, refer to the [PXF upgrade documentation](#).

Migrating PXF from Greenplum 5.x to 6.x

Note: PXF also supports `gpupgrade`-based Greenplum upgrade in addition to the manual migration described in this topic.

If you are using PXF in your Greenplum Database 5.x installation, upgrade Greenplum Database to version **5.21.2** or newer before you migrate PXF to Greenplum Database **6.10.1** or newer.

The PXF Greenplum Database 5.x to 6.x migration procedure has two parts. You perform one PXF procedure in your Greenplum Database 5.x installation, then install, configure, and migrate data to Greenplum 6.x:

- [Step 1: Complete PXF Greenplum Database 5.x Pre-Migration Actions](#)
- [Step 2: Migrate PXF to Greenplum Database 6.x](#)

Prerequisites

Before migrating PXF from Greenplum 5.x to Greenplum 6.x, ensure that you can:

- Identify your OS Version. Greenplum Database 6.x does not support running PXF on CentOS 6.x or RHEL 6.x due to a limitation with the version of `cURL`. See [Known Issues and Limitations](#) in the Greenplum Database release notes for more details.
- Identify the version number of your Greenplum 5.x installation. If it is older than 5.21.2, upgrade to a newer 5.x version.
- Identify the version of PXF running in the Greenplum 5.x cluster.
- Identify the location of your PXF installation:
 - If you installed PXF from a separate `rpm` or `deb`, the PXF install location is `/usr/local/pxf-gp<greenplum-major-version>`.
 - If you are running the PXF bundled in the Greenplum Database 5.x Server installation, the PXF install location is `$GPHOME/pxf`.
- Determine if you have `gphdfs` external tables defined in your Greenplum 5.x installation.
- Identify the file system location of the PXF `$PXF_CONF` directory in your Greenplum 5.x installation. (If you are unsure of the location, you can find the value in `pxf-env-default.sh`.) In Greenplum 5.15 and later, `$PXF_CONF` identifies the user configuration directory that was provided to the `pxf cluster init` command. This directory contains PXF server configurations, security keytab files, and log files.

Step 1: Complete PXF Greenplum Database 5.x Pre-Migration Actions

Perform this procedure in your Greenplum Database 5.x installation:

1. Log in to the Greenplum Database master node. For example:

```
$ ssh gpadmin@<gp5master>
```

2. Identify and note the Greenplum Database version number of your 5.x installation. For example:

```
gpadmin@gp5master$ psql -d postgres
```

```
SELECT version();

      version
```

PostgreSQL 8.3.23 (Greenplum Database 5.21.2 build

commit:610b6d777436fe4a281a371cae85ac40f01f4f5e) on x86_64-pc-linux-gnu, compiled by GCC gcc (GCC) 6.2.0, 64-bit compiled on Aug 7 2019 20:38:47 (1 row) ""

1. Identify and note the version number of PXF running in your Greenplum 5.x installation. For example:

```
gpadmin@gp5master$ pxf version
```

2. Greenplum 6 removes the `gpghdfs` external table protocol. If you have `gpghdfs` external tables defined in your Greenplum 5.x installation, you must delete or migrate them to `pxf` as described in [Migrating gpghdfs External Tables to PXF](#).
3. Stop PXF on each segment host as described in [Stopping PXF](#).
4. If you plan to install Greenplum Database 6.x on a new set of hosts, be sure to save a copy of the `$PXF_CONF` directory in your Greenplum 5.x installation.
5. Install and configure Greenplum Database 6.x, migrate Greenplum 5.x table definitions and data to your Greenplum 6.x installation, and then continue your PXF migration with [Step 2: Migrating PXF to Greenplum 6.x](#).

Step 2: Migrating PXF to Greenplum 6.x

After you upgrade to Greenplum Database 6.x, and table definitions and data from the Greenplum 5.x installation have been migrated or upgraded, perform the following procedure to configure and start the new PXF software:

1. Log in to the Greenplum Database 6.x master node. For example:

```
$ ssh gpadmin@<gp6master>
```

2. Identify and note the version number of your Greenplum Database 6.x installation.
3. PXF releases different software packages for Greenplum Database version 5 and version 6.
 1. If you are running version 6.x of the independent PXF distribution that you installed via an `rpm` or `deb` in your Greenplum 5.x installation:
 1. Install the same PXF 6.x version *for Greenplum 6* on your Greenplum 6.x hosts as described in [Installing PXF](#).
 2. Copy the PXF extension control file from the PXF installation directory to the new Greenplum 6.x install directory:

```
gpadmin@gp6master$ pxf cluster register
```

3. Start PXF on each host:

```
gpadmin@gp6master$ pxf cluster start
```

4. Skip the following steps and exit this procedure.
2. If you are running PXF version 5.x, you must install the latest independent PXF 5.16.x distribution for Greenplum 6 on your Greenplum 6.x hosts as described in [Installing PXF](#).

Note: If you are interested in running PXF version 6.x, upgrade to that version **after** you complete this entire procedure and verify that PXF is working in your Greenplum 6.x installation.

4. Identify and note the PXF (to) version number. For example:

```
gpadmin@gp6master$ pxf version
```

5. If you installed Greenplum Database 6.x on a new set of hosts, copy the `$PXF_CONF` directory from your Greenplum 5.x installation to the master node. Consider copying the directory to the same file system location at which it resided in the 5.x cluster. For example, if `PXF_CONF=/usr/local/greenplum-pxf`:

```
gpadmin@gp6master$ scp -r gpadmin@<gp5master>:/usr/local/greenplum-pxf /usr/local/
```

6. Initialize PXF on each segment host as described in [Initializing PXF](#), specifying the `PXF_CONF` directory that you copied in the step above.
7. **If you are migrating PXF from Greenplum Database version 5.23 or earlier** and you have configured any JDBC servers that access Kerberos-secured Hive, you must now set the `hadoop.security.authentication` property in the `jdbc-site.xml` file to explicitly identify use of the Kerberos authentication method. Perform the following for each of these server configs:
 1. Navigate to the server configuration directory.
 2. Open the `jdbc-site.xml` file in the editor of your choice and uncomment or add the following property block to the file:

```
<property>
  <name>hadoop.security.authentication</name>
  <value>kerberos</value>
</property>
```

3. Save the file and exit the editor.
8. **If you are migrating PXF from Greenplum Database version 5.26 or earlier:** The PXF `Hive` and `HiveRC` profiles now support column projection using column name-based mapping. If you have any existing PXF external tables that specify one of these profiles, and the external table relied on column index-based mapping, you may be required to drop and recreate the tables:
 1. Identify all PXF external tables that you created that specify a `Hive` or `HiveRC` profile.
 2. For *each* external table that you identify in step 1, examine the definitions of both the PXF external table and the referenced Hive table. If the column names of the PXF external table *do not* match the column names of the Hive table:

1. Drop the existing PXF external table. For example:

```
DROP EXTERNAL TABLE pxf_hive_table1;
```

2. Recreate the PXF external table using the Hive column names. For example:

```
CREATE EXTERNAL TABLE pxf_hive_table1( hivecolname int, hivecolname2 text )
  LOCATION( 'pxf://default.hive_table_name?PROFILE=Hive')
  FORMAT 'custom' (FORMATTER='pxfwritable_import');
```

3. Review any SQL scripts that you may have created that reference the PXF external table, and update column names if required.
9. Synchronize the PXF configuration from the Greenplum Database 6.x master host to the standby master and each segment host in the cluster. For example:

```
gpadmin@gp6master$ pxf cluster sync
```

10. Start PXF on each Greenplum Database 6.x segment host:

```
gpadmin@gp6master$ pxf cluster start
```

Your Greenplum Database cluster is now running version 5.16.x of PXF, and running it from the PXF installation directory (`/usr/local/pxf-gp<greenplum-major-version>`). Should you wish to upgrade PXF in the future, consult the [PXF upgrade documentation](#).

11. Verify the migration by testing that each PXF external table can access the referenced data store.

Migrating gpghdfs External Tables to PXF

You may be using the `gpghdfs` external table protocol in a Greenplum Database version 4 or 5 cluster to access data stored in Hadoop. Greenplum Database version 6 removes support for the `gpghdfs` protocol. To maintain access to Hadoop data in Greenplum 6, you must migrate your `gpghdfs` external tables to use the Greenplum Platform Extension Framework (PXF). This involves setting up PXF and creating new external tables that use the `pxf` external table protocol.

To migrate your `gpghdfs` external tables to use the `pxf` external table protocol, you:

1. [Prepare](#) for the migration.
2. Map configuration properties, and then [set up PXF] (`#id_cfg_prop`).
3. [Create](#) a new `pxf` external table to replace each `gpghdfs` external table.
4. [Verify](#) access to Hadoop files with the `pxf` external tables.
5. [Remove](#) the `gpghdfs` external tables.
6. [Revoke](#) privileges to the `gpghdfs` protocol.
7. Migrate data to Greenplum 6.

Note: If you are migrating `gpghdfs` from a Greenplum Database 5 installation, you perform the migration in the order above in your Greenplum 5 cluster before you migrate data to Greenplum 6.

Note: If you are migrating `gpghdfs` from a Greenplum Database 4 installation, you perform the migration in a similar order. However, since PXF is not available in Greenplum Database 4, you must perform certain actions in the Greenplum 6 installation before you migrate the data:

1. Greenplum 4: [Prepare](#) for the migration.
2. Greenplum 6:
 1. Install and configure the Greenplum 6 software.
 2. Map configuration properties, and then [install and set up PXF](#).
 3. [Create](#) a new `pxf` external table to replace each `gpghdfs` external table.
 4. [Verify](#) access to Hadoop files with the `pxf` external tables.
3. Greenplum 4:
 1. [Remove](#) the `gpghdfs` external tables.
 2. [Revoke](#) privileges to the `gpghdfs` protocol.
4. Migrate Greenplum 4 data to Greenplum 6.

Preparing for the Migration

As you prepare for migrating from `gphdfs` to PXF:

1. Determine which `gphdfs` tables you want to migrate.

You can run the following query to list the `gphdfs` external tables in a database:

```
SELECT n.nspname, d.objid::regclass as tablename
FROM pg_depend d
JOIN pg_exttable x ON ( d.objid = x.reloid )
JOIN pg_extprotocol p ON ( p.oid = d.refobjid )
JOIN pg_class c ON ( c.oid = d.objid )
JOIN pg_namespace n ON ( c.relnamespace = n.oid )
WHERE d.refclassid = 'pg_extprotocol'::regclass AND p.ptcname = 'gphdfs';
```

2. For each table that you choose to migrate, identify the format of the external data and the column definitions. Also identify the options with which the `gphdfs` table was created. You can use the `\dt+` SQL meta-command to obtain this information. For example:

```
\dt+ public.gphdfs_writable_parquet
      External table "public.gphdfs_writable_parquet"
  Column | Type   | Modifiers | Storage | Description
-----+-----+-----+-----+-----
 id      | integer |           | plain   |
 msg     | text    |           | extended |
Type: writable
Encoding: UTF8
Format type: parquet
Format options: formatter 'gphdfs_export'
External options: {}
External location: gphdfs://hdfshost:8020/data/dir1/gphdfs_writepq?codec=GZIP
Execute on: all segments
```

3. Save the information that you gathered above.

Setting Up PXF

PXF does not use the following `gphdfs` configuration options:

gphdfs Configuration Option	Description	pxf Consideration
HADOOP_HOME	Environment variable that identifies the Hadoop installation directory	Not applicable; PXF is bundled with the required dependent Hadoop libraries and JARs
CLASSPATH	Environment variable that identifies the locations of Hadoop JAR and configuration files	Not applicable, PXF automatically includes the Hadoop libraries, JARs, and configuration files that it bundles in the <code>CLASSPATH</code> . PXF also automatically includes user-registered dependencies found in the <code>\$PXF_CONF/lib</code> directory in the <code>CLASSPATH</code> .
gp_hadoop_target_version	Server configuration parameter that identifies the Hadoop distribution	Not applicable, PXF works out-of-the-box with the different Hadoop distributions
gp_hadoop_home	Server configuration parameter that identifies the Hadoop installation directory	Not applicable, PXF works out-of-the-box with the different Hadoop distributions

Configuration properties required by PXF, and the `gphdfs` equivalent, if applicable, include:

Configuration Item	Description	gphdfs Config	pxf Config
JAVA_HOME	Environment variable that identifies the Java installation directory	Set <code>JAVA_HOME</code> on each segment host	Set <code>JAVA_HOME</code> on each segment host
JVM option settings	Options with which to start the JVM	Set options in the <code>GP_JAVA_OPT</code> environment variable in <code>hadoop_env.sh</code>	Set options in the <code>PXF_JVM_OPTS</code> environment variable in <code>\$PX_CONF/conf/pxf-env.sh</code>
PXF Server	PXF server configuration for Hadoop	Not applicable	Configure a PXF server for Hadoop
Privileges	The Greenplum Database privileges required to create external tables in the given protocol	Grant <code>SELECT</code> and <code>INSERT</code> privileges on the <code>gphdfs</code> protocol to appropriate users	Grant <code>SELECT</code> and <code>INSERT</code> privileges on the <code>pxf</code> protocol to appropriate users

After you determine the equivalent PXF configuration properties, you will:

1. Update the Java version installed on each Greenplum Database host, if necessary. PXF supports Java version 8 and 11. If your Greenplum Database cluster hosts are running Java 7, upgrade to Java version 8 or 11 as described in [Installing Java for PXF](#). Note the `$JAVA_HOME` setting.
2. If you are migrating from Greenplum Database 4, or you have not previously used PXF in your Greenplum 5 installation:
 1. [Install](#) the newest version of the independent PXF distribution on your Greenplum Database hosts.
 2. Inform PXF of the `$JAVA_HOME` setting by specifying its value in the `pxf-env.sh` [configuration file](#).

- Edit the `pxf-env.sh` file on the Greenplum master node.

```
gpadmin@gpmaster$ vi /usr/local/pxf-gp6/conf/pxf-env.sh
```

- Locate the `JAVA_HOME` setting in the `pxf-env.sh` file, uncomment if necessary, and set it to your `$JAVA_HOME` value. For example:

```
export JAVA_HOME=/usr/lib/jvm/java-1.8.0-openjdk/jre/
```

3. Register the PXF extension with Greenplum Database:

You must initialize PXF before you can access Hadoop.

1. [Enable the PXF extension](#) and [grant users access to PXF](#).
3. [Configure the PXF Hadoop Connectors](#). This procedure creates a PXF server configuration that provides PXF the information that it requires to access Hadoop. This procedure also synchronizes the configuration changes to all hosts in your Greenplum cluster.
4. Start or restart PXF in your Greenplum Database cluster:

```
gpadmin@gpmaster$ pxf cluster start
```

Creating a PXF External Table

`gphdfs` and `pxf` are both external table protocols. Creating an external table using these protocols is

similar. You specify the external table name and its column definitions. You also specify `LOCATION` and `FORMAT` clauses. `gphdfs` and `pxf` use information in these clauses to determine the location and type of the external data.

Mapping the LOCATION Clause

The `LOCATION` clause of an external table identifies the external table protocol, location of the external data, and protocol- and operation-specific custom options.

The format of `gphdfs`'s `LOCATION` clause is as follows:

```
LOCATION('gphdfs://<hdfs_host>:<hdfs_port>/<path-to-data>? [&<custom-option>=<value>[...]]')
```

`PXF`'s `LOCATION` clause takes the following format when you access data stored on Hadoop:

```
LOCATION('pxf://<path-to-data>?PROFILE=<profile_name> [&SERVER=<server_name>] [&<custom-option>=<value>[...]]')
```

You are not required to specify the HDFS host and port number when you create a PXF external table. PXF obtains this information from the `default` server configuration, or from the server configuration name that you specify in `<server_name>`.

Refer to [Creating an External Table](#) in the PXF documentation for more information about the PXF `CREATE EXTERNAL TABLE` syntax and keywords.

When you create an external table specifying the `gphdfs` protocol, you identify the format of the external data in the `FORMAT` clause (discussed in the next section). PXF uses a `PROFILE` option in the `LOCATION` clause to identify the source and type of the external data.

Data Format	pxf PROFILE
Avro	hdfs:avro
Parquet	hdfs:parquet
Text	hdfs:text

Refer to [Connectors, Data Formats, and Profiles](#) in the PXF documentation for more information about the PXF profiles supported for Hadoop.

Both `gphdfs` and `pxf` utilize custom options in the `LOCATION` clause to identify data-format-, operation-, or profile-specific options supported by the protocol. For example, both `gphdfs` and `pxf` support parquet and compression options on `INSERT` operations.

Should you need to migrate a `gphdfs` writable external table that references an HDFS file to PXF, map `gphdfs` to PXF writable external table compression options as follows:

Description	gphdfs LOCATION Option	pxf LOCATION Option
Use of Compression	compress	Not applicable; depends on the profile - may be uncompressed by default or specified via <code>COMPRESSION_CODEC</code>
Type of compression	compression_type	<code>COMPRESSION_TYPE</code>
Compression codec	codec	<code>COMPRESSION_CODEC</code>

Description	gphdfs LOCATION Option	pxf LOCATION Option
Level of Compression ¹	codec_level	CODEC_LEVEL (supported in PXF 5.14.0 and newer versions)

¹ Avro format `deflate` codec only.

If the HDFS file is a Parquet-format file, map these additional parquet options as follows:

Description	gphdfs LOCATION Option	pxf LOCATION Option
Parquet schema	schema	SCHEMA
Page size	pagesize	PAGE_SIZE
Row group size	rowgroupsize	ROWGROUP_SIZE
Parquet version	parquetversion or pqversion	PARQUET_VERSION
Enable a dictionary	dictionaryenable	The dictionary is always enabled when writing Parquet data with PXF
Dictionary page size	dictionarypagesize	DICTIONARY_PAGE_SIZE

Mapping the FORMAT Options

The `gphdfs` protocol uses the `FORMAT` clause to determine the format of the external data. For Avro- and Parquet-format data, the PXF `FORMAT` clause must identify the name of a custom formatter.

Data Format	gphdfs FORMAT Option	pxf FORMAT Option
Avro	FORMAT 'AVRO'	FORMAT 'CUSTOM' (FORMATTER= 'pxfwritable_import') (read) FORMAT 'CUSTOM' (FORMATTER= 'pxfwritable_export') (write)
Parquet	FORMAT 'PARQUET'	FORMAT 'CUSTOM' (FORMATTER= 'pxfwritable_import') (read) FORMAT 'CUSTOM' (FORMATTER= 'pxfwritable_export') (write)
Text	FORMAT 'TEXT' (DELIMITER ' ')	FORMAT 'TEXT' (DELIMITER ';')

For text data, the `FORMAT` clause may identify a delimiter or other formatting option as described on the [CREATE EXTERNAL TABLE](#) command reference page.

Example gphdfs to pxf External Table Mapping for an HDFS Text File

Example `gphdfs CREATE EXTERNAL TABLE` command to read a text file on HDFS:

```
CREATE EXTERNAL TABLE ext_expenses (
    name text,
    date date,
    amount float4,
    category text,
    desc1 text )
```

```
LOCATION ('gphdfs://hdfshost-1:8081/dir/filename.txt')
FORMAT 'TEXT' (DELIMITER ',');
```

Equivalent `pxf CREATE EXTERNAL TABLE` command, providing that the `default` PXF server contains the Hadoop configuration:

```
CREATE EXTERNAL TABLE ext_expenses_pxf (
    name text,
    date date,
    amount float4,
    category text,
    desc1 text )
LOCATION ('pxf://dir/filename.txt?PROFILE=hdfs:text')
FORMAT 'TEXT' (DELIMITER ',');
```

Verifying Access with PXF

Ensure that you can read from, or write to, each `pxf` external table that you have created.

Removing the gphdfs External Tables

You must remove all `gphdfs` external tables before you can successfully migrate a Greenplum Database 4 or 5 database to Greenplum 6.

Drop an external table as follows:

```
DROP EXTERNAL TABLE <schema_name>.<external_table_name>;
```

Revoking Privileges to the gphdfs Protocol

Before you migrate, you must revoke privileges to the `gphdfs` protocol from each Greenplum Database role to which you assigned the privileges.

Revoke the privilege as follows:

```
ALTER ROLE <role_name> NOCREATEEXTTABLE(protocol='gphdfs',type='readable');
ALTER ROLE <role_name> NOCREATEEXTTABLE(protocol='gphdfs',type='writable');
```

Upgrading PXF When You Upgrade from a Previous Greenplum Database 6.x Version

Note: Starting in Greenplum Database version 6.19.0, the PXF software is no longer bundled in the Greenplum Server distribution. You may be required to download and install the PXF `rpm` or `deb` package to use PXF in your Greenplum cluster as described in the procedures below.

If you are using PXF in your current Greenplum Database 6.x installation, you must perform some PXF upgrade actions when you upgrade to a newer version of Greenplum Database 6.x. This procedure uses *PXF.from* to refer to your currently-installed PXF version.

Note: if you are planning to upgrade a PXF `rpm` or `deb` installation, refer to the [PXF upgrade documentation](#).

The PXF upgrade procedure has two parts. You perform one procedure before, and one procedure after, you upgrade to a new version of Greenplum Database:

- [Step 1: PXF Pre-Upgrade Actions](#)

- Upgrade to a new Greenplum Database version
- [Step 2: Upgrading PXF](#)

Step 1: PXF Pre-Upgrade Actions

Perform this procedure before you upgrade to a new version of Greenplum Database:

1. Log in to the Greenplum Database master node. For example:

```
$ ssh gpadmin@<gpmaster>
```

2. Identify and note the *PXF.from* version number. For example:

```
gpadmin@gpmaster$ pxf version
```

3. Determine if *PXF.from* is a PXF *rpm* or *deb* installation (*/usr/local/pxf-gp<greenplum-major-version>*), or if you are running *PXF.from* from the Greenplum Database server installation (*\$GPHOME/pxf*), and note the answer.
4. If the *PXF.from* version is 5.x, identify the file system location of the *\$PXF_CONF* setting in your PXF 5.x PXF installation; you might need this later. If you are unsure of the location, you can find the value in *pxf-env-default.sh*.
5. Stop PXF on each segment host as described in [Stopping PXF](#).
6. Upgrade to the new version of Greenplum Database and then continue your PXF upgrade with [Step 2: Upgrading PXF](#).

Step 2: Registering or Upgrading PXF

After you upgrade to the new version of Greenplum Database, perform the following procedure to configure the PXF software; you may be required to install the standalone PXF distribution:

1. Log in to the Greenplum Database master node. For example:

```
$ ssh gpadmin@<gpmaster>
```

2. If you previously installed the PXF *rpm* or *deb* on your Greenplum 6.x hosts, you must register it to continue using PXF:

1. Copy the PXF extension files from the PXF installation directory to the new Greenplum 6.x install directory:

```
gpadmin@gpmaster pxf cluster register
```

2. Start PXF on each segment host as described in [Starting PXF](#).
3. Skip the following steps and exit this procedure.
3. Starting in Greenplum Database version 6.19.0, PXF is removed from the Greenplum Server distribution. You must download and install the standalone PXF *rpm* or *deb* package as described in [Installing PXF](#). **Install the same PXF 5.x version as *PXF.from*.**
4. Synchronize the PXF configuration from the master host to the standby master and each Greenplum Database segment host. For example:

```
gpadmin@gpmaster$ $GPHOME/pxf/bin/pxf cluster sync
```

5. Start PXF on each segment host:

```
gpadmin@gpmaster$ $GPHOME/pxf/bin/pxf cluster start
```

Your Greenplum Database cluster is now running the same version of PXF, but running it from the PXF installation directory (`/usr/local/pxf-gp<greenplum-major-version>`). Should you wish to upgrade PXF in the future, consult the [PXF upgrade documentation](#).

Migrating Data from Greenplum 4.3 or 5 to Greenplum 6

You can migrate data from Greenplum Database 4.3 or 5 to Greenplum 6 using the standard backup and restore procedures, `gpbackup` and `gprestore`, or by using `gpcopy` for Tanzu Greenplum.

Note: Open source Greenplum Database is available only for Greenplum Database 5 and later.

Note: You can upgrade a Greenplum Database 5.28 system directly to Greenplum 6.9 or later using `gpupgrade`. You cannot upgrade a Greenplum Database 4.3 system directly to Greenplum 6.

This topic identifies known issues you may encounter when moving data from Greenplum 4.3 to Greenplum 6. You can work around these problems by making needed changes to your Greenplum 4.3 databases so that you can create backups that can be restored successfully to Greenplum 6.

- [Preparing the Greenplum 6 Cluster](#)
- [Preparing Greenplum 4.3 and 5 Databases for Backup](#)
- [Backing Up and Restoring a Database](#)
- [Completing the Migration](#)

Parent topic: [Upgrading to Greenplum 6](#)

Preparing the Greenplum 6 Cluster

- Install and initialize a new Greenplum Database 6 cluster using the version 6 `gpinitssystem` utility.

Note: `gprestore` only supports restoring data to a cluster that has an identical number of hosts and an identical number of segments per host, with each segment having the same `content_id` as the segment in the original cluster. Use `gpcopy` (Tanzu Greenplum) if you need to migrate data to a different-sized Greenplum 6 cluster.

Note: Set the Greenplum Database 6 timezone to a value that is compatible with your host systems. Setting the Greenplum Database timezone prevents Greenplum Database from selecting a timezone each time the cluster is restarted. See [Configuring Timezone and Localization Settings](#) for more information.

- Install the latest release of the Greenplum Backup and Restore utilities, available to download from [VMware Tanzu Network](#) or [github](#).
- If you intend to install Greenplum Database 6 on the same hardware as your 4.3 system, you will need enough disk space to accommodate over five times the original data set (two full copies of the primary and mirror data sets, plus the original backup data in ASCII format) in order to migrate data with `gpbackup` and `gprestore`. Keep in mind that the ASCII backup data will require more disk space than the original data, which may be stored in compressed binary format. Offline backup solutions such as Dell EMC Data Domain can reduce the required disk space on each host.

If you want to migrate your data on the same hardware but do not have enough free disk space on your host systems, `gpcopy` for Tanzu Greenplum provides the `--truncate-source-after` option to truncate each source table after copying the table to the destination cluster and validating that the copy succeeded. This reduces the amount of free space needed to

migrate clusters that reside on the same hardware. See [Migrating Data with gpcopy](#) for more information.

- Install any external modules used in your Greenplum 4.3 system in the Greenplum 6 system before you restore the backup, for example MADlib or PostGIS. If versions of the external modules are not compatible, you may need to exclude tables that reference them when restoring the Greenplum 4.3 backup to Greenplum 6.
- The Greenplum 4.3 Oracle Compatibility Functions module is not compatible with Greenplum 6. Uninstall the module from Greenplum 4.3 by running the `uninstall_orafunc.sql` script before you back up your databases:

```
$ $GPHOME/share/postgresql/contrib/uninstall_orafunc.sql
```

You will also need to drop any dependent database objects that reference compatibility functions.

Install the Oracle Compatibility Functions in Greenplum 6 by creating the `orafce` module in each database where you require the functions:

```
$ psql -d <dbname> -c 'CREATE EXTENSION orafce'
```

See [Installing Additional Supplied Modules](#) for information about installing `orafce` and other modules.

- When restoring language-based user-defined functions, the shared object file must be in the location specified in the `CREATE FUNCTION` SQL command and must have been recompiled on the Greenplum 6 system. This applies to user-defined functions, user-defined types, and any other objects that use custom functions, such as aggregates created with the `CREATE AGGREGATE` command.
- Greenplum 6 provides *resource groups*, an alternative to managing resources using resource queues. Setting the `gp_resource_manager` server configuration parameter to `queue` or `group` selects the resource management scheme the Greenplum Database system will use. The default is `queue`, so no action is required when you move from Greenplum version 4.3 to version 6. To more easily transition from resource queues to resource groups, you can set resource groups to allocate and manage memory in a way that is similar to resource queue memory management. To select this feature, set the `MEMORY_LIMIT` and `MEMORY_SPILL_RATIO` attributes of your resource groups to 0. See [Using Resource Groups](#) for information about enabling and configuring resource groups.
- Filespaces are removed in Greenplum 6. When creating a tablespace, note that different tablespace locations for a primary-mirror pair is no longer supported in Greenplum 6. See [Creating and Managing Tablespaces](#) for information about creating and configuring tablespaces.

Preparing Greenplum 4.3 and 5 Databases for Backup

Note: A Greenplum 4 system must be at least version 4.3.22 to use the `gpbackup` and `gprestore` utilities. A Greenplum 5 system must be at least version 5.5. Be sure to use the latest release of the backup and restore utilities, available for download from [VMware Tanzu Network](#) or [github](#).

Important: Make sure that you have a complete backup of all data in the Greenplum Database 4.3 or 5 cluster, and that you can successfully restore the Greenplum Database cluster if necessary.

Following are some issues that are known to cause errors when restoring a Greenplum 4.3 or 5 backup to Greenplum 6. Keep a list of any changes you make to the Greenplum 4.3 or 5 database to

enable migration so that you can fix them in Greenplum 6 after restoring the backup.

- If you have configured PXF in your Greenplum Database 5 installation, review [Migrating PXF from Greenplum 5](#) to plan for the PXF migration.
- Greenplum Database version 6 removes support for the `gphdfs` protocol. If you have created external tables that use `gphdfs`, remove the external table definitions and (optionally) recreate them to use Greenplum Platform Extension Framework (PXF) before you migrate the data to Greenplum 6. Refer to [Migrating gphdfs External Tables to PXF](#) in the PXF documentation for the migration procedure.
- References to catalog tables or their attributes can cause a restore to fail due to catalog changes from Greenplum 4.3 or 5 to Greenplum 6. Here are some catalog issues to be aware of when migrating to Greenplum 6:
 - In the `pg_class` system table, the `reltoastidxid` column has been removed.
 - In the `pg_stat_replication` system table, the `procpid` column is renamed to `pid`.
 - In the `pg_stat_activity` system table, the `procpid` column is renamed to `pid`. The `current_query` column is replaced by two columns: `state` (the state of the backend), and `query` (the last run query, or currently running query if `state` is `active`).
 - In the `gp_distribution_policy` system table, the `attrnums` column is renamed to `distkey` and its data type is changed to `int2vector`. A backend function `pg_get_table_distributedby()` was added to get the distribution policy for a table as a string.
 - The `__gp_localid` and `__gp_masterid` columns are removed from the `session_level_memory_consumption` system view in Greenplum 6. The underlying external tables and functions are removed from the `gp_toolkit` schema.
 - Filespaces are removed in Greenplum 6. The `pg_filespace` and `pg_filespace_entry` system tables are removed. Any reference to `pg_filespace` or `pg_filespace_entry` will fail in Greenplum 6.
 - Restoring a Greenplum 4 backup can fail due to lack of dependency checking in Greenplum 4 catalog tables. For example, restoring a UDF can fail if it references a custom data type that is created later in the backup file.
- The `INTO error_table` clause of the `CREATE EXTERNAL TABLE` and `COPY` commands was deprecated in Greenplum 4.3 and is unsupported in Greenplum 5 and 6. Remove this clause from any external table definitions before you create a backup of your Greenplum 4.3 system. The `ERROR_TABLE` parameter of the `gpload` utility load control YAML file must also be removed from any `gpload` YAML files before you run `gpload`.
- The `int4_avg_accum()` function signature changed in Greenplum 6 from `int4_avg_accum(bytea, integer)` to `int4_avg_accum(bigint[], integer)`. This function is the state transition function (*sfunc*) called when calculating the average of a series of 4-byte integers. If you have created a custom aggregate in a previous Greenplum release that called the built-in `int4_avg_accum()` function, you will need to revise your aggregate for the new signature.
- The `string_agg(expression)` function has been removed from Greenplum 6. The function concatenates text values into a string. You can replace the single argument function with the function `string_agg(expression, delimiter)` and specify an empty string as the `delimiter`, for example `string_agg(txt_col1, '')`.
- The `offset` argument of the `lag(value, offset[, default])` and `lead(value, offset[, default])` window functions has changed from data type `int8` (`bigint`) in Greenplum 4.3 and

5 to `int4 (integer)` in Greenplum 6. If you used these functions to create views in Greenplum 5, you must remove the views before you migrate to Greenplum 6. Refer to [About Migrating Views Created with lag\(\)/lead\(\) Functions](#) for additional information and migration actions.

- `gpbackup` saves the distribution policy and distribution key for each table in the backup so that data can be restored to the same segment. If a table's distribution key in the Greenplum 4.3 or 5 database is incompatible with Greenplum 6, `gprestore` cannot restore the table to the correct segment in the Greenplum 6 database. This can happen if the distribution key in the older Greenplum release has columns with data types not allowed in Greenplum 6 distribution keys, or if the data representation for data types has changed or is insufficient for Greenplum 6 to generate the same hash value for a distribution key. You should correct these kinds of problems by altering distribution keys in the tables before you back up the Greenplum database.
- Greenplum 6 requires primary keys and unique index keys to match a table's distribution key. The leaf partitions of partitioned tables must have the same distribution policy as the root partition. These known issues should be corrected in the source Greenplum database before you back up the database:
 - If the primary key is different than the distribution key for a table, alter the table to either remove the primary key or change the primary key to match the distribution key.
 - If the key columns for a unique index are not a subset of the distribution key columns, before you back up the source database, drop the index and, optionally, recreate it with a compatible key.
 - If a partitioned table in the source database has a `DISTRIBUTED BY` distribution policy, but has leaf partitions that are `DISTRIBUTED RANDOMLY`, alter the leaf tables to match the root table distribution policy before you back up the source database.
- In Greenplum 4.3, the name provided for a constraint in a `CREATE TABLE` command was the name of the index created to enforce the constraint, which could lead to indexes having the same name. In Greenplum 6, duplicate index names are not allowed; restoring from a Greenplum 4.3 backup that has duplicate index names will generate errors.
- Columns of type `abstime`, `reltime`, `tinterval`, `money`, or `anyarray` are not supported as distribution keys in Greenplum 6.

If you have tables distributed on columns of type `abstime`, `reltime`, `tinterval`, `money`, or `anyarray`, use the `ALTER TABLE` command to set the distribution to `RANDOM` before you back up the database. After the data is restored, you can set a new distribution policy.

- In Greenplum 4.3 and 5, it was possible to `ALTER` a table that has a primary key or unique index to be `DISTRIBUTED RANDOMLY`. Greenplum 6 does not permit tables `DISTRIBUTED RANDOMLY` to have primary keys or unique indexes. Restoring such a table from a Greenplum 4.3 or 5 backup will cause an error.
- Greenplum 6 no longer automatically converts from the deprecated timestamp format `YYYYMMDDHH24MISS`. The format could not be parsed unambiguously in previous Greenplum Database releases. You can still specify the `YYYYMMDDHH24MISS` format in conversion functions such as `to_timestamp` and `to_char` for compatibility with other database systems. You can use input formats for converting text to date or timestamp values to avoid unexpected results or query execution failures. For example, this `SELECT` command returns a timestamp in Greenplum Database 5 and fails in 6.

```
SELECT to_timestamp('20190905140000');
```

To convert the string to a timestamp in Greenplum Database 6, you must use a valid format. Both of these commands return a timestamp in Greenplum Database 6. The first example explicitly specifies a timestamp format. The second example uses the string in a format that Greenplum Database recognizes.

```
SELECT to_timestamp('20190905140000','YYYYMMDDHH24MISS');
SELECT to_timestamp('20190905 140000');
```

The timestamp issue also applies when you use the `::` syntax. In Greenplum Database 6, the first command returns an error. The second command returns a timestamp.

```
SELECT '20190905140000'::timestamp ;
SELECT '20190905 140000'::timestamp ;
```

- Creating a table using the `CREATE TABLE AS` command in Greenplum 4.3 or 5 could create a table with a duplicate distribution key. The `gpbackup` utility saves the table to the backup using a `CREATE TABLE` command that lists the duplicate keys in the `DISTRIBUTED BY` clause. Restoring this backup will cause a duplicate distribution key error. The `CREATE TABLE AS` command was fixed in Greenplum 5.10 to disallow duplicate distribution keys.
- Greenplum 4.3 supports foreign key constraints on columns of different types, for example, `numeric` and `bigint`, with implicit type conversion. Greenplum 5 and 6 do not support implicit type conversion. Restoring a table with a foreign key on columns with different data types causes an error.
- Only Boolean operators can use Boolean negators. In Greenplum Database 4.3 and 5 it was possible to create a non-Boolean operator that specifies a Boolean negator function. For example, this `CREATE OPERATOR` command creates an integer `@@` operator with a Boolean negator:

```
CREATE OPERATOR public.@@ (
    PROCEDURE = int4pl,
    LEFTARG = integer,
    RIGHTARG = integer,
    NEGATOR = OPERATOR(public.!!)
);
```

If you restore a backup containing an operator like this to a Greenplum 6 system, `gprestore` produces an error: `ERROR: only boolean operators can have negators (SQLSTATE 42P13)`.

- In Greenplum Database 4.3 and 5, the undocumented server configuration parameter `allow_system_table_mods` could have a value of `none`, `ddl`, `dml`, or `all`. In Greenplum 6, this parameter has changed to a Boolean value, with a default value of `false`. If there are any references to this parameter in the source database, remove them to prevent errors during the restore.

About Migrating Views Created with `lag()`/`lead()` Functions

The `offset` argument of the `lag(value, offset[, default])` and `lead(value, offset[, default])` window functions has changed from data type `int8 (bigint)` in Greenplum 4.3 and 5 to `int4 (integer)` in Greenplum 6. If you used these functions to create views in Greenplum 5, you must remove the views before you migrate to Greenplum 6.

In addition to the `offset` argument data type change, Greenplum Database 6 removes all data-type-specific `lag()` and `lead()` functions:

```
<data-type> lag( value <data-type>[, offset bigint[, default <data-type>]] )
```

```
<data-type> lag( value <data-type>[, offset bigint[, default <data-type>]] )
```

And replaces them with these more generic function signatures:

```
anyelement lag( value anyelement[, offset integer[, default anyelement]] )
```

```
anyelement lead( value anyelement[, offset integer[, default anyelement]] )
```

To migrate to the `lag()` and `lead()` functions in Greenplum Database 6, you must:

1. Identify all views in your Greenplum Database 5 installation that were created using the two- or three-argument `lag()` or `lead()` functions. Run the following SQL command to identify the views:

```
SELECT ev_class::regclass::text viewname
FROM pg_rewrite pgr
WHERE ev_action ~
      (SELECT $$:winfnoid ($$||string_agg(oid::text,'')||$$) :$$
      FROM (SELECT DISTINCT oid FROM pg_catalog.pg_proc WHERE (proname, proname
space) IN
      (('lag', 11), ('lead', 11)) AND proargtypes[1]=20)s1);
```

2. For each view that you identify:
 1. Note the command that you used to create the view.
 2. Drop the view in your Greenplum 5 installation.
 3. After you migrate to Greenplum 6:
 1. Recreate the view, if desired, in your Greenplum 6 installation; be sure to specify an `integer`-type `offset` argument to the function. (You are not required to modify the `value` or `default` argument types in the function because an `anyelement` type accepts any data type.)
 2. If you have any scripts that invoke `lag()` or `lead()` functions, ensure that that they reference an `integer`-type `offset`.

Backing Up and Restoring a Database

First use `gpbbackup` to create a `--metadata-only` backup from the source Greenplum database and restore it to the Greenplum 6 system. This helps find any additional problems that are not identified in [Preparing Greenplum 4.3 and 5 Databases for Backup](#). Refer to the [Greenplum Backup and Restore documentation](#) for syntax and examples for the `gpbbackup` and `gprestore` utilities.

Review the `gprestore` log file for error messages and correct any remaining problems in the source Greenplum database.

When you are able to restore a metadata backup successfully, create the full backup and then restore it to the Greenplum 6 system, or use `gpcopy` (Tanzu Greenplum) to transfer the data. If needed, use the `gpbbackup` or `gprestore` filter options to omit schemas or tables that cannot be restored without error.

If you use `gpcopy` to migrate Tanzu Greenplum data, initiate the `gpcopy` operation from the Greenplum 4.3.26 (or later) or the 5.9 (or later) cluster. See [Migrating Data with gpcopy](#) for more information.

Important: When you restore a backup taken from a Greenplum Database 4.3 or 5 system,

`gprestore` warns that the restore will use legacy hash operators when loading the data. This is because Greenplum 6 has new hash algorithms that map distribution keys to segments, but the data in the backup set must be restored to the same segments as the cluster from which the backup was taken. The `gprestore` utility sets the `gp_use_legacy_hashops` server configuration parameter to `on` when restoring to Greenplum 6 from an earlier version so that the restored tables are created using the legacy operator classes instead of the new default operator classes.

After restoring, you can redistribute these tables with the `gp_use_legacy_hashops` parameter set to `off` so that the tables use the new Greenplum 6 hash operators. See [Working With Hash Operator Classes in Greenplum 6](#) for more information and examples.

Completing the Migration

Migrate any tables you skipped during the restore using other methods, for example using the `COPY TO` command to create an external file and then loading the data from the external file into Greenplum 6 with the `COPY FROM` command.

Recreate any objects you dropped in the Greenplum 4.3 or 5 database to enable migration, such as external tables, indexes, user-defined functions, or user-defined aggregates.

Here are some additional items to consider to complete your migration to Greenplum 6.

- Greenplum Database 5 and 6 remove automatic casts between the text type and other data types. After you migrate from Greenplum Database version 4.3 to version 6, this changed behavior may impact existing applications and queries. Refer to [About Implicit Text Casting in Greenplum Database](#) for information, including a discussion about VMware supported and unsupported workarounds.
- After migrating data you may need to modify SQL scripts, administration scripts, and user-defined functions as necessary to account for changes in Greenplum Database version 6. Review the [Tanzu Greenplum 6.0.0 Release Notes](#) for features and changes that may necessitate post-migration tasks.
- To use the new Greenplum 6 default hash operator classes, use the command `ALTER TABLE <table> SET DISTRIBUTED BY (<key>)` to redistribute tables restored from Greenplum 4.3 or 5 backups. The `gp_use_legacy_hashops` parameter must be set to `off` when you run the command. See [Working With Hash Operator Classes in Greenplum 6](#) for more information about hash operator classes.

Working With Hash Operator Classes in Greenplum 6

Greenplum 6 has new *jump consistent* hash operators that map distribution keys for distributed tables to the segments. The new hash operators enable faster database expansion because they don't require redistributing rows unless they map to a different segment. The hash operators used in Greenplum 4.3 and 5 are present in Greenplum 6 as non-default legacy hash operator classes. For example, for integer columns, the new hash operator class is named `int_ops` and the legacy operator class is named `cdbhash_int_ops`.

This example creates a table using the legacy hash operator class `cdbhash_int_ops`.

```
test=# SET gp_use_legacy_hashops=on;
SET
test=# CREATE TABLE t1 (
      c1 integer,
      c2 integer,
      p integer
) DISTRIBUTED BY (c1);
CREATE TABLE
```

```
test=# \d+ t1
```

Column	Type	Modifiers	Storage	Stats target	Description
c1	integer		plain		
c2	integer		plain		
p	integer		plain		

Distributed by: (c1)

Notice that the distribution key is `c1`. If the `gp_use_legacy_hashops` parameter is `on` and the operator class is a legacy operator class, the operator class name is not shown. However, if `gp_use_legacy_hashops` is `off`, the legacy operator class name is reported with the distribution key.

```
test=# SET gp_use_legacy_hashops=off;
SET
test=# \d+ t1
```

Column	Type	Modifiers	Storage	Stats target	Description
c1	integer		plain		
c2	integer		plain		
p	integer		plain		

Distributed by: (c1 cdbhash_int4_ops)

The operator class name is reported only when it does not match the setting of the `gp_use_legacy_hashops` parameter.

To change the table to use the new jump consistent operator class, use the `ALTER TABLE` command to redistribute the table with the `gp_use_legacy_hashops` parameter set to `off`.

Note: Redistributing tables with a large amount of data can take a long time.

```
test=# SHOW gp_use_legacy_hashops;
gp_use_legacy_hashops
-----
off
(1 row)

test=# ALTER TABLE t1 SET DISTRIBUTED BY (c1);
ALTER TABLE
test=# \d+ t1
```

Column	Type	Modifiers	Storage	Stats target	Description
c1	integer		plain		
c2	integer		plain		
p	integer		plain		

Distributed by: (c1)

To verify the default jump consistent operator class has been used, set `gp_use_legacy_hashops` to `on` before you show the table definition.

```
test=# SET gp_use_legacy_hashops=on;
SET
test=# \d+ t1
```

Column	Type	Modifiers	Storage	Stats target	Description
c1	integer		plain		
c2	integer		plain		
p	integer		plain		

Distributed by: (c1 int4_ops)

Enabling iptables (Optional)

On Linux systems, you can configure and enable the `iptables` firewall to work with Greenplum Database.

Note: Greenplum Database performance might be impacted when `iptables` is enabled. You should test the performance of your application with `iptables` enabled to ensure that performance is acceptable.

For more information about `iptables` see the `iptables` and firewall documentation for your operating system. See also [Disabling SELinux and Firewall Software](#).

How to Enable iptables

1. As `gpadmin`, run this command on the Greenplum Database master host to stop Greenplum Database:

```
$ gpstop -a
```

2. On the Greenplum Database hosts:

1. Update the file `/etc/sysconfig/iptables` based on the [Example iptables Rules](#).
2. As root user, run these commands to enable `iptables`:

```
# chkconfig iptables on
# service iptables start
```

3. As `gpadmin`, run this command on the Greenplum Database master host to start Greenplum Database:

```
$ gpstart -a
```

Warning: After enabling `iptables`, this error in the `/var/log/messages` file indicates that the setting for the `iptables` table is too low and needs to be increased.

```
ip_conntrack: table full, dropping packet.
```

As root, run this command to view the `iptables` table value:

```
# sysctl net.ipv4.netfilter.ip_conntrack_max
```

To ensure that the Greenplum Database workload does not overflow the `iptables` table, as root, set it to the following value:

```
# sysctl net.ipv4.netfilter.ip_conntrack_max=6553600
```

The value might need to be adjusted for your hosts. To maintain the value after reboot, you can update the `/etc/sysctl.conf` file as discussed in [Setting the Greenplum Recommended OS Parameters](#).

Parent topic: [Installing and Upgrading Greenplum](#)

Example iptables Rules

When `iptables` is enabled, `iptables` manages the IP communication on the host system based on configuration settings (rules). The example rules are used to configure `iptables` for Greenplum

Database master host, standby master host, and segment hosts.

- [Example Master and Standby Master iptables Rules](#)
- [Example Segment Host iptables Rules](#)

The two sets of rules account for the different types of communication Greenplum Database expects on the master (primary and standby) and segment hosts. The rules should be added to the `/etc/sysconfig/iptables` file of the Greenplum Database hosts. For Greenplum Database, `iptables` rules should allow the following communication:

- For customer facing communication with the Greenplum Database master, allow at least `postgres` and `28080` (`eth1` interface in the example).
- For Greenplum Database system interconnect, allow communication using `tcp`, `udp`, and `icmp` protocols (`eth4` and `eth5` interfaces in the example).

The network interfaces that you specify in the `iptables` settings are the interfaces for the Greenplum Database hosts that you list in the `hostfile_gpinitssystem` file. You specify the file when you run the `gpinitssystem` command to initialize a Greenplum Database system. See [Initializing a Greenplum Database System](#) for information about the `hostfile_gpinitssystem` file and the `gpinitssystem` command.

- For the administration network on a Greenplum DCA, allow communication using `ssh`, `ntp`, and `icmp` protocols. (`eth0` interface in the example).

In the `iptables` file, each append rule command (lines starting with `-A`) is a single line.

The example rules should be adjusted for your configuration. For example:

- The append command, the `-A` lines and connection parameter `-i` should match the connectors for your hosts.
- the CIDR network mask information for the source parameter `-s` should match the IP addresses for your network.

Example Master and Standby Master iptables Rules

Example `iptables` rules with comments for the `/etc/sysconfig/iptables` file on the Greenplum Database master host and standby master host.

```
*filter
# Following 3 are default rules. If the packet passes through
# the rule set it gets these rule.
# Drop all inbound packets by default.
# Drop all forwarded (routed) packets.
# Let anything outbound go through.
:INPUT DROP [0:0]
:FORWARD DROP [0:0]
:OUTPUT ACCEPT [0:0]
# Accept anything on the loopback interface.
-A INPUT -i lo -j ACCEPT
# If a connection has already been established allow the
# remote host packets for the connection to pass through.
-A INPUT -m state --state ESTABLISHED,RELATED -j ACCEPT
# These rules let all tcp and udp through on the standard
# interconnect IP addresses and on the interconnect interfaces.
# NOTE: gpsyncmaster uses random tcp ports in the range 1025 to 65535
# and Greenplum Database uses random udp ports in the range 1025 to 65535.
-A INPUT -i eth4 -p udp -s 192.0.2.0/22 -j ACCEPT
-A INPUT -i eth5 -p udp -s 198.51.100.0/22 -j ACCEPT
-A INPUT -i eth4 -p tcp -s 192.0.2.0/22 -j ACCEPT --syn -m state --state NEW
-A INPUT -i eth5 -p tcp -s 198.51.100.0/22 -j ACCEPT --syn -m state --state NEW
```

```

\# Allow udp/tcp ntp connections on the admin network on Greenplum DCA.
-A INPUT -i eth0 -p udp --dport ntp -s 203.0.113.0/21 -j ACCEPT
-A INPUT -i eth0 -p tcp --dport ntp -s 203.0.113.0/21 -j ACCEPT --syn -m state --state NEW
# Allow ssh on all networks (This rule can be more strict).
-A INPUT -p tcp --dport ssh -j ACCEPT --syn -m state --state NEW
# Allow Greenplum Database on all networks.
-A INPUT -p tcp --dport postgres -j ACCEPT --syn -m state --state NEW
# Allow Greenplum Command Center on the customer facing network.
-A INPUT -i eth1 -p tcp --dport 28080 -j ACCEPT --syn -m state --state NEW
# Allow ping and any other icmp traffic on the interconnect networks.
-A INPUT -i eth4 -p icmp -s 192.0.2.0/22 -j ACCEPT
-A INPUT -i eth5 -p icmp -s 198.51.100.0/22 -j ACCEPT
\# Allow ping only on the admin network on Greenplum DCA.
-A INPUT -i eth0 -p icmp --icmp-type echo-request -s 203.0.113.0/21 -j ACCEPT
# Log an error if a packet passes through the rules to the default
# INPUT rule (a DROP).
-A INPUT -m limit --limit 5/min -j LOG --log-prefix "iptables denied: " --log-level 7
COMMIT

```

Example Segment Host iptables Rules

Example `iptables` rules for the `/etc/sysconfig/iptables` file on the Greenplum Database segment hosts. The rules for segment hosts are similar to the master rules with fewer interfaces and fewer `udp` and `tcp` services.

```

*filter
:INPUT DROP
:FORWARD DROP
:OUTPUT ACCEPT
-A INPUT -i lo -j ACCEPT
-A INPUT -m state --state ESTABLISHED,RELATED -j ACCEPT
-A INPUT -i eth2 -p udp -s 192.0.2.0/22 -j ACCEPT
-A INPUT -i eth3 -p udp -s 198.51.100.0/22 -j ACCEPT
-A INPUT -i eth2 -p tcp -s 192.0.2.0/22 -j ACCEPT --syn -m state --state NEW
-A INPUT -i eth3 -p tcp -s 198.51.100.0/22 -j ACCEPT --syn -m state --state NEW
-A INPUT -p tcp --dport ssh -j ACCEPT --syn -m state --state NEW
-A INPUT -i eth2 -p icmp -s 192.0.2.0/22 -j ACCEPT
-A INPUT -i eth3 -p icmp -s 198.51.100.0/22 -j ACCEPT
-A INPUT -i eth0 -p icmp --icmp-type echo-request -s 203.0.113.0/21 -j ACCEPT
-A INPUT -m limit --limit 5/min -j LOG --log-prefix "iptables denied: " --log-level 7
COMMIT

```

Installation Management Utilities

References for the command-line management utilities used to install and initialize a Greenplum Database system.

For a full reference of all Greenplum Database utilities, see the [Greenplum Database Utility Guide](#).

The following Greenplum Database management utilities are located in `$GPHOME/bin`.

Greenplum Environment Variables

Reference of the environment variables to set for Greenplum Database.

Set these in your user's startup shell profile (such as `~/.bashrc` or `~/.bash_profile`), or in `/etc/profile` if you want to set them for all users.

- [Required Environment Variables](#)
- [Optional Environment Variables](#)

Parent topic: [Installing and Upgrading Greenplum](#)

Required Environment Variables

Note: `GPHOME`, `PATH` and `LD_LIBRARY_PATH` can be set by sourcing the `greenplum_path.sh` file from your Greenplum Database installation directory

Parent topic: [Greenplum Environment Variables](#)

GPHOME

This is the installed location of your Greenplum Database software. For example:

```
GPHOME=/usr/local/greenplum-db-6.18.1
export GPHOME
```

PATH

Your `PATH` environment variable should point to the location of the Greenplum Database `bin` directory. For example:

```
PATH=$GPHOME/bin:$PATH
export PATH
```

LD_LIBRARY_PATH

The `LD_LIBRARY_PATH` environment variable should point to the location of the Greenplum Database/PostgreSQL library files. For example:

```
LD_LIBRARY_PATH=$GPHOME/lib
export LD_LIBRARY_PATH
```

MASTER_DATA_DIRECTORY

This should point to the directory created by the `gpinitssystem` utility in the master data directory location. For example:

```
MASTER_DATA_DIRECTORY=/data/master/gpseg-1
export MASTER_DATA_DIRECTORY
```

Optional Environment Variables

The following are standard PostgreSQL environment variables, which are also recognized in Greenplum Database. You may want to add the connection-related environment variables to your profile for convenience, so you do not have to type so many options on the command line for client connections. Note that these environment variables should be set on the Greenplum Database master host only.

Parent topic: [Greenplum Environment Variables](#)

PGAPPNAME

The name of the application that is usually set by an application when it connects to the server. This name is displayed in the activity view and in log entries. The `PGAPPNAME` environmental variable behaves the same as the `application_name` connection parameter. The default value for `application_name` is `psql`. The name cannot be longer than 63 characters.

PGDATABASE

The name of the default database to use when connecting.

PGHOST

The Greenplum Database master host name.

PGHOSTADDR

The numeric IP address of the master host. This can be set instead of or in addition to `PGHOST` to avoid DNS lookup overhead.

PGPASSWORD

The password used if the server demands password authentication. Use of this environment variable is not recommended for security reasons (some operating systems allow non-root users to see process environment variables via `ps`). Instead consider using the `~/.pgpass` file.

PGPASSFILE

The name of the password file to use for lookups. If not set, it defaults to `~/.pgpass`. See the topic about [The Password File](#) in the PostgreSQL documentation for more information.

PGOPTIONS

Sets additional configuration parameters for the Greenplum Database master server.

PGPORT

The port number of the Greenplum Database server on the master host. The default port is 5432.

PGUSER

The Greenplum Database user name used to connect.

PGDATESTYLE

Sets the default style of date/time representation for a session. (Equivalent to `SET datestyle TO...`)

PGTZ

Sets the default time zone for a session. (Equivalent to `SET timezone TO...`)

PGCLIENTENCODING

Sets the default client character set encoding for a session. (Equivalent to `SET client_encoding TO...`)

Example Ansible Playbook

A sample Ansible playbook to install a Greenplum Database software release onto the hosts that will comprise a Greenplum Database system.

This Ansible playbook shows how tasks described in [Installing the Greenplum Database Software](#) might be automated using [Ansible](#).

Important: This playbook is provided as an *example only* to illustrate how Greenplum Database cluster configuration and software installation tasks can be automated using provisioning tools such as Ansible, Chef, or Puppet. VMware does not provide support for Ansible or for the playbook presented in this example.

The example playbook is designed for use with CentOS 7. It creates the `gpadmin` user, installs the Greenplum Database software release, sets the owner and group of the installed software to `gpadmin`, and sets the Pam security limits for the `gpadmin` user.

You can revise the script to work with your operating system platform and to perform additional host configuration tasks.

Following are steps to use this Ansible playbook.

1. Install Ansible on the control node using your package manager. See the [Ansible documentation](#) for help with installation.
2. Set up passwordless SSH from the control node to all hosts that will be a part of the Greenplum Database cluster. You can use the `ssh-copy-id` command to install your public SSH key on each host in the cluster. Alternatively, your provisioning software may provide more convenient ways to securely install public keys on multiple hosts.
3. Create an Ansible inventory by creating a file called `hosts` with a list of the hosts that will comprise your Greenplum Database cluster. For example:

```
mdw
sdw1
sdw2
...
```

This file can be edited and used with the Greenplum Database `gpssh-exkeys` and `gpinitssystem` utilities later on.

4. Copy the playbook code below to a file `ansible-playbook.yml` on your Ansible control node.
5. Edit the playbook variables at the top of the playbook, such as the `gpadmin` administrative user and password to create, and the version of Greenplum Database you are installing.

6. Run the playbook, passing the package to be installed to the `package_path` parameter.

```
ansible-playbook ansible-playbook.yml -i hosts -e package_path=./greenplum-db-6.0.0-rhel7-x86_64.rpm
```

Ansible Playbook - Greenplum Database Installation for CentOS 7

```
---

- hosts: all
  vars:

Greenplum Database Security Configuration Guide

This guide describes how to secure a Greenplum Database system. The guide assumes knowledge of Linux/UNIX system administration and database management systems. Familiarity with structured query language (SQL) is helpful.

Important: Because Tanzu Greenplum is based on PostgreSQL, certain commercial security scanning software, when trying to identify Tanzu Greenplum Database vulnerabilities, may use a PostgreSQL database profile. The reports generated by these tools can produce misleading results, and cannot be trusted as an accurate assessment of vulnerabilities that may exist in Tanzu Greenplum. For further assistance, or to report any specific Tanzu Greenplum security concerns, refer to the [VMware Tanzu Security Response Center](#) guidelines.

Because Greenplum Database is based on PostgreSQL 9.4, this guide assumes some familiarity with PostgreSQL. References to [PostgreSQL documentation](#) are provided throughout this guide for features that are similar to those in Greenplum Database.

This information is intended for system administrators responsible for administering a Greenplum Database system.

- **Securing the Database**
Introduces Greenplum Database security topics.
- **Greenplum Database Ports and Protocols**
Lists network ports and protocols used within the Greenplum cluster.
- **Configuring Client Authentication**
Describes the available methods for authenticating Greenplum Database clients.
- **Configuring Database Authorization**
Describes how to restrict authorization access to database data at the user level by using roles and permissions.
- **Auditing**
Describes Greenplum Database events that are logged and should be monitored to detect security threats.
- **Encrypting Data and Database Connections**
Describes how to encrypt data at rest in the database or in transit over the network, to protect from eavesdroppers or man-in-the-middle attacks.
- **Security Best Practices**
Describes basic security best practices that you should follow to ensure the highest level of system security.

Securing the Database

Introduces Greenplum Database security topics.

The intent of security configuration is to configure the Greenplum Database server to eliminate as many security vulnerabilities as possible. This guide provides a baseline for minimum security

requirements, and is supplemented by additional security documentation.

The essential security requirements fall into the following categories:

- [Authentication](#) covers the mechanisms that are supported and that can be used by the Greenplum database server to establish the identity of a client application.
- [Authorization](#) pertains to the privilege and permission models used by the database to authorize client access.
- [Auditing](#), or log settings, covers the logging options available in Greenplum Database to track successful or failed user actions.
- [Data Encryption](#) addresses the encryption capabilities that are available for protecting data at rest and data in transit. This includes the security certifications that are relevant to the Greenplum Database.

Accessing a Kerberized Hadoop Cluster

You can use the Greenplum Platform Extension Framework (PXF) to read or write external tables referencing files in a Hadoop file system. If the Hadoop cluster is secured with Kerberos (“Kerberized”), you must configure Greenplum Database and PXF to allow users accessing external tables to authenticate with Kerberos. Refer to [Configuring PXF for Secure HDFS](#) for the procedure to perform this setup.

Platform Hardening

Platform hardening involves assessing and minimizing system vulnerability by following best practices and enforcing federal security standards. Hardening the product is based on the US Department of Defense (DoD) guidelines Security Template Implementation Guides (STIG). Hardening removes unnecessary packages, disables services that are not required, sets up restrictive file and directory permissions, removes unowned files and directories, performs authentication for single-user mode, and provides options for end users to configure the package to be compliant to the latest STIGs.

Parent topic: [Greenplum Database Security Configuration Guide](#)

Greenplum Database Ports and Protocols

Lists network ports and protocols used within the Greenplum cluster.

Greenplum Database clients connect with TCP to the Greenplum master instance at the client connection port, 5432 by default. The listen port can be reconfigured in the `postgresql.conf` configuration file. Client connections use the PostgreSQL libpq API. The `psql` command-line interface, several Greenplum utilities, and language-specific programming APIs all either use the libpq library directly or implement the libpq protocol internally.

Each segment instance also has a client connection port, used solely by the master instance to coordinate database operations with the segments. The `gpstate -p` command, run on the Greenplum master, lists the port assignments for the Greenplum master and the primary segments and mirrors. For example:

```
[gpadmin@mdw ~]$ gpstate -p
20190403:02:57:04:011030 gpstate:mdw:gpadmin-[INFO]:-Starting gpstate with args: -p

```

Additional Greenplum Database network connections are created for features such as standby replication, segment mirroring, statistics collection, and data exchange between segments. Some persistent connections are established when the database starts up and other transient connections are created during operations such as query execution. Transient connections for query execution processes, data movement, and statistics collection use available ports in the range 1025 to 65535 with both TCP and UDP protocols.

Note: To avoid port conflicts between Greenplum Database and other applications when initializing Greenplum Database, do not specify Greenplum Database ports in the range specified by the operating system parameter `net.ipv4.ip_local_port_range`. For example, if `net.ipv4.ip_local_port_range = 10000 65535`, you could set the Greenplum Database base port numbers to values outside of that range:

```

PORT_BASE = 6000
MIRROR_PORT_BASE = 7000

```

Some add-on products and services that work with Greenplum Database have additional networking requirements. The following table lists ports and protocols used within the Greenplum cluster, and includes services and applications that integrate with Greenplum Database.

Service	Protocol/Port	Description
Master SQL client connection	TCP 5432, libpq	SQL client connection port on the Greenplum master host. Supports clients using the PostgreSQL libpq API. Configurable.
Segment SQL client connection	varies, libpq	The SQL client connection port for a segment instance. Each primary and mirror segment on a host must have a unique port. Ports are assigned when the Greenplum system is initialized or expanded. The <code>gp_segment_configuration</code> system catalog records port numbers for each primary (p) or mirror (m) segment in the <code>port</code> column. Run <code>gpstate -p</code> to view the ports in use.
Segment mirroring port	varies, libpq	The port where a segment receives mirrored blocks from its primary. The port is assigned when the mirror is set up. The <code>gp_segment_configuration</code> system catalog records port numbers for each primary (p) or mirror (m) segment in the <code>port</code> column. Run <code>gpstate -p</code> to view the ports in use.
Greenplum Database Interconnect	UDP 1025-65535, dynamically allocated	The Interconnect transports database tuples between Greenplum segments during query execution.
Standby master client listener	TCP 5432, libpq	SQL client connection port on the standby master host. Usually the same as the master client connection port. Configure with the <code>gpinitstandby</code> utility <code>-P</code> option.
Standby master replicator	TCP 1025-65535, <code>gpsyncmaster</code>	The <code>gpsyncmaster</code> process on the master host establishes a connection to the secondary master host to replicate the master's log to the standby master.
Greenplum Database file load and transfer utilities: <code>gpfdist</code> , <code>gpload</code> .	TCP 8080, HTTP TCP 9000, HTTPS	The <code>gpfdist</code> file serving utility can run on Greenplum hosts or external hosts. Specify the connection port with the <code>-p</code> option when starting the server.
		The <code>gpload</code> utility runs one or more instances of <code>gpfdist</code> with ports or port ranges specified in a configuration file.
Gpperfmon agents	TCP 8888	Connection port for <code>gpperfmon</code> agents (<code>gpmmon</code> and <code>gpsmon</code>) executing on Greenplum Database hosts. Configure by setting the <code>gpperfmon_port</code> configuration variable in <code>postgresql.conf</code> on master and segment hosts.
Backup completion notification	TCP 25, TCP 587, SMTP	The <code>gpbackup</code> backup utility can optionally send email to a list of email addresses at completion of a backup. The SMTP service must be enabled on the Greenplum master host.
Greenplum Database secure shell (SSH): <code>gpssh</code> , <code>gpscp</code> , <code>gpssh-exkeys</code> , <code>gppkg</code>	TCP 22, SSH	Many Greenplum utilities use <code>scp</code> and <code>ssh</code> to transfer files between hosts and manage the Greenplum system within the cluster.
Greenplum Platform Extension Framework (PXF)	TCP 5888	The PXF Java service runs on port number 5888 on each Greenplum Database segment host.

Service	Protocol/Port	Description
Greenplum Command Center (GPCC)	TCP 28080, HTTP/HTTPS, WebSocket (WS), Secure WebSocket (WSS)	The GPCC web server (<code>gpccws</code> process) runs on the Greenplum Database master host or standby master host. The port number is configured at installation time.
Greenplum Command Center (GPCC)	TCP 8899, rpc port	A GPCC agent (<code>ccagent</code> process) on each Greenplum Database segment host connects to the GPCC rpc backend at port number 8899 on the GPCC web server host.
Greenplum Command Center (GPCC)	UNIX domain socket, agent	Greenplum Database processes transmit datagrams to the GPCC agent (<code>ccagent</code> process) on each segment host using a UNIX domain socket.
GPTText	TCP 2188 (base port)	ZooKeeper client ports. ZooKeeper uses a range of ports beginning at the base port number. The base port number and maximum port number are set in the GPTText installation configuration file at installation time. The default base port number is 2188.
GPTText	TCP 18983 (base port)	GPTText (Apache Solr) nodes. GPTText nodes use a range of ports beginning at the base port number. The base port number and maximum port number are set in the GPTText installation configuration file at installation time. The default base port number is 18983.
EMC Data Domain and DD Boost	TCP/UDP 111, NFS portmapper	Used to assign a random port for the mountd service used by NFS and DD Boost. The mountd service port can be statically assigned on the Data Domain server.
EMC Data Domain and DD Boost	TCP 2052	Main port used by NFS mountd. This port can be set on the Data Domain system using the <code>nfs set mountd-port</code> command .
EMC Data Domain and DD Boost	TCP 2049, NFS	Main port used by NFS. This port can be configured using the <code>nfs set server-port</code> command on the Data Domain server.
EMC Data Domain and DD Boost	TCP 2051, replication	Used when replication is configured on the Data Domain system. This port can be configured using the <code>replication modify</code> command on the Data Domain server.
Pgbouncer connection pooler	TCP, libpq	The pgbouncer connection pooler runs between libpq clients and Greenplum (or PostgreSQL) databases. It can be run on the Greenplum master host, but running it on a host outside of the Greenplum cluster is recommended. When it runs on a separate host, pgbouncer can act as a warm standby mechanism for the Greenplum master host, switching to the Greenplum standby host without requiring clients to reconfigure. Set the client connection port and the Greenplum master host address and port in the pgbouncer.ini configuration file.

Configuring Client Authentication

Describes the available methods for authenticating Greenplum Database clients.

When a Greenplum Database system is first initialized, the system contains one predefined superuser role. This role will have the same name as the operating system user who initialized the Greenplum Database system. This role is referred to as `gadmin`. By default, the system is configured to only allow local connections to the database from the `gadmin` role. If you want to allow any other roles to connect, or if you want to allow connections from remote hosts, you have to configure Greenplum Database to allow such connections. This section explains how to configure

client connections and authentication to Greenplum Database.

- [Allowing Connections to Greenplum Database](#)
- [Editing the pg_hba.conf File](#)
- [Authentication Methods](#)
- [Limiting Concurrent Connections](#)
- [Encrypting Client/Server Connections](#)

Parent topic: [Greenplum Database Security Configuration Guide](#)

Allowing Connections to Greenplum Database

Client access and authentication is controlled by a configuration file named `pg_hba.conf` (the standard PostgreSQL host-based authentication file). For detailed information about this file, see [The pg_hba.conf File](#) in the PostgreSQL documentation.

In Greenplum Database, the `pg_hba.conf` file of the master instance controls client access and authentication to your Greenplum system. The segments also have `pg_hba.conf` files, but these are already correctly configured to only allow client connections from the master host. The segments never accept outside client connections, so there is no need to alter the `pg_hba.conf` file on segments.

The general format of the `pg_hba.conf` file is a set of records, one per line. Blank lines are ignored, as is any text after a `#` comment character. A record is made up of a number of fields which are separated by spaces and/or tabs. Fields can contain white space if the field value is quoted. Records cannot be continued across lines.

A record can have one of seven formats:

```
local      <database> <user> <auth-method> [<auth-options>]
host       <database> <user> <address> <auth-method> [<auth-options>]
hostssl    <database> <user> <address> <auth-method> [<auth-options>]
hostnossl  <database> <user> <address> <auth-method> [<auth-options>]
host       <database> <user> <IP-address> <IP-mask> <auth-method> [<auth-options>]
]
hostssl    <database> <user> <IP-address> <IP-mask> <auth-method> [<auth-options>]
]
hostnossl  <database> <user> <IP-address> <IP-mask> <auth-method> [<auth-options>]
]
```

The meaning of the `pg_hba.conf` fields is as follows:

local

Matches connection attempts using UNIX-domain sockets. Without a record of this type, UNIX-domain socket connections are disallowed.

host

Matches connection attempts made using TCP/IP. Remote TCP/IP connections will not be possible unless the server is started with an appropriate value for the `listen_addresses` server configuration parameter. Greenplum Database by default allows connections from all hosts (`*`).

hostssl

Matches connection attempts made using TCP/IP, but only when the connection is made with SSL encryption. SSL must be enabled at server start time by setting the `ssl` configuration parameter to on. Requires SSL authentication be configured in `postgresql.conf`. See [Configuring postgresql.conf for SSL Authentication](#).

hostnossl

Matches connection attempts made over TCP/IP that do not use SSL.

database

Specifies which database names this record matches. The value `all` specifies that it matches all databases. Multiple database names can be supplied by separating them with commas. A separate file containing database names can be specified by preceding the file name with `@`.

user

Specifies which database role names this record matches. The value `all` specifies that it matches all roles. If the specified role is a group and you want all members of that group to be included, precede the role name with a `+`. Multiple role names can be supplied by separating them with commas. A separate file containing role names can be specified by preceding the file name with `@`.

address

Specifies the client machine addresses that this record matches. This field can contain either a host name, an IP address range, or one of the special key words mentioned below.

An IP address range is specified using standard numeric notation for the range's starting address, then a slash (/) and a CIDR mask length. The mask length indicates the number of high-order bits of the client IP address that must match. Bits to the right of this should be zero in the given IP address. There must not be any white space between the IP address, the /, and the CIDR mask length.

Typical examples of an IPv4 address range specified this way are `172.20.143.89/32` for a single host, or `172.20.143.0/24` for a small network, or `10.6.0.0/16` for a larger one. An IPv6 address range might look like `::1/128` for a single host (in this case the IPv6 loopback address) or `fe80::7a31:c1ff:0000:0000/96` for a small network. `0.0.0.0/0` represents all IPv4 addresses, and `::0/0` represents all IPv6 addresses. To specify a single host, use a mask length of 32 for IPv4 or 128 for IPv6. In a network address, do not omit trailing zeroes.

An entry given in IPv4 format will match only IPv4 connections, and an entry given in IPv6 format will match only IPv6 connections, even if the represented address is in the IPv4-in-IPv6 range.

Note: Entries in IPv6 format will be rejected if the host system C library does not have support for IPv6 addresses.

You can also write `all` to match any IP address, `samehost` to match any of the server's own IP addresses, or `samenet` to match any address in any subnet to which the server is directly connected.

If a host name is specified (an address that is not an IP address, IP range, or special key word is treated as a host name), that name is compared with the result of a reverse name resolution of the client IP address (for example, reverse DNS lookup, if DNS is used). Host name comparisons are case insensitive. If there is a match, then a forward name resolution (for example, forward DNS lookup) is performed on the host name to check whether any of the addresses it resolves to are equal to the client IP address. If both directions match, then the entry is considered to match.

The host name that is used in `pg_hba.conf` should be the one that address-to-name resolution of the client's IP address returns, otherwise the line won't be matched. Some host name databases allow associating an IP address with multiple host names, but the operating system will only return one host name when asked to resolve an IP address.

A host name specification that starts with a dot (.) matches a suffix of the actual host name. So `.example.com` would match `foo.example.com` (but not just `example.com`).

When host names are specified in `pg_hba.conf`, you should ensure that name resolution is reasonably fast. It can be advantageous to set up a local name resolution cache such as `nscd`.

Also, you can enable the server configuration parameter `log_hostname` to see the client host name instead of the IP address in the log.

`IP-address`

`IP-mask`

These two fields can be used as an alternative to the CIDR address notation. Instead of specifying the mask length, the actual mask is specified in a separate column. For example, `255.0.0.0` represents an IPv4 CIDR mask length of 8, and `255.255.255.255` represents a CIDR mask length of 32.

`auth-method`

Specifies the authentication method to use when a connection matches this record. See [Authentication Methods](#) for options.

`auth-options`

After the `auth-method` field, there can be field(s) of the form `name=value` that specify options for the authentication method. Details about which options are available for which authentication methods are described in [Authentication Methods](#).

Files included by `@` constructs are read as lists of names, which can be separated by either whitespace or commas. Comments are introduced by `#`, just as in `pg_hba.conf`, and nested `@` constructs are allowed. Unless the file name following `@` is an absolute path, it is taken to be relative to the directory containing the referencing file.

The `pg_hba.conf` records are examined sequentially for each connection attempt, so the order of the records is significant. Typically, earlier records will have tight connection match parameters and weaker authentication methods, while later records will have looser match parameters and stronger authentication methods. For example, you might wish to use `trust` authentication for local TCP/IP connections but require a password for remote TCP/IP connections. In this case a record specifying `trust` authentication for connections from `127.0.0.1` would appear before a record specifying `password` authentication for a wider range of allowed client IP addresses.

The `pg_hba.conf` file is read on start-up and when the main server process receives a SIGHUP signal. If you edit the file on an active system, you must reload the file using this command:

```
$ gpstop -u
```

CAUTION: For a more secure system, remove records for remote connections that use `trust` authentication from the `pg_hba.conf` file. `trust` authentication grants any user who can connect to the server access to the database using any role they specify. You can safely replace `trust` authentication with `ident` authentication for local UNIX-socket connections. You can also use `ident` authentication for local and remote TCP clients, but the client host must be running an `ident` service and you must `trust` the integrity of that machine.

Editing the `pg_hba.conf` File

Initially, the `pg_hba.conf` file is set up with generous permissions for the `gpadmin` user and no database access for other Greenplum Database roles. You will need to edit the `pg_hba.conf` file to enable users' access to databases and to secure the `gpadmin` user. Consider removing entries that have `trust` authentication, since they allow anyone with access to the server to connect with any role they choose. For local (UNIX socket) connections, use `ident` authentication, which requires the operating system user to match the role specified. For local and remote TCP connections, `ident` authentication requires the client's host to run an `ident` service. You could install an `ident` service on the master host and then use `ident` authentication for local TCP connections, for example `127.0.0.1/28`. Using `ident` authentication for remote TCP connections is less secure because it requires you to trust the integrity of the `ident` service on the client's host.

Note: Greenplum Command Center provides an interface for editing the `pg_hba.conf` file. It verifies entries before you save them, keeps a version history of the file so that you can reload a previous version of the file, and reloads the file into Greenplum Database.

This example shows how to edit the `pg_hba.conf` file on the master host to allow remote client access to all databases from all roles using encrypted password authentication.

To edit `pg_hba.conf`:

1. Open the file `$MASTER_DATA_DIRECTORY/pg_hba.conf` in a text editor.
2. Add a line to the file for each type of connection you want to allow. Records are read sequentially, so the order of the records is significant. Typically, earlier records will have tight connection match parameters and weaker authentication methods, while later records will have looser match parameters and stronger authentication methods. For example:

```
# allow the gpadmin user local access to all databases
# using ident authentication
local  all  gpadmin  ident          sameuser
host   all  gpadmin  127.0.0.1/32  ident
host   all  gpadmin  ::1/128      ident
# allow the 'dba' role access to any database from any
# host with IP address 192.168.x.x and use md5 encrypted
# passwords to authenticate the user
# Note that to use SHA-256 encryption, replace md5 with
# password in the line below
host   all  dba     192.168.0.0/32  md5
```

Authentication Methods

- [Basic Authentication](#)
- [GSSAPI Authentication](#)
- [LDAP Authentication](#)
- [SSL Client Authentication](#)
- [PAM-Based Authentication](#)
- [Radius Authentication](#)

Basic Authentication

Trust

Allows the connection unconditionally, without the need for a password or any other authentication. This entry is required for the `gpadmin` role, and for Greenplum utilities (for example `gpinitssystem`, `gpstop`, or `gpstart` amongst others) that need to connect between nodes without prompting for input or a password.

Important: For a more secure system, remove records for remote connections that use `trust` authentication from the `pg_hba.conf` file. `trust` authentication grants any user who can connect to the server access to the database using any role they specify. You can safely replace `trust` authentication with `ident` authentication for local UNIX-socket connections. You can also use `ident` authentication for local and remote TCP clients, but the client host must be running an ident service and you must `trust` the integrity of that machine.

Reject

Reject the connections with the matching parameters. You should typically use this to restrict access from specific hosts or insecure connections.

Ident

Authenticates based on the client's operating system user name. This is secure for local socket connections. Using `ident` for TCP connections from remote hosts requires that the client's host is running an ident service. The `ident` authentication method should only be used with remote hosts on a trusted, closed network.

scram-sha-256

Perform SCRAM-SHA-256 authentication as described in [RFC5802](#) to verify the user's password. SCRAM-SHA-256 authentication is a challenge-response scheme that prevents password sniffing on untrusted connections. It is more secure than the `md5` method, but might not be supported by older clients.

md5

Perform SCRAM-SHA-256 or MD5 authentication to verify the user's password. Allows falling back to a less secure challenge-response mechanism for those users with an MD5-hashed password. The fallback mechanism also prevents password sniffing, but provides no protection if an attacker manages to steal the password hash from the server, and it cannot be used when `db_user_namespace` is enabled. For all other users, `md5` works the same as `scram-sha-256`.

password

Require the client to supply an unencrypted password for authentication. Since the password is sent in clear text over the network, this authentication method should not be used on untrusted networks.

Plain `password` authentication sends the password in clear-text, and is therefore vulnerable to password sniffing attacks. It should always be avoided if possible. If the connection is protected by SSL encryption then `password` can be used safely, though. (SSL certificate authentication might be a better choice if one is depending on using SSL).

When using the Greenplum Database `SHA-256` password hashing algorithm, the `password` authentication method must be specified, and SSL-secured client connections are recommended.

Basic Authentication Examples

The password-based authentication methods are `scram-sha-256`, `md5`, and `password`. These methods operate similarly except for the way that the password is sent across the connection.

Following are some sample `pg_hba.conf` basic authentication entries:

```
hostnossl all all 0.0.0.0 reject
hostssl all testuser 0.0.0.0/0 md5
local all gpuser ident
```

Or:

```
local all gpadmin ident
host all gpadmin localhost trust
host all gpadmin mdw trust
local replication gpadmin ident
host replication gpadmin samenet trust
host all all 0.0.0.0/0 md5
```

Or:

```
# Require SCRAM authentication for most users, but make an exception
# for user 'mike', who uses an older client that doesn't support SCRAM
# authentication.
#
```

host	all	mike	.example.com	md5
host	all	all	.example.com	scram-sha-256

GSSAPI Authentication

GSSAPI is an industry-standard protocol for secure authentication defined in RFC 2743. Greenplum Database supports GSSAPI with Kerberos authentication according to RFC 1964. GSSAPI provides automatic authentication (single sign-on) for systems that support it. The authentication itself is secure, but the data sent over the database connection will be sent unencrypted unless SSL is used.

The `gss` authentication method is only available for TCP/IP connections.

When GSSAPI uses Kerberos, it uses a standard principal in the format `servicename/hostname@realm`. The Greenplum Database server will accept any principal that is included in the keytab file used by the server, but care needs to be taken to specify the correct principal details when making the connection from the client using the `krbsrvname` connection parameter. (See [Connection Parameter Key Words](#) in the PostgreSQL documentation.) In most environments, this parameter never needs to be changed. Some Kerberos implementations might require a different service name, such as Microsoft Active Directory, which requires the service name to be in upper case (POSTGRES).

`hostname` is the fully qualified host name of the server machine. The service principal's realm is the preferred realm of the server machine.

Client principals must have their Greenplum Database user name as their first component, for example `gpusername@realm`. Alternatively, you can use a user name mapping to map from the first component of the principal name to the database user name. By default, Greenplum Database does not check the realm of the client. If you have cross-realm authentication enabled and need to verify the realm, use the `krb_realm` parameter, or enable `include_realm` and use user name mapping to check the realm.

Make sure that your server keytab file is readable (and preferably only readable) by the `gpadmin` server account. The location of the key file is specified by the `krb_server_keyfile` configuration parameter. For security reasons, it is recommended to use a separate keytab just for the Greenplum Database server rather than opening up permissions on the system keytab file.

The keytab file is generated by the Kerberos software; see the Kerberos documentation for details. The following example is for MIT-compatible Kerberos 5 implementations:

```
kadmin% **ank -randkey postgres/server.my.domain.org**
kadmin% **ktadd -k krb5.keytab postgres/server.my.domain.org**
```

When connecting to the database make sure you have a ticket for a principal matching the requested database user name. For example, for database user name `fred`, principal `fred@EXAMPLE.COM` would be able to connect. To also allow principal `fred/users.example.com@EXAMPLE.COM`, use a user name map, as described in [User Name Maps](#) in the PostgreSQL documentation.

The following configuration options are supported for GSSAPI:

`include_realm`

If set to 1, the realm name from the authenticated user principal is included in the system user name that is passed through user name mapping. This is the recommended configuration as, otherwise, it is impossible to differentiate users with the same username who are from different realms. The default for this parameter is 0 (meaning to not include the realm in the system user name) but may change to 1 in a future version of Greenplum Database. You can set it explicitly to avoid any issues when upgrading.

map

Allows for mapping between system and database user names. For a GSSAPI/Kerberos principal, such as `username@EXAMPLE.COM` (or, less commonly, `username/hostbased@EXAMPLE.COM`), the default user name used for mapping is `username` (or `username/hostbased`, respectively), unless `include_realm` has been set to 1 (as recommended, see above), in which case `username@EXAMPLE.COM` (or `username/hostbased@EXAMPLE.COM`) is what is seen as the system username when mapping.

krb_realm

Sets the realm to match user principal names against. If this parameter is set, only users of that realm will be accepted. If it is not set, users of any realm can connect, subject to whatever user name mapping is done.

LDAP Authentication

You can authenticate against an LDAP directory.

- LDAPS and LDAP over TLS options encrypt the connection to the LDAP server.
- The connection from the client to the server is not encrypted unless SSL is enabled. Configure client connections to use SSL to encrypt connections from the client.
- To configure or customize LDAP settings, set the `LDAPCONF` environment variable with the path to the `ldap.conf` file and add this to the `greenplum_path.sh` script.

Following are the recommended steps for configuring your system for LDAP authentication:

1. Set up the LDAP server with the database users/roles to be authenticated via LDAP.
2. On the database:
 1. Verify that the database users to be authenticated via LDAP exist on the database. LDAP is only used for verifying username/password pairs, so the roles should exist in the database.
 2. Update the `pg_hba.conf` file in the `$MASTER_DATA_DIRECTORY` to use LDAP as the authentication method for the respective users. Note that the first entry to match the user/role in the `pg_hba.conf` file will be used as the authentication mechanism, so the position of the entry in the file is important.
 3. Reload the server for the `pg_hba.conf` configuration settings to take effect (`gpstop -u`).

Specify the following parameter `auth-options`.

ldapservers

Names or IP addresses of LDAP servers to connect to. Multiple servers may be specified, separated by spaces.

ldapprefix

String to prepend to the user name when forming the DN to bind as, when doing simple bind authentication.

ldapsuffix

String to append to the user name when forming the DN to bind as, when doing simple bind authentication.

ldapport

Port number on LDAP server to connect to. If no port is specified, the LDAP library's default port setting will be used.

ldaptls

Set to 1 to make the connection between PostgreSQL and the LDAP server use TLS encryption. Note that this only encrypts the traffic to the LDAP server — the connection to the

client will still be unencrypted unless SSL is used.

ldapbasedn

Root DN to begin the search for the user in, when doing search+bind authentication.

ldapbinddn

DN of user to bind to the directory with to perform the search when doing search+bind authentication.

ldapbindpasswd

Password for user to bind to the directory with to perform the search when doing search+bind authentication.

ldapsearchattribute

Attribute to match against the user name in the search when doing search+bind authentication.

Example:

```
ldapserver=ldap.greenplum.com prefix="cn=" suffix=", dc=greenplum, dc=com"
```

Following are sample `pg_hba.conf` file entries for LDAP authentication:

```
host all testuser 0.0.0.0/0 ldap ldap
ldapserver=ldapserver.greenplum.com ldapport=389 ldapprefix="cn=" ldapsuffix=",ou=people,dc=greenplum,dc=com"
hostssl all ldaprole 0.0.0.0/0 ldap
ldapserver=ldapserver.greenplum.com ldaptls=1 ldapprefix="cn=" ldapsuffix=",ou=people,dc=greenplum,dc=com"
```

SSL Client Authentication

SSL authentication compares the Common Name (cn) attribute of an SSL certificate provided by the connecting client during the SSL handshake to the requested database user name. The database user should exist in the database. A map file can be used for mapping between system and database user names.

SSL Authentication Parameters

Authentication method:

- Cert

Authentication options:

Hostssl

Connection type must be hostssl.

map=mapping

mapping.

: This is specified in the `pg_ident.conf`, or in the file specified in the `ident_file` server setting.

Following are sample `pg_hba.conf` entries for SSL client authentication:

```
Hostssl testdb certuser 192.168.0.0/16 cert
Hostssl testdb all 192.168.0.0/16 cert map=gpuser
```

OpenSSL Configuration

You can make changes to the OpenSSL configuration by updating the `openssl.cnf` file under your OpenSSL installation directory, or the file referenced by `$OPENSSL_CONF`, if present, and then restarting the Greenplum Database server.

Creating a Self-Signed Certificate

A self-signed certificate can be used for testing, but a certificate signed by a certificate authority (CA) (either one of the global CAs or a local one) should be used in production so that clients can verify the server's identity. If all the clients are local to the organization, using a local CA is recommended.

To create a self-signed certificate for the server:

1. Enter the following `openssl` command:

```
openssl req -new -text -out server.req
```

2. Enter the requested information at the prompts.

Make sure you enter the local host name for the Common Name. The challenge password can be left blank.

3. The program generates a key that is passphrase-protected; it does not accept a passphrase that is less than four characters long. To remove the passphrase (and you must if you want automatic start-up of the server), run the following command:

```
openssl rsa -in privkey.pem -out server.key
rm privkey.pem
```

4. Enter the old passphrase to unlock the existing key. Then run the following command:

```
openssl req -x509 -in server.req -text -key server.key -out server.crt
```

This turns the certificate into a self-signed certificate and copies the key and certificate to where the server will look for them.

5. Finally, run the following command:

```
chmod og-rwx server.key
```

For more details on how to create your server private key and certificate, refer to the OpenSSL documentation.

Configuring `postgresql.conf` for SSL Authentication

The following Server settings need to be specified in the `postgresql.conf` configuration file:

- `ssl boolean`. Enables SSL connections.
- `ssl_renegotiation_limit integer`. Specifies the data limit before key renegotiation.
- `ssl_ciphers string`. Configures the list SSL ciphers that are allowed. `ssl_ciphers` overrides any ciphers string specified in `/etc/openssl.cnf`. The default value `ALL:!ADH:!LOW:!EXP:!MD5:@STRENGTH` enables all ciphers except for ADH, LOW, EXP, and MD5 ciphers, and prioritizes ciphers by their strength.

Note: With TLS 1.2 some ciphers in MEDIUM and HIGH strength still use NULL encryption (no encryption for transport), which the default `ssl_ciphers` string allows. To bypass NULL ciphers with TLS 1.2 use a string such as `TLSv1.2:!eNULL:!aNULL`.

It is possible to have authentication without encryption overhead by using `NULL-SHA` or `NULL-MD5` ciphers. However, a man-in-the-middle could read and pass communications between client and server. Also, encryption overhead is minimal compared to the overhead of authentication. For these reasons, NULL ciphers should not be used.

The default location for the following SSL server files is the Greenplum Database master data directory (`$MASTER_DATA_DIRECTORY`):

- `server.crt` - Server certificate.
- `server.key` - Server private key.
- `root.crt` - Trusted certificate authorities.
- `root.crl` - Certificates revoked by certificate authorities.

If Greenplum Database master mirroring is enabled with SSL client authentication, the SSL server files *should not be placed* in the default directory `$MASTER_DATA_DIRECTORY`. If a `gpinitstandby` operation is performed, the contents of `$MASTER_DATA_DIRECTORY` is copied from the master to the standby master and the incorrect SSL key, and cert files (the master files, and not the standby master files) will prevent standby master start up.

You can specify a different directory for the location of the SSL server files with the `postgresql.conf` parameters `sslcert`, `sslkey`, `sslrootcert`, and `sslcr1`.

Configuring the SSL Client Connection

SSL options:

`sslmode`

Specifies the level of protection.

`require`

Only use an SSL connection. If a root CA file is present, verify the certificate in the same way as if `verify-ca` was specified.

`verify-ca`

Only use an SSL connection. Verify that the server certificate is issued by a trusted CA.

`verify-full`

Only use an SSL connection. Verify that the server certificate is issued by a trusted CA and that the server host name matches that in the certificate.

`sslcert`

The file name of the client SSL certificate. The default is

`$MASTER_DATA_DIRECTORY/postgresql.crt`.

`sslkey`

The secret key used for the client certificate. The default is

`$MASTER_DATA_DIRECTORY/postgresql.key`.

`sslrootcert`

The name of a file containing SSL Certificate Authority certificate(s). The default is

`$MASTER_DATA_DIRECTORY/root.crt`.

`sslcr1`

The name of the SSL certificate revocation list. The default is

`$MASTER_DATA_DIRECTORY/root.crl`.

The client connection parameters can be set using the following environment variables:

- `sslmode` - `PGSSLMODE`
- `sslcert` - `PGSSLCERT`

- `sslkey` - PGSSLKEY
- `sslrootcert` - PGSSLROOTCERT
- `sslcr1` - PGSSLCRL

For example, run the following command to connect to the `postgres` database from `localhost` and verify the certificate present in the default location under `$MASTER_DATA_DIRECTORY`:

```
psql "sslmode=verify-ca host=localhost dbname=postgres"
```

PAM-Based Authentication

The “PAM” (Pluggable Authentication Modules) authentication method validates username/password pairs, similar to basic authentication. To use PAM authentication, the user must already exist as a Greenplum Database role name.

Greenplum uses the `pamservice` authentication parameter to identify the service from which to obtain the PAM configuration.

Note: If PAM is set up to read `/etc/shadow`, authentication will fail because the PostgreSQL server is started by a non-root user. This is not an issue when PAM is configured to use LDAP or another authentication method.

Greenplum Database does not install a PAM configuration file. If you choose to use PAM authentication with Greenplum, you must identify the PAM service name for Greenplum and create the associated PAM service configuration file and configure Greenplum Database to use PAM authentication as described below:

1. Log in to the Greenplum Database master host and set up your environment. For example:

```
$ ssh gpadmin@<gpmaster>
gpadmin@gpmaster$ . /usr/local/greenplum-db/greenplum_path.sh
```

2. Identify the `pamservice` name for Greenplum Database. In this procedure, we choose the name `greenplum`.
3. Create the PAM service configuration file, `/etc/pam.d/greenplum`, and add the text below. You must have operating system superuser privileges to create the `/etc/pam.d` directory (if necessary) and the `greenplum` PAM configuration file.

```
##PAM-1.0
auth    include    password-auth
account include    password-auth
```

This configuration instructs PAM to authenticate the local operating system user.

4. Ensure that the `/etc/pam.d/greenplum` file is readable by all users:

```
sudo chmod 644 /etc/pam.d/greenplum
```

5. Add one or more entries to the `pg_hba.conf` configuration file to enable PAM authentication in Greenplum Database. These entries must specify the `pam auth-method`. You must also specify the `pamservice=greenplum auth-option`. For example:

```
host      <user-name>      <db-name>      <address>      pam      pamservice=greenpl
um
```

6. Reload the Greenplum Database configuration:

```
$ gpstop -u
```

Radius Authentication

RADIUS (Remote Authentication Dial In User Service) authentication works by sending an Access Request message of type 'Authenticate Only' to a configured RADIUS server. It includes parameters for user name, password (encrypted), and the Network Access Server (NAS) Identifier. The request is encrypted using the shared secret specified in the `radiussecret` option. The RADIUS server responds with either `Access Accept` or `Access Reject`.

Note: RADIUS accounting is not supported.

RADIUS authentication only works if the users already exist in the database.

The RADIUS encryption vector requires SSL to be enabled in order to be cryptographically strong.

RADIUS Authentication Options

`radiusserver`

The name of the RADIUS server.

`radiussecret`

The RADIUS shared secret.

`radiusport`

The port to connect to on the RADIUS server.

`radiusidentifier`

NAS identifier in RADIUS requests.

Following are sample `pg_hba.conf` entries for RADIUS client authentication:

```
hostssl all all 0.0.0.0/0 radius radiusserver=servername radiussecret=sharedsecret
```

Limiting Concurrent Connections

To limit the number of active concurrent sessions to your Greenplum Database system, you can configure the `max_connections` server configuration parameter. This is a local parameter, meaning that you must set it in the `postgresql.conf` file of the master, the standby master, and each segment instance (primary and mirror). The value of `max_connections` on segments must be 5-10 times the value on the master.

When you set `max_connections`, you must also set the dependent parameter `max_prepared_transactions`. This value must be at least as large as the value of `max_connections` on the master, and segment instances should be set to the same value as the master.

In `$MASTER_DATA_DIRECTORY/postgresql.conf` (including standby master):

```
max_connections=100
max_prepared_transactions=100
```

In `SEGMENT_DATA_DIRECTORY/postgresql.conf` for all segment instances:

```
max_connections=500
max_prepared_transactions=100
```

Note: Raising the values of these parameters may cause Greenplum Database to request more shared memory. To mitigate this effect, consider decreasing other memory-related parameters such as `gp_cached_segworkers_threshold`.

To change the number of allowed connections:

1. Stop your Greenplum Database system:

```
$ gpstop
```

2. On the master host, edit `$MASTER_DATA_DIRECTORY/postgresql.conf` and change the following two parameters:

- ♦ `max_connections` – the number of active user sessions you want to allow plus the number of `superuser_reserved_connections`.
- ♦ `max_prepared_transactions` – must be greater than or equal to `max_connections`.

3. On each segment instance, edit `SEGMENT_DATA_DIRECTORY/postgresql.conf` and change the following two parameters:

- ♦ `max_connections` – must be 5-10 times the value on the master.
- ♦ `max_prepared_transactions` – must be equal to the value on the master.

4. Restart your Greenplum Database system:

```
$ gpstart
```

Encrypting Client/Server Connections

Greenplum Database has native support for SSL connections between the client and the master server. SSL connections prevent third parties from snooping on the packets, and also prevent man-in-the-middle attacks. SSL should be used whenever the client connection goes through an insecure link, and must be used whenever client certificate authentication is used.

Note: For information about encrypting data between the `gpfdist` server and Greenplum Database segment hosts, see [Encrypting gpfdist Connections](#).

To enable SSL requires that OpenSSL be installed on both the client and the master server systems. Greenplum can be started with SSL enabled by setting the server configuration parameter `ssl=on` in the master `postgresql.conf`. When starting in SSL mode, the server will look for the files `server.key` (server private key) and `server.crt` (server certificate) in the master data directory. These files must be set up correctly before an SSL-enabled Greenplum system can start.

Important: Do not protect the private key with a passphrase. The server does not prompt for a passphrase for the private key, and the database startup fails with an error if one is required.

A self-signed certificate can be used for testing, but a certificate signed by a certificate authority (CA) should be used in production, so the client can verify the identity of the server. Either a global or local CA can be used. If all the clients are local to the organization, a local CA is recommended. See [Creating a Self-Signed Certificate](#) for steps to create a self-signed certificate.

Configuring Database Authorization

Describes how to restrict authorization access to database data at the user level by using roles and permissions.

Parent topic: [Greenplum Database Security Configuration Guide](#)

Access Permissions and Roles

Greenplum Database manages database access permissions using *roles*. The concept of roles subsumes the concepts of users and groups. A role can be a database user, a group, or both. Roles can own database objects (for example, tables) and can assign privileges on those objects to other roles to control access to the objects. Roles can be members of other roles, thus a member role can inherit the object privileges of its parent role.

Every Greenplum Database system contains a set of database roles (users and groups). Those roles are separate from the users and groups managed by the operating system on which the server runs. However, for convenience you may want to maintain a relationship between operating system user names and Greenplum Database role names, since many of the client applications use the current operating system user name as the default.

In Greenplum Database, users log in and connect through the master instance, which verifies their role and access privileges. The master then issues out commands to the segment instances behind the scenes using the currently logged in role.

Roles are defined at the system level, so they are valid for all databases in the system.

To bootstrap the Greenplum Database system, a freshly initialized system always contains one predefined superuser role (also referred to as the system user). This role will have the same name as the operating system user that initialized the Greenplum Database system. Customarily, this role is named `gpadmin`. To create more roles you first must connect as this initial role.

Managing Object Privileges

When an object (table, view, sequence, database, function, language, schema, or tablespace) is created, it is assigned an owner. The owner is normally the role that ran the creation statement. For most kinds of objects, the initial state is that only the owner (or a superuser) can do anything with the object. To allow other roles to use it, privileges must be granted. Greenplum Database supports the following privileges for each object type:

Object Type	Privileges
Tables, Views, Sequences	SELECT INSERT UPDATE DELETE RULE ALL
External Tables	SELECT RULE ALL
Databases	CONNECT CREATE TEMPORARY or TEMP ALL
Functions	EXECUTE
Procedural Languages	USAGE
Schemas	CREATE USAGE ALL

Privileges must be granted for each object individually. For example, granting `ALL` on a database does not grant full access to the objects within that database. It only grants all of the database-level

privileges (`CONNECT`, `CREATE`, `TEMPORARY`) to the database itself.

Use the `GRANT` SQL command to give a specified role privileges on an object. For example:

```
=# GRANT INSERT ON mytable TO jsmith;
```

To revoke privileges, use the `REVOKE` command. For example:

```
=# REVOKE ALL PRIVILEGES ON mytable FROM jsmith;
```

You can also use the `DROP OWNED` and `REASSIGN OWNED` commands for managing objects owned by deprecated roles. (Note: only an object's owner or a superuser can drop an object or reassign ownership.) For example:

```
=# REASSIGN OWNED BY sally TO bob;
=# DROP OWNED BY visitor;
```

About Object Access Privileges

Greenplum Database access control corresponds roughly to the Orange Book 'C2' level of security, not the 'B1' level. Greenplum Database currently supports access privileges at the object level. Greenplum Database does not support row-level access or row-level, labeled security.

You can simulate row-level access by using views to restrict the rows that are selected. You can simulate row-level labels by adding an extra column to the table to store sensitivity information, and then using views to control row-level access based on this column. You can then grant roles access to the views rather than the base table. While these workarounds do not provide the same as "B1" level security, they may still be a viable alternative for many organizations.

About Password Encryption in Greenplum Database

The available password encryption methods in Greenplum Database are SCRAM-SHA-256, SHA-256, and MD5 (the default).

You can set your chosen encryption method system-wide or on a per-session basis.

Using SCRAM-SHA-256 Password Encryption

To use SCRAM-SHA-256 password encryption, you must set a server configuration parameter either at the system or the session level. This section outlines how to use a server parameter to implement SCRAM-SHA-256 encrypted password storage.

Note that in order to use SCRAM-SHA-256 encryption for password storage, the `pg_hba.conf` client authentication method must be set to `scram-sha-256` rather than the default, `md5`.

Setting the SCRAM-SHA-256 Password Hash Algorithm System-wide

To set the `password_hash_algorithm` server parameter on a complete Greenplum system (master and its segments):

1. Log in to your Greenplum Database instance as a superuser.
2. Execute `gpconfig` with the `password_hash_algorithm` set to SCRAM-SHA-256:

```
$ gpconfig -c password_hash_algorithm -v 'SCRAM-SHA-256'
```

3. Verify the setting:

```
$ gpconfig -s
```

You will see:

```
Master value: SCRAM-SHA-256
Segment value: SCRAM-SHA-256
```

Setting the SCRAM-SHA-256 Password Hash Algorithm for an Individual Session

To set the `password_hash_algorithm` server parameter for an individual session:

1. Log in to your Greenplum Database instance as a superuser.
2. Set the `password_hash_algorithm` to SCRAM-SHA-256:

```
# set password_hash_algorithm = 'SCRAM-SHA-256'
```

3. Verify the setting:

```
# show password_hash_algorithm;
```

You will see:

```
SCRAM-SHA-256
```

Using SHA-256 Password Encryption

To use SHA-256 password encryption, you must set a server configuration parameter either at the system or the session level. This section outlines how to use a server parameter to implement SHA-256 encrypted password storage.

Note that in order to use SHA-256 encryption for password storage, the `pg_hba.conf` client authentication method must be set to `password` rather than the default, `md5`. (See [Configuring the SSL Client Connection](#) for more details.) **With this authentication setting, the password is transmitted in clear text over the network; it is highly recommend that you set up SSL to encrypt the client server communication channel.**

Setting the SHA-256 Password Hash Algorithm System-wide

To set the `password_hash_algorithm` server parameter on a complete Greenplum system (master and its segments):

1. Log in to your Greenplum Database instance as a superuser.
2. Execute `gpconfig` with the `password_hash_algorithm` set to SHA-256:

```
$ gpconfig -c password_hash_algorithm -v 'SHA-256'
```

3. Verify the setting:

```
$ gpconfig -s
```

You will see:

```
Master value: SHA-256
```

```
Segment value: SHA-256
```

Setting the SHA-256 Password Hash Algorithm for an Individual Session

To set the `password_hash_algorithm` server parameter for an individual session:

1. Log in to your Greenplum Database instance as a superuser.
2. Set the `password_hash_algorithm` to SHA-256:

```
# set password_hash_algorithm = 'SHA-256'
```

3. Verify the setting:

```
# show password_hash_algorithm;
```

You will see:

```
SHA-256
```

Example

An example of how to use and verify the `SHA-256 password_hash_algorithm` follows:

1. Log in as a super user and verify the password hash algorithm setting:

```
SHOW password_hash_algorithm
password_hash_algorithm
-----
SHA-256
```

2. Create a new role with password that has login privileges.

```
CREATE ROLE testdb WITH PASSWORD 'testdb12345#' LOGIN;
```

3. Change the client authentication method to allow for storage of SHA-256 encrypted passwords:

Open the `pg_hba.conf` file on the master and add the following line:

```
host all testdb 0.0.0.0/0 password
```

4. Restart the cluster.
5. Log in to the database as the user just created, `testdb`.

```
psql -U testdb
```

6. Enter the correct password at the prompt.
7. Verify that the password is stored as a SHA-256 hash.

Password hashes are stored in `pg_authid.rolpassword`.

8. Log in as the super user.
9. Execute the following query:

```
# SELECT rolpassword FROM pg_authid WHERE rolname = 'testdb';
Rolpassword
```

```
-----
sha256<64 hexadecimal characters>
```

Restricting Access by Time

Greenplum Database enables the administrator to restrict access to certain times by role. Use the `CREATE ROLE` or `ALTER ROLE` commands to specify time-based constraints.

Access can be restricted by day or by day and time. The constraints are removable without deleting and recreating the role.

Time-based constraints only apply to the role to which they are assigned. If a role is a member of another role that contains a time constraint, the time constraint is not inherited.

Time-based constraints are enforced only during login. The `SET ROLE` and `SET SESSION AUTHORIZATION` commands are not affected by any time-based constraints.

Superuser or `CREATEROLE` privileges are required to set time-based constraints for a role. No one can add time-based constraints to a superuser.

There are two ways to add time-based constraints. Use the keyword `DENY` in the `CREATE ROLE` or `ALTER ROLE` command followed by one of the following.

- A day, and optionally a time, when access is restricted. For example, no access on Wednesdays.
- An interval—that is, a beginning and ending day and optional time—when access is restricted. For example, no access from Wednesday 10 p.m. through Thursday at 8 a.m.

You can specify more than one restriction; for example, no access Wednesdays at any time and no access on Fridays between 3:00 p.m. and 5:00 p.m.

There are two ways to specify a day. Use the word `DAY` followed by either the English term for the weekday, in single quotation marks, or a number between 0 and 6, as shown in the table below.

English Term	Number
DAY 'Sunday'	DAY 0
DAY 'Monday'	DAY 1
DAY 'Tuesday'	DAY 2
DAY 'Wednesday'	DAY 3
DAY 'Thursday'	DAY 4
DAY 'Friday'	DAY 5
DAY 'Saturday'	DAY 6

A time of day is specified in either 12- or 24-hour format. The word `TIME` is followed by the specification in single quotation marks. Only hours and minutes are specified and are separated by a colon (:). If using a 12-hour format, add `AM` or `PM` at the end. The following examples show various time specifications.

```
TIME '14:00'      # 24-hour time implied
TIME '02:00 PM'   # 12-hour time specified by PM
TIME '02:00'      # 24-hour time implied. This is equivalent to TIME '02:00 AM'.
```

Important: Time-based authentication is enforced with the server time. Timezones are disregarded.

To specify an interval of time during which access is denied, use two day/time specifications with the

words **BETWEEN** and **AND**, as shown. **DAY** is always required.

```
BETWEEN DAY 'Monday' AND DAY 'Tuesday'

BETWEEN DAY 'Monday' TIME '00:00' AND
        DAY 'Monday' TIME '01:00'

BETWEEN DAY 'Monday' TIME '12:00 AM' AND
        DAY 'Tuesday' TIME '02:00 AM'

BETWEEN DAY 'Monday' TIME '00:00' AND
        DAY 'Tuesday' TIME '02:00'
        DAY 2 TIME '02:00'
```

The last three statements are equivalent.

Note: Intervals of days cannot wrap past Saturday.

The following syntax is not correct:

```
DENY BETWEEN DAY 'Saturday' AND DAY 'Sunday'
```

The correct specification uses two **DENY** clauses, as follows:

```
DENY DAY 'Saturday'
DENY DAY 'Sunday'
```

The following examples demonstrate creating a role with time-based constraints and modifying a role to add time-based constraints. Only the statements needed for time-based constraints are shown.

For more details on creating and altering roles see the descriptions of **CREATE ROLE** and **ALTER ROLE** in the *Greenplum Database Reference Guide*.

Example 1 – Create a New Role with Time-based Constraints

No access is allowed on weekends.

```
CREATE ROLE generaluser
DENY DAY 'Saturday'
DENY DAY 'Sunday'
...
```

Example 2 – Alter a Role to Add Time-based Constraints

No access is allowed every night between 2:00 a.m. and 4:00 a.m.

```
ALTER ROLE generaluser
DENY BETWEEN DAY 'Monday' TIME '02:00' AND DAY 'Monday' TIME '04:00'
DENY BETWEEN DAY 'Tuesday' TIME '02:00' AND DAY 'Tuesday' TIME '04:00'
DENY BETWEEN DAY 'Wednesday' TIME '02:00' AND DAY 'Wednesday' TIME '04:00'
DENY BETWEEN DAY 'Thursday' TIME '02:00' AND DAY 'Thursday' TIME '04:00'
DENY BETWEEN DAY 'Friday' TIME '02:00' AND DAY 'Friday' TIME '04:00'
DENY BETWEEN DAY 'Saturday' TIME '02:00' AND DAY 'Saturday' TIME '04:00'
DENY BETWEEN DAY 'Sunday' TIME '02:00' AND DAY 'Sunday' TIME '04:00'
...
```

Example 3 – Alter a Role to Add Time-based Constraints

No access is allowed Wednesdays or Fridays between 3:00 p.m. and 5:00 p.m.

```
ALTER ROLE generaluser
```

```
DENY DAY 'Wednesday'
DENY BETWEEN DAY 'Friday' TIME '15:00' AND DAY 'Friday' TIME '17:00'
```

Dropping a Time-based Restriction

To remove a time-based restriction, use the ALTER ROLE command. Enter the keywords DROP DENY FOR followed by a day/time specification to drop.

```
DROP DENY FOR DAY 'Sunday'
```

Any constraint containing all or part of the conditions in a DROP clause is removed. For example, if an existing constraint denies access on Mondays and Tuesdays, and the DROP clause removes constraints for Mondays, the existing constraint is completely dropped. The DROP clause completely removes all constraints that overlap with the constraint in the drop clause. The overlapping constraints are completely removed even if they contain more restrictions than the restrictions mentioned in the DROP clause.

Example 1 - Remove a Time-based Restriction from a Role

```
ALTER ROLE generaluser
DROP DENY FOR DAY 'Monday'
...
```

This statement would remove all constraints that overlap with a Monday constraint for the role `generaluser` in Example 2, even if there are additional constraints.

Auditing

Describes Greenplum Database events that are logged and should be monitored to detect security threats.

Greenplum Database is capable of auditing a variety of events, including startup and shutdown of the system, segment database failures, SQL statements that result in an error, and all connection attempts and disconnections. Greenplum Database also logs SQL statements and information regarding SQL statements, and can be configured in a variety of ways to record audit information with more or less detail. The `log_error_verbosity` configuration parameter controls the amount of detail written in the server log for each message that is logged. Similarly, the `log_min_error_statement` parameter allows administrators to configure the level of detail recorded specifically for SQL statements, and the `log_statement` parameter determines the kind of SQL statements that are audited. Greenplum Database records the username for all auditable events, when the event is initiated by a subject outside the Greenplum Database.

Greenplum Database prevents unauthorized modification and deletion of audit records by only allowing administrators with an appropriate role to perform any operations on log files. Logs are stored in a proprietary format using comma-separated values (CSV). Each segment and the master stores its own log files, although these can be accessed remotely by an administrator. Greenplum Database also authorizes overwriting of old log files via the `log_truncate_on_rotation` parameter. This is a local parameter and must be set on each segment and master configuration file.

Greenplum provides an administrative schema called `gp_toolkit` that you can use to query log files, as well as system catalogs and operating environment for system status information. For more information, including usage, refer to *The gp_toolkit Administrative Schema* appendix in the *Greenplum Database Reference Guide*.

Viewing the Database Server Log Files

Every database instance in Greenplum Database (master and segments) is a running PostgreSQL database server with its own server log file. Daily log files are created in the `pg_log` directory of the master and each segment data directory.

The server log files are written in comma-separated values (CSV) format. Not all log entries will have values for all of the log fields. For example, only log entries associated with a query worker process will have the `slice_id` populated. Related log entries of a particular query can be identified by its session identifier (`gp_session_id`) and command identifier (`gp_command_count`).

#	Field Name	Data Type	Description
1	event_time	timestamp with time zone	Time that the log entry was written to the log
2	user_name	varchar(100)	The database user name
3	database_name	varchar(100)	The database name
4	process_id	varchar(10)	The system process id (prefixed with "p")
5	thread_id	varchar(50)	The thread count (prefixed with "th")
6	remote_host	varchar(100)	On the master, the hostname/address of the client machine. On the segment, the hostname/address of the master.
7	remote_port	varchar(10)	The segment or master port number
8	session_start_time	timestamp with time zone	Time session connection was opened
9	transaction_id	int	Top-level transaction ID on the master. This ID is the parent of any subtransactions.
10	gp_session_id	text	Session identifier number (prefixed with "con")
11	gp_command_count	text	The command number within a session (prefixed with "cmd")
12	gp_segment	text	The segment content identifier (prefixed with "seg" for primaries or "mir" for mirrors). The master always has a content id of -1.
13	slice_id	text	The slice id (portion of the query plan being run)
14	distr_tranx_id	text	Distributed transaction ID
15	local_tranx_id	text	Local transaction ID
16	sub_tranx_id	text	Subtransaction ID
17	event_severity	varchar(10)	Values include: LOG, ERROR, FATAL, PANIC, DEBUG1, DEBUG2
18	sql_state_code	varchar(10)	SQL state code associated with the log message
19	event_message	text	Log or error message text
20	event_detail	text	Detail message text associated with an error or warning message
21	event_hint	text	Hint message text associated with an error or warning message
22	internal_query	text	The internally-generated query text
23	internal_query_pos	int	The cursor index into the internally-generated query text

#	Field Name	Data Type	Description
24	event_context	text	The context in which this message gets generated
25	debug_query_string	text	User-supplied query string with full detail for debugging. This string can be modified for internal use.
26	error_cursor_pos	int	The cursor index into the query string
27	func_name	text	The function in which this message is generated
28	file_name	text	The internal code file where the message originated
29	file_line	int	The line of the code file where the message originated
30	stack_trace	text	Stack trace text associated with this message

Greenplum provides a utility called `gplogfilter` that can be used to search through a Greenplum Database log file for entries matching the specified criteria. By default, this utility searches through the Greenplum master log file in the default logging location. For example, to display the last three lines of the master log file:

```
$ gplogfilter -n 3
```

You can also use `gplogfilter` to search through all segment log files at once by running it through the `gpssh` utility. For example, to display the last three lines of each segment log file:

```
$ gpssh -f seg_host_file
=> source /usr/local/greenplum-db/greenplum_path.sh
=> gplogfilter -n 3 /data/*/gp*/pg_log/gpdb*.csv
```

The following are the Greenplum security-related audit (or logging) server configuration parameters that are set in the `postgresql.conf` configuration file:

Field Name	Value Range	Default	Description
log_connections	Boolean	off	This outputs a line to the server log detailing each successful connection. Some client programs, like <code>psql</code> , attempt to connect twice while determining if a password is required, so duplicate "connection received" messages do not always indicate a problem.
log_disconnections	Boolean	off	This outputs a line in the server log at termination of a client session, and includes the duration of the session.
log_statement	NONE DDL MOD ALL	ALL	Controls which SQL statements are logged. DDL logs all data definition commands like <code>CREATE</code> , <code>ALTER</code> , and <code>DROP</code> commands. MOD logs all DDL statements, plus <code>INSERT</code> , <code>UPDATE</code> , <code>DELETE</code> , <code>TRUNCATE</code> , and <code>COPY FROM</code> . <code>PREPARE</code> and <code>EXPLAIN ANALYZE</code> statements are also logged if their contained command is of an appropriate type.
log_hostname	Boolean	off	By default, connection log messages only show the IP address of the connecting host. Turning on this option causes logging of the host name as well. Note that depending on your host name resolution setup this might impose a non-negligible performance penalty.
log_duration	Boolean	off	Causes the duration of every completed statement which satisfies <code>log_statement</code> to be logged.

Field Name	Value Range	Default	Description
log_error_verbosity	TERSE DEFAULT VERBOSE	DEFAULT	Controls the amount of detail written in the server log for each message that is logged.
log_min_duration_statement	number of milliseconds, 0, -1	-1	Logs the statement and its duration on a single log line if its duration is greater than or equal to the specified number of milliseconds. Setting this to 0 will print all statements and their durations. -1 disables the feature. For example, if you set it to 250 then all SQL statements that run 250ms or longer will be logged. Enabling this option can be useful in tracking down unoptimized queries in your applications.
log_min_messages	DEBUG5 DEBUG4 DEBUG3 DEBUG2 DEBUG1 INFO NOTICE WARNING ERROR LOG FATAL PANIC	NOTICE	Controls which message levels are written to the server log. Each level includes all the levels that follow it. The later the level, the fewer messages are sent to the log.
log_rotation_size	0 - INT_MAX/1024 kilobytes	1048576	When greater than 0, a new log file is created when this number of kilobytes have been written to the log. Set to zero to disable size-based creation of new log files.
log_rotation_age	Any valid time expression (number and unit)	1d	Determines the lifetime of an individual log file. When this amount of time has elapsed since the current log file was created, a new log file will be created. Set to zero to disable time-based creation of new log files.
log_statement_stats	Boolean	off	For each query, write total performance statistics of the query parser, planner, and executor to the server log. This is a crude profiling instrument.
log_truncate_on_rotation	Boolean	off	Truncates (overwrites), rather than appends to, any existing log file of the same name. Truncation will occur only when a new file is being opened due to time-based rotation. For example, using this setting in combination with a log_filename such as gpseg#-%H.log would result in generating twenty-four hourly log files and then cyclically overwriting them. When off, pre-existing files will be appended to in all cases.

Encrypting Data and Database Connections

This topic describes how to encrypt data at rest in the database or in transit over the network, to protect from eavesdroppers or man-in-the-middle attacks.

- Connections between clients and the master database can be encrypted with SSL. This is enabled with the `ssl` server configuration parameter, which is `off` by default. Setting the `ssl` parameter to `on` allows client communications with the master to be encrypted. The master database must be set up for SSL. See [OpenSSL Configuration](#) for more about encrypting client connections with SSL.

- Greenplum Database allows SSL encryption of data in transit between the Greenplum parallel file distribution server, `gpfdist`, and segment hosts. See [Encrypting gpfdist Connections](#) for more information.
- The `pgcrypto` module of encryption/decryption functions protects data at rest in the database. Encryption at the column level protects sensitive information, such as social security numbers or credit card numbers. See [Encrypting Data at Rest with pgcrypto](#) for more information.

Parent topic: [Greenplum Database Security Configuration Guide](#)

Encrypting gpfdist Connections

The `gpfdists` protocol is a secure version of the `gpfdist` protocol that securely identifies the file server and the Greenplum Database and encrypts the communications between them. Using `gpfdists` protects against eavesdropping and man-in-the-middle attacks.

The `gpfdists` protocol implements client/server SSL security with the following notable features:

- Client certificates are required.
- Multilingual certificates are not supported.
- A Certificate Revocation List (CRL) is not supported.
- A minimum TLS version of 1.2 is required.
- SSL renegotiation is supported.
- The SSL ignore host mismatch parameter is set to false.
- Private keys containing a passphrase are not supported for the `gpfdist` file server (`server.key`) or for the Greenplum Database (`client.key`).
- It is the user's responsibility to issue certificates that are appropriate for the operating system in use. Generally, converting certificates to the required format is supported, for example using the SSL Converter at <https://www.sslshopper.com/ssl-converter.html>.

A `gpfdist` server started with the `--ssl` option can only communicate with the `gpfdists` protocol. A `gpfdist` server started without the `--ssl` option can only communicate with the `gpfdist` protocol. For more detail about `gpfdist` refer to the *Greenplum Database Administrator Guide*.

There are two ways to enable the `gpfdists` protocol:

- Run `gpfdist` with the `--ssl` option and then use the `gpfdists` protocol in the `LOCATION` clause of a `CREATE EXTERNAL TABLE` statement.
- Use a YAML control file with the SSL option set to true and run `gpload`. Running `gpload` starts the `gpfdist` server with the `--ssl` option and then uses the `gpfdists` protocol.

When using `gpfdists`, the following client certificates must be located in the `$PGDATA/gpfdists` directory on each segment:

- The client certificate file, `client.crt`
- The client private key file, `client.key`
- The trusted certificate authorities, `root.crt`

Important: Do not protect the private key with a passphrase. The server does not prompt for a passphrase for the private key, and loading data fails with an error if one is required.

When using `gpload` with SSL you specify the location of the server certificates in the YAML control file. When using `gpfdist` with SSL, you specify the location of the server certificates with the `-ssl`

option.

The following example shows how to securely load data into an external table. The example creates a readable external table named `ext_expenses` from all files with the `txt` extension, using the `gpfdists` protocol. The files are formatted with a pipe (`|`) as the column delimiter and an empty space as null.

1. Run `gpfdist` with the `--ssl` option on the segment hosts.
2. Log into the database and run the following command:

```
=# CREATE EXTERNAL TABLE ext_expenses
  ( name text, date date, amount float4, category text, desc1 text )
LOCATION ('gpfdists://etlhost-1:8081/*.txt', 'gpfdists://etlhost-2:8082/*.txt')
FORMAT 'TEXT' ( DELIMITER '|' NULL ' ' ) ;
```

Encrypting Data at Rest with pgcrypto

The `pgcrypto` module for Greenplum Database provides functions for encrypting data at rest in the database. Administrators can encrypt columns with sensitive information, such as social security numbers or credit card numbers, to provide an extra layer of protection. Database data stored in encrypted form cannot be read by users who do not have the encryption key, and the data cannot be read directly from disk.

`pgcrypto` is installed by default when you install Greenplum Database. You must explicitly enable `pgcrypto` in each database in which you want to use the module.

`pgcrypto` allows PGP encryption using symmetric and asymmetric encryption. Symmetric encryption encrypts and decrypts data using the same key and is faster than asymmetric encryption. It is the preferred method in an environment where exchanging secret keys is not an issue. With asymmetric encryption, a public key is used to encrypt data and a private key is used to decrypt data. This is slower than symmetric encryption and it requires a stronger key.

Using `pgcrypto` always comes at the cost of performance and maintainability. It is important to use encryption only with the data that requires it. Also, keep in mind that you cannot search encrypted data by indexing the data.

Before you implement in-database encryption, consider the following PGP limitations.

- No support for signing. That also means that it is not checked whether the encryption subkey belongs to the master key.
- No support for encryption key as master key. This practice is generally discouraged, so this limitation should not be a problem.
- No support for several subkeys. This may seem like a problem, as this is common practice. On the other hand, you should not use your regular GPG/PGP keys with `pgcrypto`, but create new ones, as the usage scenario is rather different.

Greenplum Database is compiled with `zlib` by default; this allows PGP encryption functions to compress data before encrypting. When compiled with `OpenSSL`, more algorithms will be available.

Because `pgcrypto` functions run inside the database server, the data and passwords move between `pgcrypto` and the client application in clear-text. For optimal security, you should connect locally or use SSL connections and you should trust both the system and database administrators.

`pgcrypto` configures itself according to the findings of the main PostgreSQL configure script.

When compiled with `zlib`, `pgcrypto` encryption functions are able to compress data before encrypting.

Pgcrypto has various levels of encryption ranging from basic to advanced built-in functions. The following table shows the supported encryption algorithms.

Value Functionality	Built-in	With OpenSSL
MD5	yes	yes
SHA1	yes	yes
SHA224/256/384/512	yes	yes ¹
Other digest algorithms	no	yes ²
Blowfish	yes	yes
AES	yes	yes ³
DES/3DES/CAST5	no	yes
Raw Encryption	yes	yes
PGP Symmetric-Key	yes	yes
PGP Public Key	yes	yes

Creating PGP Keys

To use PGP asymmetric encryption in Greenplum Database, you must first create public and private keys and install them.

This section assumes you are installing Greenplum Database on a Linux machine with the Gnu Privacy Guard ([gnpg](https://www.gnupg.org/download/)) command line tool. Use the latest version of GPG to create keys. Download and install Gnu Privacy Guard (GPG) for your operating system from <https://www.gnupg.org/download/>. On the GnuPG website you will find installers for popular Linux distributions and links for Windows and Mac OS X installers.

1. As root, run the following command and choose option 1 from the menu:

```
# gpg --gen-key
gpg (GnuPG) 2.0.14; Copyright (C) 2009 Free Software Foundation, Inc.
This is free software: you are free to change and redistribute it.
There is NO WARRANTY, to the extent permitted by law.

gpg: directory '/root/.gnupg' created
gpg: new configuration file '/root/.gnupg/gpg.conf' created
gpg: WARNING: options in '/root/.gnupg/gpg.conf' are not yet active during this
run
gpg: keyring '/root/.gnupg/secring.gpg' created
gpg: keyring '/root/.gnupg/pubring.gpg' created
Please select what kind of key you want:
(1) RSA and RSA (default)
(2) DSA and Elgamal
(3) DSA (sign only)
(4) RSA (sign only)
Your selection? **1**
```

2. Respond to the prompts and follow the instructions, as shown in this example:

```
RSA keys may be between 1024 and 4096 bits long.
What keysize do you want? (2048) Press enter to accept default key size
Requested keysize is 2048 bits
Please specify how long the key should be valid.
0 = key does not expire
```

```

<n> = key expires in n days
<n>w = key expires in n weeks
<n>m = key expires in n months
<n>y = key expires in n years
Key is valid for? (0) **365**
Key expires at Wed 13 Jan 2016 10:35:39 AM PST
Is this correct? (y/N) **y**

GnuPG needs to construct a user ID to identify your key.

Real name: **John Doe**
Email address: **jdoe@email.com**
Comment:
You selected this USER-ID:
  "John Doe <jdoe@email.com>"

Change (N)ame, (C)omment, (E)mail or (O)key/(Q)uit? **O**
You need a Passphrase to protect your secret key.
*(For this demo the passphrase is blank.)*
can't connect to '/root/.gnupg/S.gpg-agent': No such file or directory
You don't want a passphrase - this is probably a *bad* idea!
I will do it anyway. You can change your passphrase at any time,
using this program with the option "--edit-key".

We need to generate a lot of random bytes. It is a good idea to perform
some other action (type on the keyboard, move the mouse, utilize the
disks) during the prime generation; this gives the random number
generator a better chance to gain enough entropy.
We need to generate a lot of random bytes. It is a good idea to perform

gpg: depth: 0  valid:   1  signed:   0  trust: 0-, 0q, 0n, 0m, 0f, 1u
gpg: next trustdb check due at 2016-01-13
pub   2048R/2027CC30 2015-01-13 [expires: 2016-01-13]
      Key fingerprint = 7EDA 6AD0 F5E0 400F 4D45   3259 077D 725E 2027 CC30
uid           John Doe <jdoe@email.com>
sub   2048R/4FD2EFBB 2015-01-13 [expires: 2016-01-13]

```

3. List the PGP keys by entering the following command:

```

gpg --list-secret-keys
/root/.gnupg/secring.gpg
-----
sec   2048R/2027CC30 2015-01-13 [expires: 2016-01-13]
uid           John Doe <jdoe@email.com>
ssb   2048R/4FD2EFBB 2015-01-13

```

2027CC30 is the public key and will be used to *encrypt* data in the database. 4FD2EFBB is the private (secret) key and will be used to *decrypt* data.

4. Export the keys using the following commands:

```

# gpg -a --export 4FD2EFBB > public.key
# gpg -a --export-secret-keys 2027CC30 > secret.key

```

See the [pgcrypto](#) documentation for more information about PGP encryption functions.

Encrypting Data in Tables using PGP

This section shows how to encrypt data inserted into a column using the PGP keys you generated.

1. Dump the contents of the `public.key` file and then copy it to the clipboard:

```
# cat public.key
-----BEGIN PGP PUBLIC KEY BLOCK-----
Version: GnuPG v2.0.14 (GNU/Linux)

mQENBFS1Zf0BCADNw8Qvk1V1C36Kfcdw3Kpm/dijPfRyyEwB6PqKyA05jtWiXZTh

=XZ8J
-----END PGP PUBLIC KEY BLOCK-----');

```

```
pgp_key_id | 9D4D255F4FD2EFBB
```

This shows that the PGP key ID used to encrypt the `ssn` column is 9D4D255F4FD2EFBB. It is recommended to perform this step whenever a new key is created and then store the ID for tracking.

You can use this key to see which key pair was used to encrypt the data:

```
SELECT username, pgp_key_id(ssn) As key_used
```

```
FROM userssn;
username | Bob
key_used | 9D4D255F4FD2EFBB
-----+-----
username | Alice
key_used | 9D4D255F4FD2EFBB
```

Note: Different keys may have the same ID. This is rare, but is a normal event. The client application should try to decrypt with each one to see which fits — like handling [ANYKEY](#). See [pgp_key_id\(\)](#) in the [pgcrypto](#) documentation.

5. Decrypt the data using the private key.

```
SELECT username, pgp_pub_decrypt(ssn, keys.privkey)
AS decrypted_ssn FROM userssn
CROSS JOIN
(SELECT dearmor('-----BEGIN PGP PRIVATE KEY BLOCK-----

(2 rows)

```

If you created a key with passphrase, you may have to enter it here. However for the purpose of this example, the passphrase is blank.

Key Management

Whether you are using symmetric (single private key) or asymmetric (public and private key) cryptography, it is important to store the master or private key securely. There are many options for storing encryption keys, for example, on a file system, key vault, encrypted USB, trusted platform module (TPM), or hardware security module (HSM).

Consider the following questions when planning for key management:

- Where will the keys be stored?
- When should keys expire?
- How are keys protected?
- How are keys accessed?
- How can keys be recovered and revoked?

The Open Web Application Security Project (OWASP) provides a very comprehensive [guide to securing encryption keys](#).

¹ SHA2 algorithms were added to OpenSSL in version 0.9.8. For older versions, pgcrypto will use built-in code.

² Any digest algorithm OpenSSL supports is automatically picked up. This is not possible with ciphers, which need to be supported explicitly.

³ AES is included in OpenSSL since version 0.9.7. For older versions, pgcrypto will use built-in code.

Security Best Practices

Describes basic security best practices that you should follow to ensure the highest level of system security.

In the default Greenplum Database security configuration:

- Only local connections are allowed.
- Basic authentication is configured for the superuser (`gpadmin`).
- The superuser is authorized to do anything.
- Only database role passwords are encrypted.

System User (gppadmin)

Secure and limit access to the `gppadmin` system user.

Greenplum requires a UNIX user id to install and initialize the Greenplum Database system. This system user is referred to as `gppadmin` in the Greenplum documentation. The `gppadmin` user is the default database superuser in Greenplum Database, as well as the file system owner of the Greenplum installation and its underlying data files. The default administrator account is fundamental to the design of Greenplum Database. The system cannot run without it, and there is no way to limit the access of the `gppadmin` user id.

The `gppadmin` user can bypass all security features of Greenplum Database. Anyone who logs on to a Greenplum host with this user id can read, alter, or delete any data, including system catalog data and database access rights. Therefore, it is very important to secure the `gppadmin` user id and only allow essential system administrators access to it.

Administrators should only log in to Greenplum as `gppadmin` when performing certain system maintenance tasks (such as upgrade or expansion).

Database users should never log on as `gppadmin`, and ETL or production workloads should never run as `gppadmin`.

Superusers

Roles granted the `SUPERUSER` attribute are superusers. Superusers bypass all access privilege checks and resource queues. Only system administrators should be given superuser rights.

See “Altering Role Attributes” in the *Greenplum Database Administrator Guide*.

Login Users

Assign a distinct role to each user who logs in and set the `LOGIN` attribute.

For logging and auditing purposes, each user who is allowed to log in to Greenplum Database should be given their own database role. For applications or web services, consider creating a distinct role for each application or service. See “Creating New Roles (Users)” in the *Greenplum Database Administrator Guide*.

Each login role should be assigned to a single, non-default resource queue.

Groups

Use groups to manage access privileges.

Create a group for each logical grouping of object/access permissions.

Every login user should belong to one or more roles. Use the `GRANT` statement to add group access to a role. Use the `REVOKE` statement to remove group access from a role.

The `LOGIN` attribute should not be set for group roles.

See “Creating Groups (Role Membership)” in the *Greenplum Database Administrator Guide*.

Object Privileges

Only the owner and superusers have full permissions to new objects. Permission must be granted to allow other roles (users or groups) to access objects. Each type of database object has different privileges that may be granted. Use the `GRANT` statement to add a permission to a role and the `REVOKE`

statement to remove the permission.

You can change the owner of an object using the `REASSIGN OWNED BY` statement. For example, to prepare to drop a role, change the owner of the objects that belong to the role. Use the `DROP OWNED BY` to drop objects, including dependent objects, that are owned by a role.

Schemas can be used to enforce an additional layer of object permissions checking, but schema permissions do not override object privileges set on objects contained within the schema.

Operating System Users and File System

Note: Commands shown in this section should be run as the root user.

To protect the network from intrusion, system administrators should verify the passwords used within an organization are sufficiently strong. The following recommendations can strengthen a password:

- Minimum password length recommendation: At least 9 characters. MD5 passwords should be 15 characters or longer.
- Mix upper and lower case letters.
- Mix letters and numbers.
- Include non-alphanumeric characters.
- Pick a password you can remember.

The following are recommendations for password cracker software that you can use to determine the strength of a password.

- John The Ripper. A fast and flexible password cracking program. It allows the use of multiple word lists and is capable of brute-force password cracking. It is available online at <http://www.openwall.com/john/>.
- Crack. Perhaps the most well-known password cracking software, Crack is also very fast, though not as easy to use as John The Ripper. It can be found online at <https://dropsafe.crypticide.com/alecm/software/crack/c50-faq.html>.

The security of the entire system depends on the strength of the root password. This password should be at least 12 characters long and include a mix of capitalized letters, lowercase letters, special characters, and numbers. It should not be based on any dictionary word.

Password expiration parameters should be configured. The following commands must be run as `root` or using `sudo`.

Ensure the following line exists within the file `/etc/libuser.conf` under the `[import]` section.

```
login_defs = /etc/login.defs
```

Ensure no lines in the `[userdefaults]` section begin with the following text, as these words override settings from `/etc/login.defs`:

- `LU_SHADOWMAX`
- `LU_SHADOWMIN`
- `LU_SHADOWWARNING`

Ensure the following command produces no output. Any accounts listed by running this command should be locked.

```
grep "^+:" /etc/passwd /etc/shadow /etc/group
```

Note: We strongly recommend that customers change their passwords after initial setup.

```
cd /etc
chown root:root passwd shadow group gshadow
chmod 644 passwd group
chmod 400 shadow gshadow
```

Find all the files that are world-writable and that do not have their sticky bits set.

```
find / -xdev -type d \( -perm -0002 -a ! -perm -1000 \) -print
```

Set the sticky bit (`# chmod +t {dir}`) for all the directories that result from running the previous command.

Find all the files that are world-writable and fix each file listed.

```
find / -xdev -type f -perm -0002 -print
```

Set the right permissions (`# chmod o-w {file}`) for all the files generated by running the aforementioned command.

Find all the files that do not belong to a valid user or group and either assign an owner or remove the file, as appropriate.

```
find / -xdev \( -nouser -o -nogroup \) -print
```

Find all the directories that are world-writable and ensure they are owned by either root or a system account (assuming only system accounts have a User ID lower than 500). If the command generates any output, verify the assignment is correct or reassign it to root.

```
find / -xdev -type d -perm -0002 -uid +500 -print
```

Authentication settings such as password quality, password expiration policy, password reuse, password retry attempts, and more can be configured using the Pluggable Authentication Modules (PAM) framework. PAM looks in the directory `/etc/pam.d` for application-specific configuration information. Running `authconfig` or `system-config-authentication` will re-write the PAM configuration files, destroying any manually made changes and replacing them with system defaults.

The default `pam_cracklib` PAM module provides strength checking for passwords. To configure `pam_cracklib` to require at least one uppercase character, lowercase character, digit, and special character, as recommended by the U.S. Department of Defense guidelines, edit the file `/etc/pam.d/system-auth` to include the following parameters in the line corresponding to password requisite `pam_cracklib.so try_first_pass`.

```
retry=3:
dcredit=-1. Require at least one digit
ucredit=-1. Require at least one upper case character
```

```
ocredit=-1. Require at least one special character
lcredit=-1. Require at least one lower case character
minlen=14. Require a minimum password length of 14.
```

For example:

```
password required pam_cracklib.so try_first_pass retry=3\minlen=14 dcredit=-1 ucredit=-1 ocredit=-1 lcredit=-1
```

These parameters can be set to reflect your security policy requirements. Note that the password restrictions are not applicable to the root password.

The `pam_tally2` PAM module provides the capability to lock out user accounts after a specified number of failed login attempts. To enforce password lockout, edit the file `/etc/pam.d/system-auth` to include the following lines:

- The first of the auth lines should include:

```
auth required pam_tally2.so deny=5 onerr=fail unlock_time=900
```

- The first of the account lines should include:

```
account required pam_tally2.so
```

Here, the deny parameter is set to limit the number of retries to 5 and the `unlock_time` has been set to 900 seconds to keep the account locked for 900 seconds before it is unlocked. These parameters may be configured appropriately to reflect your security policy requirements. A locked account can be manually unlocked using the `pam_tally2` utility:

```
/sbin/pam_tally2 --user {username} --reset
```

You can use PAM to limit the reuse of recent passwords. The remember option for the `pam_unix` module can be set to remember the recent passwords and prevent their reuse. To accomplish this, edit the appropriate line in `/etc/pam.d/system-auth` to include the remember option.

For example:

```
password sufficient pam_unix.so [ ... existing_options ...]
remember=5
```

You can set the number of previous passwords to remember to appropriately reflect your security policy requirements.

```
cd /etc
chown root:root passwd shadow group gshadow
chmod 644 passwd group
chmod 400 shadow gshadow
```

Managing Data

This collection of topics provides information about using SQL commands, Greenplum utilities, and advanced analytics integrations to manage data in your Greenplum Database cluster.

- [Defining Database Objects](#)
This topic covers data definition language (DDL) in Greenplum Database and how to create and manage database objects.
- [Working with External Data](#)
Both external and foreign tables provide access to data stored in data sources outside of Greenplum Database as if the data were stored in regular database tables. You can read data from and write data to external and foreign tables.
- [Loading and Unloading Data](#)
Greenplum Database supports high-performance parallel data loading and unloading, and for smaller amounts of data, single file, non-parallel data import and export. The topics in this section describe methods for loading and writing data into and out of a Greenplum Database, and how to format data files.
- [Querying Data](#)
This topic provides information about using SQL queries to view, change, and analyze data in a database using the `psql` interactive SQL client and other client tools.
- [Advanced Analytics](#)
Greenplum offers a unique combination of a powerful, massively parallel processing (MPP) database and advanced data analytics. This combination creates an ideal framework for data scientists, data architects and business decision makers to explore artificial intelligence (AI), machine learning, deep learning, text analytics, and geospatial analytics.
- [Inserting, Updating, and Deleting Data](#)
This topic provides information about manipulating data and concurrent access in Greenplum Database.

Defining Database Objects

This section covers data definition language (DDL) in Greenplum Database and how to create and manage database objects.

Creating objects in a Greenplum Database includes making up-front choices about data distribution, storage options, data loading, and other Greenplum features that will affect the ongoing performance of your database system. Understanding the options that are available and how the database will be used will help you make the right decisions.

Most of the advanced Greenplum features are enabled with extensions to the SQL `CREATE` DDL statements.

Parent topic: [Greenplum Database Administrator Guide](#)

Creating and Managing Databases

A Greenplum Database system is a single instance of Greenplum Database. There can be several separate Greenplum Database systems installed, but usually just one is selected by environment variable settings. See your Greenplum administrator for details.

There can be multiple databases in a Greenplum Database system. This is different from some database management systems (such as Oracle) where the database instance *is* the database. Although you can create many databases in a Greenplum system, client programs can connect to and access only one database at a time — you cannot cross-query between databases.

Parent topic: [Defining Database Objects](#)

About Template and Default Databases

Greenplum Database provides some template databases and a default database, *template1*, *template0*, and *postgres*.

By default, each new database you create is based on a *template* database. Greenplum Database uses *template1* to create databases unless you specify another template. Creating objects in *template1* is not recommended. The objects will be in every database you create using the default template database.

Greenplum Database uses another database template, *template0*, internally. Do not drop or modify *template0*. You can use *template0* to create a completely clean database containing only the standard objects predefined by Greenplum Database at initialization.

You can use the *postgres* database to connect to Greenplum Database for the first time. Greenplum Database uses *postgres* as the default database for administrative connections. For example, *postgres* is used by startup processes, the Global Deadlock Detector process, and the FTS (Fault Tolerance Server) process for catalog access.

Creating a Database

The `CREATE DATABASE` command creates a new database. For example:

```
=> CREATE DATABASE <new_dbname>;
```

To create a database, you must have privileges to create a database or be a Greenplum Database superuser. If you do not have the correct privileges, you cannot create a database. Contact your Greenplum Database administrator to either give you the necessary privilege or to create a database for you.

You can also use the client program `createdb` to create a database. For example, running the following command in a command line terminal connects to Greenplum Database using the provided

host name and port and creates a database named *mydatabase*:

```
$ createdb -h masterhost -p 5432 mydatabase
```

The host name and port must match the host name and port of the installed Greenplum Database system.

Some objects, such as roles, are shared by all the databases in a Greenplum Database system. Other objects, such as tables that you create, are known only in the database in which you create them.

Warning: The `CREATE DATABASE` command is not transactional.

Cloning a Database

By default, a new database is created by cloning the standard system database template, *template1*. Any database can be used as a template when creating a new database, thereby providing the capability to ‘clone’ or copy an existing database and all objects and data within that database. For example:

```
=> CREATE DATABASE <new_dbname> TEMPLATE <old_dbname>;
```

Creating a Database with a Different Owner

Another database owner can be assigned when a database is created:

```
=> CREATE DATABASE <new_dbname> WITH <owner=new_user>;
```

Viewing the List of Databases

If you are working in the `psql` client program, you can use the `\l` meta-command to show the list of databases and templates in your Greenplum Database system. If using another client program and you are a superuser, you can query the list of databases from the `pg_database` system catalog table. For example:

```
=> SELECT datname from pg_database;
```

Altering a Database

The `ALTER DATABASE` command changes database attributes such as owner, name, or default configuration attributes. For example, the following command alters a database by setting its default schema search path (the `search_path` configuration parameter):

```
=> ALTER DATABASE mydatabase SET search_path TO myschema, public, pg_catalog;
```

To alter a database, you must be the owner of the database or a superuser.

Dropping a Database

The `DROP DATABASE` command drops (or deletes) a database. It removes the system catalog entries for the database and deletes the database directory on disk that contains the data. You must be the database owner or a superuser to drop a database, and you cannot drop a database while you or anyone else is connected to it. Connect to `postgres` (or another database) before dropping a database. For example:

```
=> DROP DATABASE mydatabase;
```

```
=> \c postgres
=> DROP DATABASE mydatabase;
```

You can also use the client program `dropdb` to drop a database. For example, the following command connects to Greenplum Database using the provided host name and port and drops the database *mydatabase*:

```
$ dropdb -h masterhost -p 5432 mydatabase
```

Warning: Dropping a database cannot be undone.

The `DROP DATABASE` command is not transactional.

Creating and Managing Tablespaces

Tablespaces allow database administrators to have multiple file systems per machine and decide how to best use physical storage to store database objects. Tablespaces allow you to assign different storage for frequently and infrequently used database objects or to control the I/O performance on certain database objects. For example, place frequently-used tables on file systems that use high performance solid-state drives (SSD), and place other tables on standard hard drives.

A tablespace requires a host file system location to store its database files. In Greenplum Database, the file system location must exist on all hosts including the hosts running the master, standby master, each primary segment, and each mirror segment.

A tablespace is Greenplum Database system object (a global object), you can use a tablespace from any database if you have appropriate privileges.

Note: Greenplum Database does not support different tablespace locations for a primary-mirror pair with the same content ID. It is only possible to configure different locations for different content IDs. Do not modify symbolic links under the `pg_tblspc` directory so that primary-mirror pairs point to different file locations; this will lead to erroneous behavior.

Parent topic: [Defining Database Objects](#)

Creating a Tablespace

The `CREATE TABLESPACE` command defines a tablespace. For example:

```
CREATE TABLESPACE fastspace LOCATION '/fastdisk/gpdb';
```

Database superusers define tablespaces and grant access to database users with the `GRANT CREATE` command. For example:

```
GRANT CREATE ON TABLESPACE fastspace TO admin;
```

Using a Tablespace to Store Database Objects

Users with the `CREATE` privilege on a tablespace can create database objects in that tablespace, such as tables, indexes, and databases. The command is:

```
CREATE TABLE tablename(options) TABLESPACE spacename
```

For example, the following command creates a table in the tablespace *space1*:

```
CREATE TABLE foo(i int) TABLESPACE spacel;
```

You can also use the `default_tablespace` parameter to specify the default tablespace for `CREATE TABLE` and `CREATE INDEX` commands that do not specify a tablespace:

```
SET default_tablespace = spacel;
CREATE TABLE foo(i int);
```

There is also the `temp_tablespaces` configuration parameter, which determines the placement of temporary tables and indexes, as well as temporary files that are used for purposes such as sorting large data sets. This can be a comma-separate list of tablespace names, rather than only one, so that the load associated with temporary objects can be spread over multiple tablespaces. A random member of the list is picked each time a temporary object is to be created.

The tablespace associated with a database stores that database's system catalogs, temporary files created by server processes using that database, and is the default tablespace selected for tables and indexes created within the database, if no `TABLESPACE` is specified when the objects are created. If you do not specify a tablespace when you create a database, the database uses the same tablespace used by its template database.

You can use a tablespace from any database in the Greenplum Database system if you have appropriate privileges.

Viewing Existing Tablespaces

Every Greenplum Database system has the following default tablespaces.

- `pg_global` for shared system catalogs.
- `pg_default`, the default tablespace. Used by the `template1` and `template0` databases.

These tablespaces use the default system location, the data directory locations created at system initialization.

To see tablespace information, use the `pg_tablespace` catalog table to get the object ID (OID) of the tablespace and then use `gp_tablespace_location()` function to display the tablespace directories. This is an example that lists one user-defined tablespace, `myspace`:

```
SELECT oid, * FROM pg_tablespace ;
```

oid	spcname	spcowner	spcacl	spcoptions
1663	pg_default	10		
1664	pg_global	10		
16391	myspace	10		

(3 rows)

The OID for the tablespace `myspace` is `16391`. Run `gp_tablespace_location()` to display the tablespace locations for a system that consists of two segment instances and the master.

```
# SELECT * FROM gp_tablespace_location(16391);
```

gp_segment_id	tblspc_loc
0	/data/mytblspace
1	/data/mytblspace
-1	/data/mytblspace

(3 rows)

This query uses `gp_tablespace_location()` the `gp_segment_configuration` catalog table to display segment instance information with the file system location for the `myspace` tablespace.

```
WITH spc AS (SELECT * FROM gp_tablespace_location(16391))
SELECT seg.role, spc.gp_segment_id as seg_id, seg.hostname, seg.datadir, tblspc_loc
FROM spc, gp_segment_configuration AS seg
WHERE spc.gp_segment_id = seg.content ORDER BY seg_id;
```

This is information for a test system that consists of two segment instances and the master on a single host.

role	seg_id	hostname	datadir	tblspc_loc
p	-1	testhost	/data/master/gpseg-1	/data/mytblspace
p	0	testhost	/data/data1/gpseg0	/data/mytblspace
p	1	testhost	/data/data2/gpseg1	/data/mytblspace

(3 rows)

Dropping Tablespaces

To drop a tablespace, you must be the tablespace owner or a superuser. You cannot drop a tablespace until all objects in all databases using the tablespace are removed.

The `DROP TABLESPACE` command removes an empty tablespace.

Note: You cannot drop a tablespace if it is not empty or if it stores temporary or transaction files.

Moving the Location of Temporary or Transaction Files

You can move temporary or transaction files to a specific tablespace to improve database performance when running queries, creating backups, and to store data more sequentially.

The Greenplum Database server configuration parameter `temp_tablespaces` controls the location for both temporary tables and temporary spill files for hash aggregate and hash join queries. Temporary files for purposes such as sorting large data sets are also created in these tablespaces.

`temp_tablespaces` specifies tablespaces in which to create temporary objects (temp tables and indexes on temp tables) when a `CREATE` command does not explicitly specify a tablespace.

Also note the following information about temporary or transaction files:

- You can dedicate only one tablespace for temporary or transaction files, although you can use the same tablespace to store other types of files.
- You cannot drop a tablespace if it used by temporary files.

Creating and Managing Schemas

Schemas logically organize objects and data in a database. Schemas allow you to have more than one object (such as tables) with the same name in the database without conflict if the objects are in different schemas.

Parent topic: [Defining Database Objects](#)

The Default “Public” Schema

Every database has a default schema named *public*. If you do not create any schemas, objects are created in the *public* schema. All database roles (users) have **CREATE** and **USAGE** privileges in the *public* schema. When you create a schema, you grant privileges to your users to allow access to the schema.

Creating a Schema

Use the **CREATE SCHEMA** command to create a new schema. For example:

```
=> CREATE SCHEMA myschema;
```

To create or access objects in a schema, write a qualified name consisting of the schema name and table name separated by a period. For example:

```
myschema.table
```

See [Schema Search Paths](#) for information about accessing a schema.

You can create a schema owned by someone else, for example, to restrict the activities of your users to well-defined namespaces. The syntax is:

```
=> CREATE SCHEMA `schemaname` AUTHORIZATION `username`;
```

Schema Search Paths

To specify an object's location in a database, use the schema-qualified name. For example:

```
=> SELECT * FROM myschema.mytable;
```

You can set the **search_path** configuration parameter to specify the order in which to search the available schemas for objects. The schema listed first in the search path becomes the *default* schema. If a schema is not specified, objects are created in the default schema.

Setting the Schema Search Path

The **search_path** configuration parameter sets the schema search order. The **ALTER DATABASE** command sets the search path. For example:

```
=> ALTER DATABASE mydatabase SET search_path TO myschema,  
public, pg_catalog;
```

You can also set **search_path** for a particular role (user) using the **ALTER ROLE** command. For example:

```
=> ALTER ROLE sally SET search_path TO myschema, public,  
pg_catalog;
```

Viewing the Current Schema

Use the **current_schema()** function to view the current schema. For example:

```
=> SELECT current_schema();
```

Use the `SHOW` command to view the current search path. For example:

```
=> SHOW search_path;
```

Dropping a Schema

Use the `DROP SCHEMA` command to drop (delete) a schema. For example:

```
=> DROP SCHEMA myschema;
```

By default, the schema must be empty before you can drop it. To drop a schema and all of its objects (tables, data, functions, and so on) use:

```
=> DROP SCHEMA myschema CASCADE;
```

System Schemas

The following system-level schemas exist in every database:

- `pg_catalog` contains the system catalog tables, built-in data types, functions, and operators. It is always part of the schema search path, even if it is not explicitly named in the search path.
- `information_schema` consists of a standardized set of views that contain information about the objects in the database. These views get system information from the system catalog tables in a standardized way.
- `pg_toast` stores large objects such as records that exceed the page size. This schema is used internally by the Greenplum Database system.
- `pg_bitmapindex` stores bitmap index objects such as lists of values. This schema is used internally by the Greenplum Database system.
- `pg_aoseg` stores append-optimized table objects. This schema is used internally by the Greenplum Database system.
- `gp_toolkit` is an administrative schema that contains external tables, views, and functions that you can access with SQL commands. All database users can access `gp_toolkit` to view and query the system log files and other system metrics.

Creating and Managing Tables

Greenplum Database tables are similar to tables in any relational database, except that table rows are distributed across the different segments in the system. When you create a table, you specify the table's distribution policy.

Creating a Table

The `CREATE TABLE` command creates a table and defines its structure. When you create a table, you define:

- The columns of the table and their associated data types. See [Choosing Column Data Types](#).

- Any table or column constraints to limit the data that a column or table can contain. See [Setting Table and Column Constraints](#).
- The distribution policy of the table, which determines how Greenplum Database divides data across the segments. See [Choosing the Table Distribution Policy](#).
- The way the table is stored on disk. See [Choosing the Table Storage Model](#).
- The table partitioning strategy for large tables. See [Creating and Managing Databases](#).

Choosing Column Data Types

The data type of a column determines the types of data values the column can contain. Choose the data type that uses the least possible space but can still accommodate your data and that best constrains the data. For example, use character data types for strings, date or timestamp data types for dates, and numeric data types for numbers.

For table columns that contain textual data, specify the data type `VARCHAR` or `TEXT`. Specifying the data type `CHAR` is not recommended. In Greenplum Database, the data types `VARCHAR` or `TEXT` handle padding added to the data (space characters added after the last non-space character) as significant characters, the data type `CHAR` does not. For information on the character data types, see the `CREATE TABLE` command in the *Greenplum Database Reference Guide*.

Use the smallest numeric data type that will accommodate your numeric data and allow for future expansion. For example, using `BIGINT` for data that fits in `INT` or `SMALLINT` wastes storage space. If you expect that your data values will expand over time, consider that changing from a smaller datatype to a larger datatype after loading large amounts of data is costly. For example, if your current data values fit in a `SMALLINT` but it is likely that the values will expand, `INT` is the better long-term choice.

Use the same data types for columns that you plan to use in cross-table joins. Cross-table joins usually use the primary key in one table and a foreign key in the other table. When the data types are different, the database must convert one of them so that the data values can be compared correctly, which adds unnecessary overhead.

Greenplum Database has a rich set of native data types available to users. See the *Greenplum Database Reference Guide* for information about the built-in data types.

Setting Table and Column Constraints

You can define constraints on columns and tables to restrict the data in your tables. Greenplum Database support for constraints is the same as PostgreSQL with some limitations, including:

- `CHECK` constraints can refer only to the table on which they are defined.
- `UNIQUE` and `PRIMARY KEY` constraints must be compatible with their table's distribution key and partitioning key, if any.

Note: `UNIQUE` and `PRIMARY KEY` constraints are not allowed on append-optimized tables because the `UNIQUE` indexes that are created by the constraints are not allowed on append-optimized tables.

- `FOREIGN KEY` constraints are allowed, but not enforced.
- Constraints that you define on partitioned tables apply to the partitioned table as a whole. You cannot define constraints on the individual parts of the table.

Check Constraints

Check constraints allow you to specify that the value in a certain column must satisfy a Boolean

(truth-value) expression. For example, to require positive product prices:

```
=> CREATE TABLE products
      ( product_no integer,
        name text,
        price numeric CHECK (price > 0) );
```

Not-Null Constraints

Not-null constraints specify that a column must not assume the null value. A not-null constraint is always written as a column constraint. For example:

```
=> CREATE TABLE products
      ( product_no integer NOT NULL,
        name text NOT NULL,
        price numeric );
```

Unique Constraints

Unique constraints ensure that the data contained in a column or a group of columns is unique with respect to all the rows in the table. The table must be hash-distributed or replicated (not **DISTRIBUTED RANDOMLY**). If the table is hash-distributed, the constraint columns must be the same as (or a superset of) the table's distribution key columns. For example:

```
=> CREATE TABLE products
      ( `product_no` integer `UNIQUE`,
        name text,
        price numeric)
`
DISTRIBUTED BY (`product_no`);
```

Primary Keys

A primary key constraint is a combination of a **UNIQUE** constraint and a **NOT NULL** constraint. The table must be hash-distributed (not **DISTRIBUTED RANDOMLY**), and the primary key columns must be the same as (or a superset of) the table's distribution key columns. If a table has a primary key, this column (or group of columns) is chosen as the distribution key for the table by default. For example:

```
=> CREATE TABLE products
      ( `product_no` integer `PRIMARY KEY`,
        name text,
        price numeric)
`
DISTRIBUTED BY (`product_no`);
```

Foreign Keys

Foreign keys are not supported. You can declare them, but referential integrity is not enforced.

Foreign key constraints specify that the values in a column or a group of columns must match the values appearing in some row of another table to maintain referential integrity between two related tables. Referential integrity checks cannot be enforced between the distributed table segments of a Greenplum database.

Choosing the Table Distribution Policy

All Greenplum Database tables are distributed. When you create or alter a table, you optionally specify `DISTRIBUTED BY` (hash distribution), `DISTRIBUTED RANDOMLY` (round-robin distribution), or `DISTRIBUTED REPLICATED` (fully distributed) to determine the table row distribution.

Note: The Greenplum Database server configuration parameter `gp_create_table_random_default_distribution` controls the table distribution policy if the `DISTRIBUTED BY` clause is not specified when you create a table.

For information about the parameter, see “Server Configuration Parameters” of the *Greenplum Database Reference Guide*.

Consider the following points when deciding on a table distribution policy.

- **Even Data Distribution** — For the best possible performance, all segments should contain equal portions of data. If the data is unbalanced or skewed, the segments with more data must work harder to perform their portion of the query processing. Choose a distribution key that is unique for each record, such as the primary key.
- **Local and Distributed Operations** — Local operations are faster than distributed operations. Query processing is fastest if the work associated with join, sort, or aggregation operations is done locally, at the segment level. Work done at the system level requires distributing tuples across the segments, which is less efficient. When tables share a common distribution key, the work of joining or sorting on their shared distribution key columns is done locally. With a random distribution policy, local join operations are not an option.
- **Even Query Processing** — For best performance, all segments should handle an equal share of the query workload. Query workload can be skewed if a table’s data distribution policy and the query predicates are not well matched. For example, suppose that a sales transactions table is distributed on the customer ID column (the distribution key). If a predicate in a query references a single customer ID, the query processing work is concentrated on just one segment.

The replicated table distribution policy (`DISTRIBUTED REPLICATED`) should be used only for small tables. Replicating data to every segment is costly in both storage and maintenance, and prohibitive for large fact tables. The primary use cases for replicated tables are to:

- remove restrictions on operations that user-defined functions can perform on segments, and
- improve query performance by making it unnecessary to broadcast frequently used tables to all segments.

Note: The hidden system columns (`ctid`, `cmin`, `cmax`, `xmin`, `xmax`, and `gp_segment_id`) cannot be referenced in user queries on replicated tables because they have no single, unambiguous value. Greenplum Database returns a `column does not exist` error for the query.

Declaring Distribution Keys

`CREATE TABLE`’s optional clauses `DISTRIBUTED BY`, `DISTRIBUTED RANDOMLY`, and `DISTRIBUTED REPLICATED` specify the distribution policy for a table. The default is a hash distribution policy that uses either the `PRIMARY KEY` (if the table has one) or the first column of the table as the distribution key. Columns with geometric or user-defined data types are not eligible as Greenplum Database distribution key columns. If a table does not have an eligible column, Greenplum Database distributes the rows randomly or in round-robin fashion.

Replicated tables have no distribution key because every row is distributed to every Greenplum Database segment instance.

To ensure even distribution of hash-distributed data, choose a distribution key that is unique for each record. If that is not possible, choose `DISTRIBUTED RANDOMLY`. For example:

```
=> CREATE TABLE products
`
        (name varchar(40),
        prod_id integer,
        supplier_id integer)
        DISTRIBUTED BY (prod_id);
`
```

```
=> CREATE TABLE random_stuff
`
        (things text,
        doodads text,
        etc text)
        DISTRIBUTED RANDOMLY;
`
```

Important: If a primary key exists, it is the default distribution key for the table. If no primary key exists, but a unique key exists, this is the default distribution key for the table.

Custom Distribution Key Hash Functions

The hash function used for hash distribution policy is defined by the hash operator class for the column's data type. As the default Greenplum Database uses the data type's default hash operator class, the same operator class used for hash joins and hash aggregates, which is suitable for most use cases. However, you can declare a non-default hash operator class in the **DISTRIBUTED BY** clause.

Using a custom hash operator class can be useful to support co-located joins on a different operator than the default equality operator (**=**).

Example Custom Hash Operator Class

This example creates a custom hash operator class for the integer data type that is used to improve query performance. The operator class compares the absolute values of integers.

Create a function and an equality operator that returns true if the absolute values of two integers are equal.

```
CREATE FUNCTION abseq(int, int) RETURNS BOOL AS
$$
    begin return abs($1) = abs($2); end;
$$ LANGUAGE plpgsql STRICT IMMUTABLE;

CREATE OPERATOR |=| (
    PROCEDURE = abseq,
    LEFTARG = int,
    RIGHTARG = int,
    COMMUTATOR = |=|,
    hashes, merges);
```

Now, create a hash function and operator class that uses the operator.

```
CREATE FUNCTION abshashfunc(int) RETURNS int AS
$$
    begin return hashint4(abs($1)); end;
$$ LANGUAGE plpgsql STRICT IMMUTABLE;

CREATE OPERATOR CLASS abs_int_hash_ops FOR TYPE int4
    USING hash AS
    OPERATOR 1 |=|,
    FUNCTION 1 abshashfunc(int);
```

Also, create less than and greater than operators, and a btree operator class for them. We don't need them for our queries, but the Postgres Planner will not consider co-location of joins without them.

```
CREATE FUNCTION abslt(int, int) RETURNS BOOL AS
$$
begin return abs($1) < abs($2); end;
$$ LANGUAGE plpgsql STRICT IMMUTABLE;

CREATE OPERATOR |<| (
  PROCEDURE = abslt,
  LEFTARG = int,
  RIGHTARG = int);

CREATE FUNCTION absgt(int, int) RETURNS BOOL AS
$$
begin return abs($1) > abs($2); end;
$$ LANGUAGE plpgsql STRICT IMMUTABLE;

CREATE OPERATOR |>| (
  PROCEDURE = absgt,
  LEFTARG = int,
  RIGHTARG = int);

CREATE FUNCTION abscmp(int, int) RETURNS int AS
$$
begin return btint4cmp(abs($1),abs($2)); end;
$$ LANGUAGE plpgsql STRICT IMMUTABLE;

CREATE OPERATOR CLASS abs_int_btree_ops FOR TYPE int4
  USING btree AS
  OPERATOR 1 |<|,
  OPERATOR 3 |=|,
  OPERATOR 5 |>|,
  FUNCTION 1 abscmp(int, int);
```

Now, you can use the custom hash operator class in tables.

```
CREATE TABLE atab (a int) DISTRIBUTED BY (a abs_int_hash_ops);
CREATE TABLE btab (b int) DISTRIBUTED BY (b abs_int_hash_ops);

INSERT INTO atab VALUES (-1), (0), (1);
INSERT INTO btab VALUES (-1), (0), (1), (2);
```

Queries that perform a join that use the custom equality operator `|=|` can take advantage of the co-location.

With the default integer opclass, this query requires Redistribute Motion nodes.

```
EXPLAIN (COSTS OFF) SELECT a, b FROM atab, btab WHERE a = b;
               QUERY PLAN
-----
 Gather Motion 4:1  (slice3; segments: 4)
   -> Hash Join
       Hash Cond: (atab.a = btab.b)
       -> Redistribute Motion 4:4  (slice1; segments: 4)
           Hash Key: atab.a
           -> Seq Scan on atab
       -> Hash
           -> Redistribute Motion 4:4  (slice2; segments: 4)
               Hash Key: btab.b
               -> Seq Scan on btab
 Optimizer: Postgres query optimizer
```

```
(11 rows)
```

With the custom opclass, a more efficient plan is possible.

```
EXPLAIN (COSTS OFF) SELECT a, b FROM atab, btab WHERE a |=| b;
               QUERY PLAN
-----
 Gather Motion 4:1  (slice1; segments: 4)
   -> Hash Join
       Hash Cond: (atab.a |=| btab.b)
       -> Seq Scan on atab
       -> Hash
           -> Seq Scan on btab
Optimizer: Postgres query optimizer
(7 rows)
```

Choosing the Table Storage Model

Greenplum Database supports several storage models and a mix of storage models. When you create a table, you choose how to store its data. This topic explains the options for table storage and how to choose the best storage model for your workload.

- [Heap Storage](#)
- [Append-Optimized Storage](#)
- [Choosing Row or Column-Oriented Storage](#)
- [Using Compression \(Append-Optimized Tables Only\)](#)
- [Checking the Compression and Distribution of an Append-Optimized Table](#)
- [Altering a Table](#)
- [Dropping a Table](#)

Note: To simplify the creation of database tables, you can specify the default values for some table storage options with the Greenplum Database server configuration parameter

`gp_default_storage_options`.

For information about the parameter, see “Server Configuration Parameters” in the *Greenplum Database Reference Guide*.

Parent topic: [Defining Database Objects](#)

Heap Storage

By default, Greenplum Database uses the same heap storage model as PostgreSQL. Heap table storage works best with OLTP-type workloads where the data is often modified after it is initially loaded. `UPDATE` and `DELETE` operations require storing row-level versioning information to ensure reliable database transaction processing. Heap tables are best suited for smaller tables, such as dimension tables, that are often updated after they are initially loaded.

Append-Optimized Storage

Append-optimized table storage works best with denormalized fact tables in a data warehouse environment. Denormalized fact tables are typically the largest tables in the system. Fact tables are usually loaded in batches and accessed by read-only queries. Moving large fact tables to an append-optimized storage model eliminates the storage overhead of the per-row update visibility information, saving about 20 bytes per row. This allows for a leaner and easier-to-optimize page structure. The storage model of append-optimized tables is optimized for bulk data loading. Single

row `INSERT` statements are not recommended.

To create a heap table

Row-oriented heap tables are the default storage type.

```
=> CREATE TABLE foo (a int, b text) DISTRIBUTED BY (a);
```

Use the `WITH` clause of the `CREATE TABLE` command to declare the table storage options. The default is to create the table as a regular row-oriented heap-storage table. For example, to create an append-optimized table with no compression:

```
=> CREATE TABLE bar (a int, b text)
    WITH (appendoptimized=true)
    DISTRIBUTED BY (a);
```

Note: You use the `appendoptimized=value` syntax to specify the append-optimized table storage type. `appendoptimized` is a thin alias for the `appendonly` legacy storage option. Greenplum Database stores `appendonly` in the catalog, and displays the same when listing storage options for append-optimized tables.

`UPDATE` and `DELETE` are not allowed on append-optimized tables in a repeatable read or serializable transaction and will cause the transaction to end prematurely. `DECLARE...FOR UPDATE` and triggers are not supported with append-optimized tables. `CLUSTER` on append-optimized tables is only supported over B-tree indexes.

Choosing Row or Column-Oriented Storage

Greenplum provides a choice of storage orientation models: row, column, or a combination of both. This topic provides general guidelines for choosing the optimum storage orientation for a table. Evaluate performance using your own data and query workloads.

- **Row-oriented storage:** good for OLTP types of workloads with many iterative transactions and many columns of a single row needed all at once, so retrieving is efficient.
- **Column-oriented storage:** good for data warehouse workloads with aggregations of data computed over a small number of columns, or for single columns that require regular updates without modifying other column data.

For most general purpose or mixed workloads, row-oriented storage offers the best combination of flexibility and performance. However, there are use cases where a column-oriented storage model provides more efficient I/O and storage. Consider the following requirements when deciding on the storage orientation model for a table:

- **Updates of table data.** If you load and update the table data frequently, choose a row-oriented heap table. Column-oriented table storage is only available on append-optimized tables.
See [Heap Storage](#) for more information.
- **Frequent INSERTs.** If rows are frequently inserted into the table, consider a row-oriented model. Column-oriented tables are not optimized for write operations, as column values for a row must be written to different places on disk.
- **Number of columns requested in queries.** If you typically request all or the majority of columns in the `SELECT` list or `WHERE` clause of your queries, consider a row-oriented model. Column-oriented tables are best suited to queries that aggregate many values of a single column where the `WHERE` or `HAVING` predicate is also on the aggregate column. For example:

```
SELECT SUM(salary)...
```

```
SELECT AVG(salary)... WHERE salary > 10000
```

Or where the **WHERE** predicate is on a single column and returns a relatively small number of rows. For example:

```
SELECT salary, dept ... WHERE state='CA'
```

- **Number of columns in the table.** Row-oriented storage is more efficient when many columns are required at the same time, or when the row-size of a table is relatively small. Column-oriented tables can offer better query performance on tables with many columns where you access a small subset of columns in your queries.
- **Compression.** Column data has the same data type, so storage size optimizations are available in column-oriented data that are not available in row-oriented data. For example, many compression schemes use the similarity of adjacent data to compress. However, the greater adjacent compression achieved, the more difficult random access can become, as data must be uncompressed to be read.

To create a column-oriented table

The **WITH** clause of the **CREATE TABLE** command specifies the table's storage options. The default is a row-oriented heap table. Tables that use column-oriented storage must be append-optimized tables. For example, to create a column-oriented table:

```
=> CREATE TABLE bar (a int, b text)
    WITH (appendoptimized=true, orientation=column)
    DISTRIBUTED BY (a);
```

Using Compression (Append-Optimized Tables Only)

There are two types of in-database compression available in the Greenplum Database for append-optimized tables:

- Table-level compression is applied to an entire table.
- Column-level compression is applied to a specific column. You can apply different column-level compression algorithms to different columns.

The following table summarizes the available compression algorithms.

Table Orientation	Available Compression Types	Supported Algorithms
Row	Table	ZLIB , ZSTD , and QUICKLZ *
Column	Column and Table	RLE_TYPE , ZLIB , ZSTD , and QUICKLZ *

Note: *QuickLZ compression is not available in the open source version of Greenplum Database.

When choosing a compression type and level for append-optimized tables, consider these factors:

- CPU usage. Your segment systems must have the available CPU power to compress and uncompress the data.
- Compression ratio/disk size. Minimizing disk size is one factor, but also consider the time and CPU capacity required to compress and scan data. Find the optimal settings for efficiently compressing data without causing excessively long compression times or slow scan rates.

- Speed of compression. QuickLZ compression generally uses less CPU capacity and compresses data faster at a lower compression ratio than zlib. zlib provides higher compression ratios at lower speeds.

For example, at compression level 1 (`compresslevel=1`), QuickLZ and zlib have comparable compression ratios, though at different speeds. Using zlib with `compresslevel=6` can significantly increase the compression ratio compared to QuickLZ, though with lower compression speed. Zstandard compression can provide for either good compression ratio or speed, depending on compression level, or a good compromise on both.

- Speed of decompression/scan rate. Performance with compressed append-optimized tables depends on hardware, query tuning settings, and other factors. Perform comparison testing to determine the actual performance in your environment.

Note: Do not create compressed append-optimized tables on file systems that use compression. If the file system on which your segment data directory resides is a compressed file system, your append-optimized table must not use compression.

Performance with compressed append-optimized tables depends on hardware, query tuning settings, and other factors. You should perform comparison testing to determine the actual performance in your environment.

Note: Zstd compression level can be set to values between 1 and 19. QuickLZ compression level can only be set to level 1; no other values are available. Compression level with zlib can be set to values from 1 - 9. Compression level with RLE can be set to values from 1 - 4.

An `ENCODING` clause specifies compression type and level for individual columns. When an `ENCODING` clause conflicts with a `WITH` clause, the `ENCODING` clause has higher precedence than the `WITH` clause.

To create a compressed table

The `WITH` clause of the `CREATE TABLE` command declares the table storage options. Tables that use compression must be append-optimized tables. For example, to create an append-optimized table with zlib compression at a compression level of 5:

```
=> CREATE TABLE foo (a int, b text)
    WITH (appendoptimized=true, compresstype=zlib, compresslevel=5);
```

Checking the Compression and Distribution of an Append-Optimized Table

Greenplum provides built-in functions to check the compression ratio and the distribution of an append-optimized table. The functions take either the object ID or a table name. You can qualify the table name with a schema name.

Table 2. Functions for compressed append-optimized table metadata

Function	Return Type	Description
<code>get_ao_distribution(name)</code> <code>get_ao_distribution(oid)</code>	Set of (dbid, tuplecount) rows	Shows the distribution of an append-optimized table's rows across the array. Returns a set of rows, each of which includes a segment <i>dbid</i> and the number of tuples stored on the segment.
<code>get_ao_compression_ratio(name)</code> <code>get_ao_compression_ratio(oid)</code>	float8	Calculates the compression ratio for a compressed append-optimized table. If information is not available, this function returns a value of -1.

The compression ratio is returned as a common ratio. For example, a returned value of 3.19, or 3.19:1, means that the uncompressed table is slightly larger than three times the size of the compressed table.

The distribution of the table is returned as a set of rows that indicate how many tuples are stored on each segment. For example, in a system with four primary segments with *dbid* values ranging from 0 - 3, the function returns four rows similar to the following:

```
=# SELECT get_ao_distribution('lineitem_comp');
get_ao_distribution
-----
(0,7500721)
(1,7501365)
(2,7499978)
(3,7497731)
(4 rows)
```

Support for Run-length Encoding

Greenplum Database supports Run-length Encoding (RLE) for column-level compression. RLE data compression stores repeated data as a single data value and a count. For example, in a table with two columns, a date and a description, that contains 200,000 entries containing the value *date1* and 400,000 entries containing the value *date2*, RLE compression for the date field is similar to *date1 200000 date2 400000*. RLE is not useful with files that do not have large sets of repeated data as it can greatly increase the file size.

There are four levels of RLE compression available. The levels progressively increase the compression ratio, but decrease the compression speed.

Greenplum Database versions 4.2.1 and later support column-oriented RLE compression. To backup a table with RLE compression that you intend to restore to an earlier version of Greenplum Database, alter the table to have no compression or a compression type supported in the earlier version (*ZLIB* or *QUICKLZ*) before you start the backup operation.

Greenplum Database combines delta compression with RLE compression for data in columns of type *BIGINT*, *INTEGER*, *DATE*, *TIME*, or *TIMESTAMP*. The delta compression algorithm is based on the change between consecutive column values and is designed to improve compression when data is loaded in sorted order or when the compression is applied to data in sorted order.

Adding Column-level Compression

You can add the following storage directives to a column for append-optimized tables with column orientation:

- Compression type
- Compression level
- Block size for a column

Add storage directives using the *CREATE TABLE*, *ALTER TABLE*, and *CREATE TYPE* commands.

The following table details the types of storage directives and possible values for each.

Table 3. Storage Directives for Column-level Compression

Name	Definition	Values	Comment
------	------------	--------	---------

<code>compresstype</code>	Type of compression.	<code>zstd</code> : Zstandard algorithm <code>zlib</code> : deflate algorithm <code>quicklz</code> : fast compression <code>RLE_TYPE</code> : run-length encoding <code>none</code> : no compression	Values are not case-sensitive.
<code>compresslevel</code>	Compression level.	<code>zlib</code> compression: 1-9 <code>zstd</code> compression: 1-19 <code>QuickLZ</code> compression: 1 – use compression <code>RLE_TYPE</code> compression: 1 – 4 1 - apply RLE only 2 - apply RLE then apply <code>zlib</code> compression level 1 3 - apply RLE then apply <code>zlib</code> compression level 5 4 - apply RLE then apply <code>zlib</code> compression level 9	1 is the fastest method with the least compression. 1 is the default. 9 is the slowest method with the most compression. 1 is the fastest method with the least compression. 1 is the default. 19 is the slowest method with the most compression. 1 is the default. 1 is the fastest method with the least compression. 4 is the slowest method with the most compression. 1 is the default.
<code>blocksize</code>	The size in bytes for each block in the table	8192 – 2097152	The value must be a multiple of 8192.

The following is the format for adding storage directives.

```
[ ENCODING ( <storage_directive> [, ...] ) ]
```

where the word ENCODING is required and the storage directive has three parts:

- The name of the directive
- An equals sign
- The specification

Separate multiple storage directives with a comma. Apply a storage directive to a single column or designate it as the default for all columns, as shown in the following `CREATE TABLE` clauses.

General Usage:

```
<column_name> <data_type> ENCODING ( <storage_directive> [, ...] ), ...
```

```
COLUMN <column_name> ENCODING ( <storage_directive> [, ...] ), ...
```

```
DEFAULT COLUMN ENCODING ( <storage_directive> [, ...] )
```

Example:

```
C1 char ENCODING (compresstype=quicklz, blocksize=65536)
```

```
COLUMN C1 ENCODING (compresstype=zlib, compresslevel=6, blocksize=65536)
```

```
DEFAULT COLUMN ENCODING (compresstype=quicklz)
```

Default Compression Values

If the compression type, compression level and block size are not defined, the default is no compression, and the block size is set to the Server Configuration Parameter `block_size`.

Precedence of Compression Settings

Column compression settings are inherited from the type level to the table level to the partition level to the subpartition level. The lowest-level settings have priority.

- Column compression settings defined at the table level override any compression settings for the type.
- Column compression settings specified at the table level override any compression settings for the entire table.
- Column compression settings specified for partitions override any compression settings at the column or table levels.
- Column compression settings specified for subpartitions override any compression settings at the partition, column or table levels.
- When an `ENCODING` clause conflicts with a `WITH` clause, the `ENCODING` clause has higher precedence than the `WITH` clause.

Note: The `INHERITS` clause is not allowed in a table that contains a storage directive or a column reference storage directive.

Tables created using the `LIKE` clause ignore storage directive and column reference storage directives.

Optimal Location for Column Compression Settings

The best practice is to set the column compression settings at the level where the data resides. See [Example 5](#), which shows a table with a partition depth of 2. `RLE_TYPE` compression is added to a column at the subpartition level.

Storage Directives Examples

The following examples show the use of storage directives in `CREATE TABLE` statements.

Example 1

In this example, column `c1` is compressed using `zstd` and uses the block size defined by the system. Column `c2` is compressed with `quicklz`, and uses a block size of `65536`. Column `c3` is not compressed and uses the block size defined by the system.

```
CREATE TABLE T1 (c1 int ENCODING (compresstype=zstd),
                  c2 char ENCODING (compresstype=quicklz, blocksize=65536),
                  c3 char) WITH (appendoptimized=true, orientation=column);
```

Example 2

In this example, column `c1` is compressed using `zlib` and uses the block size defined by the system. Column `c2` is compressed with `quicklz`, and uses a block size of `65536`. Column `c3` is compressed using `RLE_TYPE` and uses the block size defined by the system.

```
CREATE TABLE T2 (c1 int ENCODING (compresstype=zlib),
                  c2 char ENCODING (compresstype=quicklz, blocksize=65536),
                  c3 char,
                  COLUMN c3 ENCODING (compresstype=RLE_TYPE)
                  )
WITH (appendoptimized=true, orientation=column);
```

Example 3

In this example, column `c1` is compressed using `zlib` and uses the block size defined by the system. Column `c2` is compressed with `quicklz`, and uses a block size of `65536`. Column `c3` is compressed using `zlib` and uses the block size defined by the system. Note that column `c3` uses `zlib` (not `RLE_TYPE`) in the partitions, because the column storage in the partition clause has precedence over the storage directive in the column definition for the table.

```
CREATE TABLE T3 (c1 int ENCODING (compresstype=zlib),
                  c2 char ENCODING (compresstype=quicklz, blocksize=65536),
                  c3 text, COLUMN c3 ENCODING (compresstype=RLE_TYPE) )
WITH (appendoptimized=true, orientation=column)
PARTITION BY RANGE (c3) (START ('1900-01-01'::DATE)
                        END ('2100-12-31'::DATE),
                        COLUMN c3 ENCODING (compresstype=zlib));
```

Example 4

In this example, `CREATE TABLE` assigns the `zlib` `compresstype` storage directive to `c1`. Column `c2` has no storage directive and inherits the compression type (`quicklz`) and block size (`65536`) from the `DEFAULT COLUMN ENCODING` clause.

Column `c3`'s `ENCODING` clause defines its compression type, `RLE_TYPE`. The `ENCODING` clause defined for a specific column overrides the `DEFAULT ENCODING` clause, so column `c3` uses the default block size, `32768`.

Column `c4` has a compress type of `none` and uses the default block size.

```
CREATE TABLE T4 (c1 int ENCODING (compresstype=zlib),
                  c2 char,
                  c3 text,
                  c4 smallint ENCODING (compresstype=none),
                  DEFAULT COLUMN ENCODING (compresstype=quicklz,
                                           blocksize=65536),
                  COLUMN c3 ENCODING (compresstype=RLE_TYPE)
                  )
WITH (appendoptimized=true, orientation=column);
```

Example 5

This example creates an append-optimized, column-oriented table, T5. T5 has two partitions, `p1` and `p2`, each of which has subpartitions. Each subpartition has `ENCODING` clauses:

- The `ENCODING` clause for partition `p1`'s subpartition `sp1` defines column `i`'s compression type as `zlib` and block size as 65536.
- The `ENCODING` clauses for partition `p2`'s subpartition `sp1` defines column `i`'s compression type as `rle_type` and block size is the default value. Column `k` uses the default compression and its block size is 8192.

```
CREATE TABLE T5(i int, j int, k int, l int)
  WITH (appendoptimized=true, orientation=column)
  PARTITION BY range(i) SUBPARTITION BY range(j)
  (
    partition p1 start(1) end(2)
      ( subpartition sp1 start(1) end(2)
        column i encoding(compresstype=zlib, blocksize=65536)
      ),
    partition p2 start(2) end(3)
      ( subpartition sp1 start(1) end(2)
        column i encoding(compresstype=rle_type)
        column k encoding(blocksize=8192)
      )
  );
```

For an example showing how to add a compressed column to an existing table with the `ALTER TABLE` command, see [Adding a Compressed Column to Table](#).

Adding Compression in a TYPE Command

When you create a new type, you can define default compression attributes for the type. For example, the following `CREATE TYPE` command defines a type named `int33` that specifies `quicklz` compression.

First, you must define the input and output functions for the new type, `int33_in` and `int33_out`:

```
CREATE FUNCTION int33_in(cstring) RETURNS int33
  STRICT IMMUTABLE LANGUAGE internal AS 'int4in';
CREATE FUNCTION int33_out(int33) RETURNS cstring
  STRICT IMMUTABLE LANGUAGE internal AS 'int4out';
```

Next, you define the type named `int33`:

```
CREATE TYPE int33 (
  internallength = 4,
  input = int33_in,
  output = int33_out,
  alignment = int4,
  default = 123,
  passedbyvalue,
  compresstype="zlib",
  blocksize=65536,
  compresslevel=1
);
```

When you specify `int33` as a column type in a `CREATE TABLE` command, the column is created with the storage directives you specified for the type:

```
CREATE TABLE t2 (c1 int33)
  WITH (appendoptimized=true, orientation=column);
```

Table- or column- level storage attributes that you specify in a table definition override type-level storage attributes. For information about creating and adding compression attributes to a type, see [CREATE TYPE](#). For information about changing compression specifications in a type, see [ALTER TYPE](#).

Choosing Block Size

The blocksize is the size, in bytes, for each block in a table. Block sizes must be between 8192 and 2097152 bytes, and be a multiple of 8192. The default is 32768.

Specifying large block sizes can consume large amounts of memory. Block size determines buffering in the storage layer. Greenplum maintains a buffer per partition, and per column in column-oriented tables. Tables with many partitions or columns consume large amounts of memory.

Altering a Table

The `ALTER TABLE` command changes the definition of a table. Use `ALTER TABLE` to change table attributes such as column definitions, distribution policy, storage model, and partition structure (see also [Maintaining Partitioned Tables](#)). For example, to add a not-null constraint to a table column:

```
=> ALTER TABLE address ALTER COLUMN street SET NOT NULL;
```

Altering Table Distribution

`ALTER TABLE` provides options to change a table's distribution policy. When the table distribution options change, the table data may be redistributed on disk, which can be resource intensive. You can also redistribute table data using the existing distribution policy.

Changing the Distribution Policy

For partitioned tables, changes to the distribution policy apply recursively to the child partitions. This operation preserves the ownership and all other attributes of the table. For example, the following command redistributes the table `sales` across all segments using the `customer_id` column as the distribution key:

```
ALTER TABLE sales SET DISTRIBUTED BY (customer_id);
```

When you change the hash distribution of a table, table data is automatically redistributed. Changing the distribution policy to a random distribution does not cause the data to be redistributed. For example, the following `ALTER TABLE` command has no immediate effect:

```
ALTER TABLE sales SET DISTRIBUTED RANDOMLY;
```

Changing the distribution policy of a table to `DISTRIBUTED REPLICATED` or from `DISTRIBUTED REPLICATED` automatically redistributes the table data.

Redistributing Table Data

To redistribute table data for tables with a random distribution policy (or when the hash distribution policy has not changed) use `REORGANIZE=TRUE`. Reorganizing data may be necessary to correct a data skew problem, or when segment resources are added to the system. For example, the following command redistributes table data across all segments using the current distribution policy, including

random distribution.

```
ALTER TABLE sales SET WITH (REORGANIZE=TRUE);
```

Changing the distribution policy of a table to **DISTRIBUTED REPLICATED** or from **DISTRIBUTED REPLICATED** always redistributes the table data, even when you use **REORGANIZE=FALSE**.

Altering the Table Storage Model

Table storage, compression, and orientation can be declared only at creation. To change the storage model, you must create a table with the correct storage options, load the original table data into the new table, drop the original table, and rename the new table with the original table's name. You must also re-grant any table permissions. For example:

```
CREATE TABLE sales2 (LIKE sales)
WITH (appendoptimized=true, compresstype=quicklz,
      compresslevel=1, orientation=column);
INSERT INTO sales2 SELECT * FROM sales;
DROP TABLE sales;
ALTER TABLE sales2 RENAME TO sales;
GRANT ALL PRIVILEGES ON sales TO admin;
GRANT SELECT ON sales TO guest;
```

Note: The **LIKE** clause does not copy over partition structures when creating a new table.

See [Splitting a Partition](#) to learn how to change the storage model of a partitioned table.

Adding a Compressed Column to Table

Use **ALTER TABLE** command to add a compressed column to a table. All of the options and constraints for compressed columns described in [Adding Column-level Compression](#) apply to columns added with the **ALTER TABLE** command.

The following example shows how to add a column with **zlib** compression to a table, **T1**.

```
ALTER TABLE T1
  ADD COLUMN c4 int DEFAULT 0
  ENCODING (compresstype=zlib);
```

Inheritance of Compression Settings

A partition added to a table that has subpartitions defined with compression settings inherits the compression settings from the subpartition. The following example shows how to create a table with subpartition encodings, then alter it to add a partition.

```
CREATE TABLE ccddl (i int, j int, k int, l int)
WITH
  (appendoptimized = TRUE, orientation=COLUMN)
PARTITION BY range(j)
SUBPARTITION BY list (k)
SUBPARTITION template(
  SUBPARTITION sp1 values(1, 2, 3, 4, 5),
  COLUMN i ENCODING(compresstype=ZLIB),
  COLUMN j ENCODING(compresstype=QUICKLZ),
  COLUMN k ENCODING(compresstype=ZLIB),
  COLUMN l ENCODING(compresstype=ZLIB))
(PARTITION p1 START(1) END(10),
```

```

PARTITION p2 START(10) END(20)
;

ALTER TABLE ccddl
  ADD PARTITION p3 START(20) END(30)
;

```

Running the `ALTER TABLE` command creates partitions of table `ccddl` named `ccddl_1_prt_p3` and `ccddl_1_prt_p3_2_prt_sp1`. Partition `ccddl_1_prt_p3` inherits the different compression encodings of subpartition `sp1`.

Dropping a Table

The `DROP TABLE` command removes tables from the database. For example:

```
DROP TABLE mytable;
```

To empty a table of rows without removing the table definition, use `DELETE` or `TRUNCATE`. For example:

```

DELETE FROM mytable;

TRUNCATE mytable;

```

`DROP TABLE` always removes any indexes, rules, triggers, and constraints that exist for the target table. Specify `CASCADE` to drop a table that is referenced by a view. `CASCADE` removes dependent views.

Partitioning Large Tables

Table partitioning enables supporting very large tables, such as fact tables, by logically dividing them into smaller, more manageable pieces. Partitioned tables can improve query performance by allowing the Greenplum Database query optimizer to scan only the data needed to satisfy a given query instead of scanning all the contents of a large table.

- [About Table Partitioning](#)
- [Deciding on a Table Partitioning Strategy](#)
- [Creating Partitioned Tables](#)
- [Loading Partitioned Tables](#)
- [Verifying Your Partition Strategy](#)
- [Viewing Your Partition Design](#)
- [Maintaining Partitioned Tables](#)

Parent topic: [Defining Database Objects](#)

About Table Partitioning

Partitioning does not change the physical distribution of table data across the segments. Table distribution is physical: Greenplum Database physically divides partitioned tables and non-partitioned tables across segments to enable parallel query processing. Table *partitioning* is logical: Greenplum Database logically divides big tables to improve query performance and facilitate data warehouse maintenance tasks, such as rolling old data out of the data warehouse.

Greenplum Database supports:

- *range partitioning*: division of data based on a numerical range, such as date or price.
- *list partitioning*: division of data based on a list of values, such as sales territory or product line.
- A combination of both types.

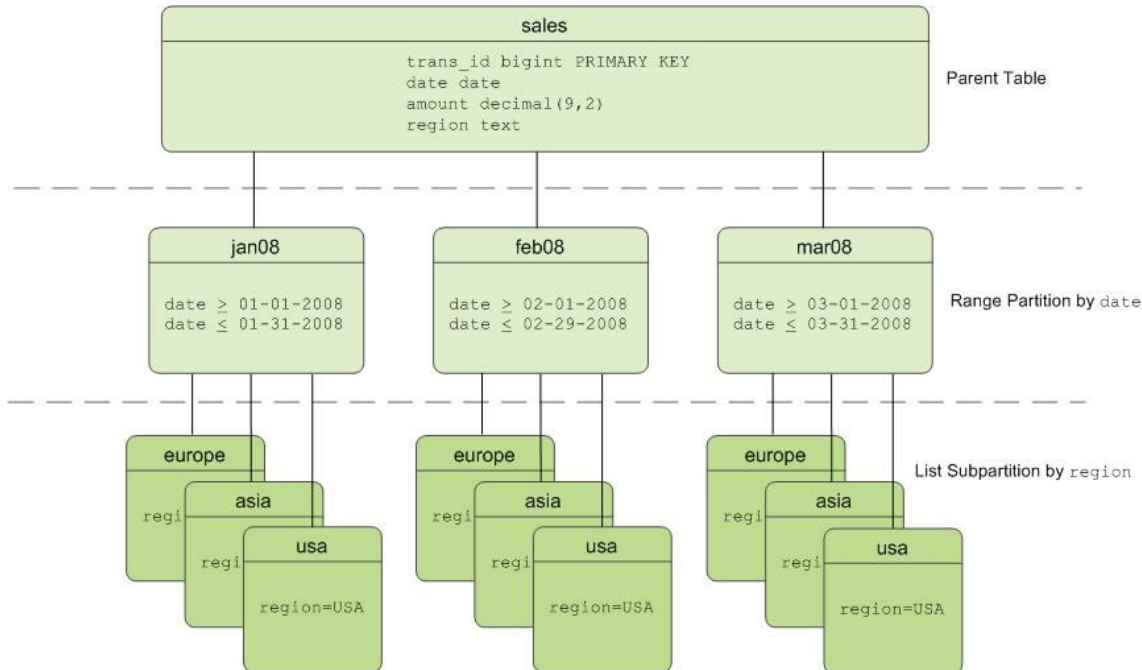

Table Partitioning in Greenplum Database

Greenplum Database divides tables into parts (also known as partitions) to enable massively parallel processing. Tables are partitioned during `CREATE TABLE` using the `PARTITION BY` (and optionally the `SUBPARTITION BY`) clause. Partitioning creates a top-level (or parent) table with one or more levels of sub-tables (or child tables). Internally, Greenplum Database creates an inheritance relationship between the top-level table and its underlying partitions, similar to the functionality of the `INHERITS` clause of PostgreSQL.

Greenplum uses the partition criteria defined during table creation to create each partition with a distinct `CHECK` constraint, which limits the data that table can contain. The query optimizer uses `CHECK` constraints to determine which table partitions to scan to satisfy a given query predicate.

The Greenplum system catalog stores partition hierarchy information so that rows inserted into the top-level parent table propagate correctly to the child table partitions. To change the partition design or table structure, alter the parent table using `ALTER TABLE` with the `PARTITION` clause.

To insert data into a partitioned table, you specify the root partitioned table, the table created with the `CREATE TABLE` command. You also can specify a leaf child table of the partitioned table in an `INSERT` command. An error is returned if the data is not valid for the specified leaf child table. Specifying a non-leaf or a non-root partition table in the DML command is not supported.

Deciding on a Table Partitioning Strategy

Greenplum Database does not support partitioning replicated tables (`DISTRIBUTED REPLICATED`). Not all hash-distributed or randomly distributed tables are good candidates for partitioning. If the answer is yes to all or most of the following questions, table partitioning is a viable database design strategy for improving query performance. If the answer is no to most of the following questions, table

partitioning is not the right solution for that table. Test your design strategy to ensure that query performance improves as expected.

- **Is the table large enough?** Large fact tables are good candidates for table partitioning. If you have millions or billions of records in a table, you may see performance benefits from logically breaking that data up into smaller chunks. For smaller tables with only a few thousand rows or less, the administrative overhead of maintaining the partitions will outweigh any performance benefits you might see.
- **Are you experiencing unsatisfactory performance?** As with any performance tuning initiative, a table should be partitioned only if queries against that table are producing slower response times than desired.
- **Do your query predicates have identifiable access patterns?** Examine the `WHERE` clauses of your query workload and look for table columns that are consistently used to access data. For example, if most of your queries tend to look up records by date, then a monthly or weekly date-partitioning design might be beneficial. Or if you tend to access records by region, consider a list-partitioning design to divide the table by region.
- **Does your data warehouse maintain a window of historical data?** Another consideration for partition design is your organization's business requirements for maintaining historical data. For example, your data warehouse may require that you keep data for the past twelve months. If the data is partitioned by month, you can easily drop the oldest monthly partition from the warehouse and load current data into the most recent monthly partition.
- **Can the data be divided into somewhat equal parts based on some defining criteria?** Choose partitioning criteria that will divide your data as evenly as possible. If the partitions contain a relatively equal number of records, query performance improves based on the number of partitions created. For example, by dividing a large table into 10 partitions, a query will run 10 times faster than it would against the unpartitioned table, provided that the partitions are designed to support the query's criteria.

Do not create more partitions than are needed. Creating too many partitions can slow down management and maintenance jobs, such as vacuuming, recovering segments, expanding the cluster, checking disk usage, and others.

Partitioning does not improve query performance unless the query optimizer can eliminate partitions based on the query predicates. Queries that scan every partition run slower than if the table were not partitioned, so avoid partitioning if few of your queries achieve partition elimination. Check the explain plan for queries to make sure that partitions are eliminated. See [Query Profiling](#) for more about partition elimination.

Warning: Be very careful with multi-level partitioning because the number of partition files can grow very quickly. For example, if a table is partitioned by both day and city, and there are 1,000 days of data and 1,000 cities, the total number of partitions is one million. Column-oriented tables store each column in a physical table, so if this table has 100 columns, the system would be required to manage 100 million files for the table, for each segment.

Before settling on a multi-level partitioning strategy, consider a single level partition with bitmap indexes. Indexes slow down data loads, so performance testing with your data and schema is recommended to decide on the best strategy.

Creating Partitioned Tables

You partition tables when you create them with `CREATE TABLE`. This topic provides examples of SQL syntax for creating a table with various partition designs.

To partition a table:

1. Decide on the partition design: date range, numeric range, or list of values.
2. Choose the column(s) on which to partition the table.
3. Decide how many levels of partitions you want. For example, you can create a date range partition table by month and then subpartition the monthly partitions by sales region.
4. [Defining Date Range Table Partitions](#)
5. [Defining Numeric Range Table Partitions](#)
6. [Defining List Table Partitions](#)
7. [Defining Multi-level Partitions](#)
8. [Partitioning an Existing Table](#)

Defining Date Range Table Partitions

A date range partitioned table uses a single `date` or `timestamp` column as the partition key column. You can use the same partition key column to create subpartitions if necessary, for example, to partition by month and then subpartition by day. Consider partitioning by the most granular level. For example, for a table partitioned by date, you can partition by day and have 365 daily partitions, rather than partition by year then subpartition by month then subpartition by day. A multi-level design can reduce query planning time, but a flat partition design runs faster.

You can have Greenplum Database automatically generate partitions by giving a `START` value, an `END` value, and an `EVERY` clause that defines the partition increment value. By default, `START` values are always inclusive and `END` values are always exclusive. For example:

```
CREATE TABLE sales (id int, date date, amt decimal(10,2))
DISTRIBUTED BY (id)
PARTITION BY RANGE (date)
( START (date '2016-01-01') INCLUSIVE
  END (date '2017-01-01') EXCLUSIVE
  EVERY (INTERVAL '1 day') );
```

You can also declare and name each partition individually. For example:

```
CREATE TABLE sales (id int, date date, amt decimal(10,2))
DISTRIBUTED BY (id)
PARTITION BY RANGE (date)
( PARTITION Jan16 START (date '2016-01-01') INCLUSIVE ,
  PARTITION Feb16 START (date '2016-02-01') INCLUSIVE ,
  PARTITION Mar16 START (date '2016-03-01') INCLUSIVE ,
  PARTITION Apr16 START (date '2016-04-01') INCLUSIVE ,
  PARTITION May16 START (date '2016-05-01') INCLUSIVE ,
  PARTITION Jun16 START (date '2016-06-01') INCLUSIVE ,
  PARTITION Jul16 START (date '2016-07-01') INCLUSIVE ,
  PARTITION Aug16 START (date '2016-08-01') INCLUSIVE ,
  PARTITION Sep16 START (date '2016-09-01') INCLUSIVE ,
  PARTITION Oct16 START (date '2016-10-01') INCLUSIVE ,
  PARTITION Nov16 START (date '2016-11-01') INCLUSIVE ,
  PARTITION Dec16 START (date '2016-12-01') INCLUSIVE
  END (date '2017-01-01') EXCLUSIVE );
```

You do not have to declare an `END` value for each partition, only the last one. In this example, `Jan16` ends where `Feb16` starts.

Defining Numeric Range Table Partitions

A numeric range partitioned table uses a single numeric data type column as the partition key column. For example:

```
CREATE TABLE rank (id int, rank int, year int, gender
char(1), count int)
DISTRIBUTED BY (id)
PARTITION BY RANGE (year)
( START (2006) END (2016) EVERY (1),
  DEFAULT PARTITION extra );
```

For more information about default partitions, see [Adding a Default Partition](#).

Defining List Table Partitions

A list partitioned table can use any data type column that allows equality comparisons as its partition key column. A list partition can also have a multi-column (composite) partition key, whereas a range partition only allows a single column as the partition key. For list partitions, you must declare a partition specification for every partition (list value) you want to create. For example:

```
CREATE TABLE rank (id int, rank int, year int, gender
char(1), count int )
DISTRIBUTED BY (id)
PARTITION BY LIST (gender)
( PARTITION girls VALUES ('F'),
  PARTITION boys VALUES ('M'),
  DEFAULT PARTITION other );
```

Note: The current Postgres Planner allows list partitions with multi-column (composite) partition keys. A range partition only allows a single column as the partition key. GPORCA does not support composite keys, so you should not use composite partition keys.

For more information about default partitions, see [Adding a Default Partition](#).

Defining Multi-level Partitions

You can create a multi-level partition design with subpartitions of partitions. Using a *subpartition template* ensures that every partition has the same subpartition design, including partitions that you add later. For example, the following SQL creates the two-level partition design shown in [Figure 1](#):

```
CREATE TABLE sales (trans_id int, date date, amount
decimal(9,2), region text)
DISTRIBUTED BY (trans_id)
PARTITION BY RANGE (date)
SUBPARTITION BY LIST (region)
SUBPARTITION TEMPLATE
( SUBPARTITION usa VALUES ('usa'),
  SUBPARTITION asia VALUES ('asia'),
  SUBPARTITION europe VALUES ('europe'),
  DEFAULT SUBPARTITION other_regions)
(START (date '2011-01-01') INCLUSIVE
  END (date '2012-01-01') EXCLUSIVE
  EVERY (INTERVAL '1 month'),
  DEFAULT PARTITION outlying_dates );
```

The following example shows a three-level partition design where the `sales` table is partitioned by `year`, then `month`, then `region`. The `SUBPARTITION TEMPLATE` clauses ensure that each yearly partition has the same subpartition structure. The example declares a `DEFAULT` partition at each level of the

hierarchy.

```
CREATE TABLE p3_sales (id int, year int, month int, day int,
region text)
DISTRIBUTED BY (id)
PARTITION BY RANGE (year)
    SUBPARTITION BY RANGE (month)
        SUBPARTITION TEMPLATE (
            START (1) END (13) EVERY (1),
            DEFAULT SUBPARTITION other_months )
        SUBPARTITION BY LIST (region)
            SUBPARTITION TEMPLATE (
                SUBPARTITION usa VALUES ('usa'),
                SUBPARTITION europe VALUES ('europe'),
                SUBPARTITION asia VALUES ('asia'),
                DEFAULT SUBPARTITION other_regions )
    ( START (2002) END (2012) EVERY (1),
      DEFAULT PARTITION outlying_years );
```

CAUTION: When you create multi-level partitions on ranges, it is easy to create a large number of subpartitions, some containing little or no data. This can add many entries to the system tables, which increases the time and memory required to optimize and run queries. Increase the range interval or choose a different partitioning strategy to reduce the number of subpartitions created.

Partitioning an Existing Table

Tables can be partitioned only at creation. If you have a table that you want to partition, you must create a partitioned table, load the data from the original table into the new table, drop the original table, and rename the partitioned table with the original table's name. You must also re-grant any table permissions. For example:

```
CREATE TABLE sales2 (LIKE sales)
PARTITION BY RANGE (date)
( START (date '2016-01-01') INCLUSIVE
  END (date '2017-01-01') EXCLUSIVE
  EVERY (INTERVAL '1 month') );
INSERT INTO sales2 SELECT * FROM sales;
DROP TABLE sales;
ALTER TABLE sales2 RENAME TO sales;
GRANT ALL PRIVILEGES ON sales TO admin;
GRANT SELECT ON sales TO guest;
```

Note: The `LIKE` clause does not copy over partition structures when creating a new table.

Limitations of Partitioned Tables

For each partition level, a partitioned table can have a maximum of 32,767 partitions.

A primary key or unique constraint on a partitioned table must contain all the partitioning columns. A unique index can omit the partitioning columns; however, it is enforced only on the parts of the partitioned table, not on the partitioned table as a whole.

Tables created with the `DISTRIBUTED REPLICATED` distribution policy cannot be partitioned.

GPORCA, the Greenplum next generation query optimizer, supports uniform multi-level partitioned tables. If GPORCA is enabled (the default) and the multi-level partitioned table is not uniform, Greenplum Database runs queries against the table with the Postgres Planner. For information about uniform multi-level partitioned tables, see [About Uniform Multi-level Partitioned Tables](#).

For information about exchanging a leaf child partition with an external table, see [Exchanging a Leaf](#)

Child Partition with an External Table.

These are limitations for partitioned tables when a leaf child partition of the table is an external table:

- Queries that run against partitioned tables that contain external table partitions are run with the Postgres Planner.
- The external table partition is a read only external table. Commands that attempt to access or modify data in the external table partition return an error. For example:
 - `INSERT`, `DELETE`, and `UPDATE` commands that attempt to change data in the external table partition return an error.
 - `TRUNCATE` commands return an error.
 - `COPY` commands cannot copy data to a partitioned table that updates an external table partition.

- `COPY` commands that attempt to copy from an external table partition return an error unless you specify the `IGNORE EXTERNAL PARTITIONS` clause with `COPY` command. If you specify the clause, data is not copied from external table partitions.

To use the `COPY` command against a partitioned table with a leaf child table that is an external table, use an SQL query to copy the data. For example, if the table `my_sales` contains a with a leaf child table that is an external table, this command sends the data to `stdout`:

```
COPY (SELECT * from my_sales ) TO stdout
```

- `VACUUM` commands skip external table partitions.
- The following operations are supported if no data is changed on the external table partition. Otherwise, an error is returned.
 - Adding or dropping a column.
 - Changing the data type of column.
- These `ALTER PARTITION` operations are not supported if the partitioned table contains an external table partition:
 - Setting a subpartition template.
 - Altering the partition properties.
 - Creating a default partition.
 - Setting a distribution policy.
 - Setting or dropping a `NOT NULL` constraint of column.
 - Adding or dropping constraints.
 - Splitting an external partition.
- The Greenplum Database `gpbackup` utility does not back up data from a leaf child partition of a partitioned table if the leaf child partition is a readable external table.

Loading Partitioned Tables

After you create the partitioned table structure, top-level parent tables are empty. Data is routed to the bottom-level child table partitions. In a multi-level partition design, only the subpartitions at the bottom of the hierarchy can contain data.

Rows that cannot be mapped to a child table partition are rejected and the load fails. To avoid

unmapped rows being rejected at load time, define your partition hierarchy with a `DEFAULT` partition. Any rows that do not match a partition's `CHECK` constraints load into the `DEFAULT` partition. See [Adding a Default Partition](#).

At runtime, the query optimizer scans the entire table inheritance hierarchy and uses the `CHECK` table constraints to determine which of the child table partitions to scan to satisfy the query's conditions. The `DEFAULT` partition (if your hierarchy has one) is always scanned. `DEFAULT` partitions that contain data slow down the overall scan time.

When you use `COPY` or `INSERT` to load data into a parent table, the data is automatically rerouted to the correct partition, just like a regular table.

Best practice for loading data into partitioned tables is to create an intermediate staging table, load it, and then exchange it into your partition design. See [Exchanging a Partition](#).

Verifying Your Partition Strategy

When a table is partitioned based on the query predicate, you can use `EXPLAIN` to verify that the query optimizer scans only the relevant data to examine the query plan.

For example, suppose a `sales` table is date-range partitioned by month and subpartitioned by region as shown in [Figure 1](#). For the following query:

```
EXPLAIN SELECT * FROM sales WHERE date='01-07-12' AND
region='usa';
```

The query plan for this query should show a table scan of only the following tables:

- the default partition returning 0-1 rows (if your partition design has one)
- the January 2012 partition (`sales_1_prt_1`) returning 0-1 rows
- the USA region subpartition (`sales_1_2_prt_usa`) returning *some number* of rows.

The following example shows the relevant portion of the query plan.

```
-> `Seq Scan on `sales_1_prt_1` sales (cost=0.00..0.00 `rows=0`
    width=0)
Filter: "date"=01-07-12::date AND region='USA'::text
-> `Seq Scan on `sales_1_2_prt_usa` sales (cost=0.00..9.87
    `rows=20`
    width=40)
```

Ensure that the query optimizer does not scan unnecessary partitions or subpartitions (for example, scans of months or regions not specified in the query predicate), and that scans of the top-level tables return 0-1 rows.

Troubleshooting Selective Partition Scanning

The following limitations can result in a query plan that shows a non-selective scan of your partition hierarchy.

- The query optimizer can selectively scan partitioned tables only when the query contains a direct and simple restriction of the table using immutable operators such as:

=, <, <=, >, >=, and <>
- Selective scanning recognizes `STABLE` and `IMMUTABLE` functions, but does not recognize `VOLATILE` functions within a query. For example, `WHERE` clauses such as `date > CURRENT_DATE`

cause the query optimizer to selectively scan partitioned tables, but `time > TIMEOFDAY` does not.

Viewing Your Partition Design

You can look up information about your partition design using the `pg_partitions` system view. For example, to see the partition design of the `sales` table:

```
SELECT partitionboundary, partitiontablename, partitionname,
partitionlevel, partitionrank
FROM pg_partitions
WHERE tablename='sales';
```

The following table and views also show information about partitioned tables.

- `pg_partition`- Tracks partitioned tables and their inheritance level relationships.
- `pg_partition_templates`- Shows the subpartitions created using a subpartition template.
- `pg_partition_columns` - Shows the partition key columns used in a partition design.

Maintaining Partitioned Tables

To maintain a partitioned table, use the `ALTER TABLE` command against the top-level parent table. The most common scenario is to drop old partitions and add new ones to maintain a rolling window of data in a range partition design. You can convert (*exchange*) older partitions to the append-optimized compressed storage format to save space. If you have a default partition in your partition design, you add a partition by *splitting* the default partition.

- [Adding a Partition](#)
- [Renaming a Partition](#)
- [Adding a Default Partition](#)
- [Dropping a Partition](#)
- [Truncating a Partition](#)
- [Exchanging a Partition](#)
- [Splitting a Partition](#)
- [Modifying a Subpartition Template](#)
- [Exchanging a Leaf Child Partition with an External Table](#)

Important: When defining and altering partition designs, use the given partition name, not the table object name. The given partition name is the `partitionname` column value in the `pg_partitions` system view. Although you can query and load any table (including partitioned tables) directly using SQL commands, you can only modify the structure of a partitioned table using the `ALTER TABLE...PARTITION` clauses.

Partitions are not required to have names. If a partition does not have a name, use one of the following expressions to specify a partition: `PARTITION FOR (value)` or `PARTITION FOR (RANK(number))`.

For a multi-level partitioned table, you identify a specific partition to change with `ALTER PARTITION` clauses. For each partition level in the table hierarchy that is above the target partition, specify the partition that is related to the target partition in an `ALTER PARTITION` clause. For example, if you have a partitioned table that consists of three levels, year, quarter, and region, this `ALTER TABLE` command

exchanges a leaf partition `region` with the table `region_new`.

```
ALTER TABLE sales ALTER PARTITION year_1 ALTER PARTITION quarter_4 EXCHANGE PARTITION
region WITH TABLE region_new ;
```

The two `ALTER PARTITION` clauses identify which `region` partition to exchange. Both clauses are required to identify the specific leaf partition to exchange.

Adding a Partition

You can add a partition to a partition design with the `ALTER TABLE` command. If the original partition design included subpartitions defined by a *subpartition template*, the newly added partition is subpartitioned according to that template. For example:

```
ALTER TABLE sales ADD PARTITION
    START (date '2017-02-01') INCLUSIVE
    END (date '2017-03-01') EXCLUSIVE;
```

If you did not use a subpartition template when you created the table, you define subpartitions when adding a partition:

```
ALTER TABLE sales ADD PARTITION
    START (date '2017-02-01') INCLUSIVE
    END (date '2017-03-01') EXCLUSIVE
    ( SUBPARTITION usa VALUES ('usa'),
      SUBPARTITION asia VALUES ('asia'),
      SUBPARTITION europe VALUES ('europe') );
```

When you add a subpartition to an existing partition, you can specify the partition to alter. For example:

```
ALTER TABLE sales ALTER PARTITION FOR (RANK(12))
    ADD PARTITION africa VALUES ('africa');
```

Note: You cannot add a partition to a partition design that has a default partition. You must split the default partition to add a partition. See [Splitting a Partition](#).

Renaming a Partition

Partitioned tables use the following naming convention. Partitioned subtable names are subject to uniqueness requirements and length limitations.

```
<parentname>_<level>_prt_<partition_name>
```

For example:

```
sales_1_prt_jan16
```

For auto-generated range partitions, where a number is assigned when no name is given):

```
sales_1_prt_1
```

To rename a partitioned child table, rename the top-level parent table. The `<parentname>` changes in the table names of all associated child table partitions. For example, the following command:

```
ALTER TABLE sales RENAME TO globalsales;
```

Changes the associated table names:

```
globalsales_1_prt_1
```

You can change the name of a partition to make it easier to identify. For example:

```
ALTER TABLE sales RENAME PARTITION FOR ('2016-01-01') TO jan16;
```

Changes the associated table name as follows:

```
sales_1_prt_jan16
```

When altering partitioned tables with the `ALTER TABLE` command, always refer to the tables by their partition name (*jan16*) and not their full table name (*sales_1_prt_jan16*).

Note: The table name cannot be a partition name in an `ALTER TABLE` statement. For example, `ALTER TABLE sales...` is correct, `ALTER TABLE sales_1_part_jan16...` is not allowed.

Adding a Default Partition

You can add a default partition to a partition design with the `ALTER TABLE` command.

```
ALTER TABLE sales ADD DEFAULT PARTITION other;
```

If your partition design is multi-level, each level in the hierarchy must have a default partition. For example:

```
ALTER TABLE sales ALTER PARTITION FOR (RANK(1)) ADD DEFAULT
PARTITION other;

ALTER TABLE sales ALTER PARTITION FOR (RANK(2)) ADD DEFAULT
PARTITION other;

ALTER TABLE sales ALTER PARTITION FOR (RANK(3)) ADD DEFAULT
PARTITION other;
```

If incoming data does not match a partition's `CHECK` constraint and there is no default partition, the data is rejected. Default partitions ensure that incoming data that does not match a partition is inserted into the default partition.

Dropping a Partition

You can drop a partition from your partition design using the `ALTER TABLE` command. When you drop a partition that has subpartitions, the subpartitions (and all data in them) are automatically dropped as well. For range partitions, it is common to drop the older partitions from the range as old data is rolled out of the data warehouse. For example:

```
ALTER TABLE sales DROP PARTITION FOR (RANK(1));
```

Truncating a Partition

You can truncate a partition using the `ALTER TABLE` command. When you truncate a partition that has subpartitions, the subpartitions are automatically truncated as well.

```
ALTER TABLE sales TRUNCATE PARTITION FOR (RANK(1));
```

Exchanging a Partition

You can exchange a partition using the `ALTER TABLE` command. Exchanging a partition swaps one table in place of an existing partition. You can exchange partitions only at the lowest level of your partition hierarchy (only partitions that contain data can be exchanged).

You cannot exchange a partition with a replicated table. Exchanging a partition with a partitioned table or a child partition of a partitioned table is not supported.

Partition exchange can be useful for data loading. For example, load a staging table and swap the loaded table into your partition design. You can use partition exchange to change the storage type of older partitions to append-optimized tables. For example:

```
CREATE TABLE jan12 (LIKE sales) WITH (appendoptimized=true);
INSERT INTO jan12 SELECT * FROM sales_1_prt_1 ;
ALTER TABLE sales EXCHANGE PARTITION FOR (DATE '2012-01-01')
WITH TABLE jan12;
```

Note: This example refers to the single-level definition of the table `sales`, before partitions were added and altered in the previous examples.

Warning: If you specify the `WITHOUT VALIDATION` clause, you must ensure that the data in table that you are exchanging for an existing partition is valid against the constraints on the partition. Otherwise, queries against the partitioned table might return incorrect results.

The Greenplum Database server configuration parameter `gp_enable_exchange_default_partition` controls availability of the `EXCHANGE DEFAULT PARTITION` clause. The default value for the parameter is `off`, the clause is not available and Greenplum Database returns an error if the clause is specified in an `ALTER TABLE` command.

For information about the parameter, see “Server Configuration Parameters” in the *Greenplum Database Reference Guide*.

Warning: Before you exchange the default partition, you must ensure the data in the table to be exchanged, the new default partition, is valid for the default partition. For example, the data in the new default partition must not contain data that would be valid in other leaf child partitions of the partitioned table. Otherwise, queries against the partitioned table with the exchanged default partition that are run by GPORCA might return incorrect results.

Splitting a Partition

Splitting a partition divides a partition into two partitions. You can split a partition using the `ALTER TABLE` command. You can split partitions only at the lowest level of your partition hierarchy (partitions that contain data). For a multi-level partition, only range partitions can be split, not list partitions. The split value you specify goes into the *latter* partition.

For example, to split a monthly partition into two with the first partition containing dates January 1-15 and the second partition containing dates January 16-31:

```
ALTER TABLE sales SPLIT PARTITION FOR ('2017-01-01')
AT ('2017-01-16')
INTO (PARTITION jan171to15, PARTITION jan1716to31);
```

If your partition design has a default partition, you must split the default partition to add a partition.

When using the `INTO` clause, specify the current default partition as the second partition name. For example, to split a default range partition to add a new monthly partition for January 2017:

```
ALTER TABLE sales SPLIT DEFAULT PARTITION
START ('2017-01-01') INCLUSIVE
END ('2017-02-01') EXCLUSIVE
INTO (PARTITION jan17, default partition);
```

Modifying a Subpartition Template

Use `ALTER TABLE SET SUBPARTITION TEMPLATE` to modify the subpartition template of a partitioned table. Partitions added after you set a new subpartition template have the new partition design. Existing partitions are not modified.

The following example alters the subpartition template of this partitioned table:

```
CREATE TABLE sales (trans_id int, date date, amount decimal(9,2), region text)
DISTRIBUTED BY (trans_id)
PARTITION BY RANGE (date)
SUBPARTITION BY LIST (region)
SUBPARTITION TEMPLATE
( SUBPARTITION usa VALUES ('usa'),
  SUBPARTITION asia VALUES ('asia'),
  SUBPARTITION europe VALUES ('europe'),
  DEFAULT SUBPARTITION other_regions )
( START (date '2014-01-01') INCLUSIVE
  END (date '2014-04-01') EXCLUSIVE
  EVERY (INTERVAL '1 month') );
```

This `ALTER TABLE` command, modifies the subpartition template.

```
ALTER TABLE sales SET SUBPARTITION TEMPLATE
( SUBPARTITION usa VALUES ('usa'),
  SUBPARTITION asia VALUES ('asia'),
  SUBPARTITION europe VALUES ('europe'),
  SUBPARTITION africa VALUES ('africa'),
  DEFAULT SUBPARTITION regions );
```

When you add a date-range partition of the table `sales`, it includes the new regional list subpartition for Africa. For example, the following command creates the subpartitions `usa`, `asia`, `europe`, `africa`, and a default partition named `other`:

```
ALTER TABLE sales ADD PARTITION "4"
START ('2014-04-01') INCLUSIVE
END ('2014-05-01') EXCLUSIVE ;
```

To view the tables created for the partitioned table `sales`, you can use the command `\dt sales*` from the `psql` command line.

To remove a subpartition template, use `SET SUBPARTITION TEMPLATE` with empty parentheses. For example, to clear the `sales` table subpartition template:

```
ALTER TABLE sales SET SUBPARTITION TEMPLATE ();
```

Exchanging a Leaf Child Partition with an External Table

You can exchange a leaf child partition of a partitioned table with a readable external table. The external table data can reside on a host file system, an NFS mount, or a Hadoop file system (HDFS).

For example, if you have a partitioned table that is created with monthly partitions and most of the queries against the table only access the newer data, you can copy the older, less accessed data to external tables and exchange older partitions with the external tables. For queries that only access the newer data, you could create queries that use partition elimination to prevent scanning the older, unneeded partitions.

Exchanging a leaf child partition with an external table is not supported if the partitioned table contains a column with a check constraint or a `NOT NULL` constraint.

For information about exchanging and altering a leaf child partition, see the `ALTER TABLE` command in the *Greenplum Database Command Reference*.

For information about limitations of partitioned tables that contain a external table partition, see [Limitations of Partitioned Tables](#).

Example Exchanging a Partition with an External Table

This is a simple example that exchanges a leaf child partition of this partitioned table for an external table. The partitioned table contains data for the years 2010 through 2013.

```
CREATE TABLE sales (id int, year int, qtr int, day int, region text)
  DISTRIBUTED BY (id)
  PARTITION BY RANGE (year)
  ( PARTITION yr START (2010) END (2014) EVERY (1) ) ;
```

There are four leaf child partitions for the partitioned table. Each leaf child partition contains the data for a single year. The leaf child partition table `sales_1_prt_yr_1` contains the data for the year 2010. These steps exchange the table `sales_1_prt_yr_1` with an external table the uses the `gpfdist` protocol:

1. Ensure that the external table protocol is enabled for the Greenplum Database system.

This example uses the `gpfdist` protocol. This command starts the `gpfdist` protocol.

```
$ gpfdist
```

2. Create a writable external table.

This `CREATE WRITABLE EXTERNAL TABLE` command creates a writable external table with the same columns as the partitioned table.

```
CREATE WRITABLE EXTERNAL TABLE my_sales_ext ( LIKE sales_1_prt_yr_1 )
  LOCATION ( 'gpfdist://gpdb_test/sales_2010' )
  FORMAT 'csv'
  DISTRIBUTED BY (id) ;
```

3. Create a readable external table that reads the data from that destination of the writable external table created in the previous step.

This `CREATE EXTERNAL TABLE` create a readable external that uses the same external data as the writable external data.

```
CREATE EXTERNAL TABLE sales_2010_ext ( LIKE sales_1_prt_yr_1 )
  LOCATION ( 'gpfdist://gpdb_test/sales_2010' )
  FORMAT 'csv' ;
```

4. Copy the data from the leaf child partition into the writable external table.

This `INSERT` command copies the data from the child leaf partition table of the partitioned table into the external table.

```
INSERT INTO my_sales_ext SELECT * FROM sales_1_prt_yr_1 ;
```

5. Exchange the existing leaf child partition with the external table.

This `ALTER TABLE` command specifies the `EXCHANGE PARTITION` clause to switch the readable external table and the leaf child partition.

```
ALTER TABLE sales ALTER PARTITION yr_1
EXCHANGE PARTITION yr_1
WITH TABLE sales_2010_ext WITHOUT VALIDATION;
```

The external table becomes the leaf child partition with the table name `sales_1_prt_yr_1` and the old leaf child partition becomes the table `sales_2010_ext`.

Warning: In order to ensure queries against the partitioned table return the correct results, the external table data must be valid against the `CHECK` constraints on the leaf child partition. In this case, the data was taken from the child leaf partition table on which the `CHECK` constraints were defined.

6. Drop the table that was rolled out of the partitioned table.

```
DROP TABLE sales_2010_ext ;
```

You can rename the name of the leaf child partition to indicate that `sales_1_prt_yr_1` is an external table.

This example command changes the `partitionname` to `yr_1_ext` and the name of the child leaf partition table to `sales_1_prt_yr_1_ext`.

```
ALTER TABLE sales RENAME PARTITION yr_1 TO yr_1_ext ;
```

Creating and Using Sequences

A Greenplum Database sequence object is a special single row table that functions as a number generator. You can use a sequence to generate unique integer identifiers for a row that you add to a table. Declaring a column of type `SERIAL` implicitly creates a sequence counter for use in that table column.

Greenplum Database provides commands to create, alter, and drop a sequence. Greenplum Database also provides built-in functions to return the next value in the sequence (`nextval()`) or to set the sequence to a specific start value (`setval()`).

Note: The PostgreSQL `currval()` and `lastval()` sequence functions are not supported in Greenplum Database.

Attributes of a sequence object include the name of the sequence, its increment value, and the last, minimum, and maximum values of the sequence counter. Sequences also have a special boolean attribute named `is_called` that governs the auto-increment behavior of a `nextval()` operation on the sequence counter. When a sequence's `is_called` attribute is `true`, `nextval()` increments the sequence counter before returning the value. When the `is_called` attribute value of a sequence is `false`, `nextval()` does not increment the counter before returning the value.

Parent topic: [Defining Database Objects](#)

Creating a Sequence

The `CREATE SEQUENCE` command creates and initializes a sequence with the given sequence name and optional start value. The sequence name must be distinct from the name of any other sequence, table, index, or view in the same schema. For example:

```
CREATE SEQUENCE myserial START 101;
```

When you create a new sequence, Greenplum Database sets the sequence `is_called` attribute to `false`. Invoking `nextval()` on a newly-created sequence does not increment the sequence counter, but returns the sequence start value and sets `is_called` to `true`.

Using a Sequence

After you create a sequence with the `CREATE SEQUENCE` command, you can examine the sequence and use the sequence built-in functions.

Examining Sequence Attributes

To examine the current attributes of a sequence, query the sequence directly. For example, to examine a sequence named `myserial`:

```
SELECT * FROM myserial;
```

Returning the Next Sequence Counter Value

You can invoke the `nextval()` built-in function to return and use the next value in a sequence. The following command inserts the next value of the sequence named `myserial` into the first column of a table named `vendors`:

```
INSERT INTO vendors VALUES (nextval('myserial'), 'acme');
```

`nextval()` uses the sequence's `is_called` attribute value to determine whether or not to increment the sequence counter before returning the value. `nextval()` advances the counter when `is_called` is `true`. `nextval()` sets the sequence `is_called` attribute to `true` before returning.

A `nextval()` operation is never rolled back. A fetched value is considered used, even if the transaction that performed the `nextval()` fails. This means that failed transactions can leave unused holes in the sequence of assigned values.

Note: You cannot use the `nextval()` function in `UPDATE` or `DELETE` statements if mirroring is enabled in Greenplum Database.

Setting the Sequence Counter Value

You can use the Greenplum Database `setval()` built-in function to set the counter value for a sequence. For example, the following command sets the counter value of the sequence named `myserial` to 201:

```
SELECT setval('myserial', 201);
```

`setval()` has two function signatures: `setval(sequence, start_val)` and `setval(sequence, start_val, is_called)`. The default behaviour of `setval(sequence, start_val)` sets the sequence `is_called` attribute value to `true`.

If you do not want the sequence counter advanced on the next `nextval()` call, use the `setval(sequence, start_val, is_called)` function signature, passing a `false` argument:

```
SELECT setval('myserial', 201, false);
```

`setval()` operations are never rolled back.

Altering a Sequence

The **ALTER SEQUENCE** command changes the attributes of an existing sequence. You can alter the sequence start, minimum, maximum, and increment values. You can also restart the sequence at the start value or at a specified value.

Any parameters not set in the **ALTER SEQUENCE** command retain their prior settings.

`ALTER SEQUENCE sequence START WITH start_value` sets the sequence's `start_value` attribute to the new starting value. It has no effect on the `last_value` attribute or the value returned by the `nextval(sequence)` function.

`ALTER SEQUENCE sequence RESTART` resets the sequence's `last_value` attribute to the current value of the `start_value` attribute and the `is_called` attribute to `false`. The next call to the `nextval(sequence)` function returns `start_value`.

`ALTER SEQUENCE sequence RESTART WITH restart_value` sets the sequence's `last_value` attribute to the new value and the `is_called` attribute to `false`. The next call to the `nextval(sequence)` returns `restart_value`. This is the equivalent of calling `setval(sequence, restart_value, false)`.

The following command restarts the sequence named `myserial` at value 105:

```
ALTER SEQUENCE myserial RESTART WITH 105;
```

Dropping a Sequence

The **DROP SEQUENCE** command removes a sequence. For example, the following command removes the sequence named `myserial`:

```
DROP SEQUENCE myserial;
```

Specifying a Sequence as the Default Value for a Column

You can reference a sequence directly in the **CREATE TABLE** command in addition to using the `SERIAL` or `BIGSERIAL` types. For example:

```
CREATE TABLE tablename ( id INT4 DEFAULT nextval('myserial'), name text );
```

You can also alter a table column to set its default value to a sequence counter:

```
ALTER TABLE tablename ALTER COLUMN id SET DEFAULT nextval('myserial');
```

Sequence Wraparound

By default, a sequence does not wrap around. That is, when a sequence reaches the max value (+32767 for `SMALLSERIAL`, +2147483647 for `SERIAL`, +9223372036854775807 for `BIGSERIAL`), every subsequent `nextval()` call produces an error. You can alter a sequence to make it cycle around and start at 1 again:

```
ALTER SEQUENCE myserial CYCLE;
```

You can also specify the wraparound behaviour when you create the sequence:

```
CREATE SEQUENCE myserial CYCLE;
```

Using Indexes in Greenplum Database

In most traditional databases, indexes can greatly improve data access times. However, in a distributed database such as Greenplum, indexes should be used more sparingly. Greenplum Database performs very fast sequential scans; indexes use a random seek pattern to locate records on disk. Greenplum data is distributed across the segments, so each segment scans a smaller portion of the overall data to get the result. With table partitioning, the total data to scan may be even smaller. Because business intelligence (BI) query workloads generally return very large data sets, using indexes is not efficient.

First try your query workload without adding indexes. Indexes are more likely to improve performance for OLTP workloads, where the query is returning a single record or a small subset of data. Indexes can also improve performance on compressed append-optimized tables for queries that return a targeted set of rows, as the optimizer can use an index access method rather than a full table scan when appropriate. For compressed data, an index access method means only the necessary rows are uncompressed.

Greenplum Database automatically creates `PRIMARY KEY` constraints for tables with primary keys. To create an index on a partitioned table, create an index on the partitioned table that you created. The index is propagated to all the child tables created by Greenplum Database. Creating an index on a table that is created by Greenplum Database for use by a partitioned table is not supported.

Note that a `UNIQUE CONSTRAINT` (such as a `PRIMARY KEY CONSTRAINT`) implicitly creates a `UNIQUE INDEX` that must include all the columns of the distribution key and any partitioning key. The `UNIQUE CONSTRAINT` is enforced across the entire table, including all table partitions (if any).

Indexes add some database overhead — they use storage space and must be maintained when the table is updated. Ensure that the query workload uses the indexes that you create, and check that the indexes you add improve query performance (as compared to a sequential scan of the table). To determine whether indexes are being used, examine the query `EXPLAIN` plans. See [Query Profiling](#).

Consider the following points when you create indexes.

- **Your Query Workload.** Indexes improve performance for workloads where queries return a single record or a very small data set, such as OLTP workloads.
- **Compressed Tables.** Indexes can improve performance on compressed append-optimized tables for queries that return a targeted set of rows. For compressed data, an index access method means only the necessary rows are uncompressed.
- **Avoid indexes on frequently updated columns.** Creating an index on a column that is frequently updated increases the number of writes required when the column is updated.

- **Create selective B-tree indexes.** Index selectivity is a ratio of the number of distinct values a column has divided by the number of rows in a table. For example, if a table has 1000 rows and a column has 800 distinct values, the selectivity of the index is 0.8, which is considered good. Unique indexes always have a selectivity ratio of 1.0, which is the best possible. Greenplum Database allows unique indexes only on distribution key columns.
- ****Use Bitmap indexes for low selectivity columns.****The Greenplum Database Bitmap index type is not available in regular PostgreSQL. See [About Bitmap Indexes](#).
- **Index columns used in joins.** An index on a column used for frequent joins (such as a foreign key column) can improve join performance by enabling more join methods for the query optimizer to use.
- **Index columns frequently used in predicates.** Columns that are frequently referenced in `WHERE` clauses are good candidates for indexes.
- **Avoid overlapping indexes.** Indexes that have the same leading column are redundant.
- **Drop indexes for bulk loads.** For mass loads of data into a table, consider dropping the indexes and re-creating them after the load completes. This is often faster than updating the indexes.
- **Consider a clustered index.** Clustering an index means that the records are physically ordered on disk according to the index. If the records you need are distributed randomly on disk, the database has to seek across the disk to fetch the records requested. If the records are stored close together, the fetching operation is more efficient. For example, a clustered index on a date column where the data is ordered sequentially by date. A query against a specific date range results in an ordered fetch from the disk, which leverages fast sequential access.

To cluster an index in Greenplum Database

Using the `CLUSTER` command to physically reorder a table based on an index can take a long time with very large tables. To achieve the same results much faster, you can manually reorder the data on disk by creating an intermediate table and loading the data in the desired order. For example:

```
CREATE TABLE new_table (LIKE old_table)
    AS SELECT * FROM old_table ORDER BY myixcolumn;
DROP old_table;
ALTER TABLE new_table RENAME TO old_table;
CREATE INDEX myixcolumn_ix ON old_table;
VACUUM ANALYZE old_table;
```

Parent topic: [Defining Database Objects](#)

Index Types

Greenplum Database supports the Postgres index types B-tree, GiST, SP-GiST, and GIN. Hash indexes are not supported. Each index type uses a different algorithm that is best suited to different types of queries. B-tree indexes fit the most common situations and are the default index type. See [Index Types](#) in the PostgreSQL documentation for a description of these types.

Note: Greenplum Database allows unique indexes only if the columns of the index key are the same as (or a superset of) the Greenplum distribution key. Unique indexes are not supported on append-optimized tables. On partitioned tables, a unique index cannot be enforced across all child table partitions of a partitioned table. A unique index is supported only within a partition.

About Bitmap Indexes

Greenplum Database provides the Bitmap index type. Bitmap indexes are best suited to data warehousing applications and decision support systems with large amounts of data, many ad hoc queries, and few data modification (DML) transactions.

An index provides pointers to the rows in a table that contain a given key value. A regular index stores a list of tuple IDs for each key corresponding to the rows with that key value. Bitmap indexes store a bitmap for each key value. Regular indexes can be several times larger than the data in the table, but bitmap indexes provide the same functionality as a regular index and use a fraction of the size of the indexed data.

Each bit in the bitmap corresponds to a possible tuple ID. If the bit is set, the row with the corresponding tuple ID contains the key value. A mapping function converts the bit position to a tuple ID. Bitmaps are compressed for storage. If the number of distinct key values is small, bitmap indexes are much smaller, compress better, and save considerable space compared with a regular index. The size of a bitmap index is proportional to the number of rows in the table times the number of distinct values in the indexed column.

Bitmap indexes are most effective for queries that contain multiple conditions in the `WHERE` clause. Rows that satisfy some, but not all, conditions are filtered out before the table is accessed. This improves response time, often dramatically.

When to Use Bitmap Indexes

Bitmap indexes are best suited to data warehousing applications where users query the data rather than update it. Bitmap indexes perform best for columns that have between 100 and 100,000 distinct values and when the indexed column is often queried in conjunction with other indexed columns. Columns with fewer than 100 distinct values, such as a gender column with two distinct values (male and female), usually do not benefit much from any type of index. On a column with more than 100,000 distinct values, the performance and space efficiency of a bitmap index decline.

Bitmap indexes can improve query performance for ad hoc queries. `AND` and `OR` conditions in the `WHERE` clause of a query can be resolved quickly by performing the corresponding Boolean operations directly on the bitmaps before converting the resulting bitmap to tuple ids. If the resulting number of rows is small, the query can be answered quickly without resorting to a full table scan.

When Not to Use Bitmap Indexes

Do not use bitmap indexes for unique columns or columns with high cardinality data, such as customer names or phone numbers. The performance gains and disk space advantages of bitmap indexes start to diminish on columns with 100,000 or more unique values, regardless of the number of rows in the table.

Bitmap indexes are not suitable for OLTP applications with large numbers of concurrent transactions modifying the data.

Use bitmap indexes sparingly. Test and compare query performance with and without an index. Add an index only if query performance improves with indexed columns.

Creating an Index

The `CREATE INDEX` command defines an index on a table. A B-tree index is the default index type. For example, to create a B-tree index on the column *gender* in the table *employee*:

```
CREATE INDEX gender_idx ON employee (gender);
```

To create a bitmap index on the column *title* in the table *films*:

```
CREATE INDEX title_bmp_idx ON films USING bitmap (title);
```

Indexes on Expressions

An index column need not be just a column of the underlying table, but can be a function or scalar expression computed from one or more columns of the table. This feature is useful to obtain fast access to tables based on the results of computations.

Index expressions are relatively expensive to maintain, because the derived expressions must be computed for each row upon insertion and whenever it is updated. However, the index expressions are not recomputed during an indexed search, since they are already stored in the index. In both of the following examples, the system sees the query as just `WHERE indexedcolumn = 'constant'` and so the speed of the search is equivalent to any other simple index query. Thus, indexes on expressions are useful when retrieval speed is more important than insertion and update speed.

The first example is a common way to do case-insensitive comparisons with the `lower` function:

```
SELECT * FROM test1 WHERE lower(col1) = 'value';
```

This query can use an index if one has been defined on the result of the `lower(col1)` function:

```
CREATE INDEX test1_lower_col1_idx ON test1 (lower(col1));
```

This example assumes the following type of query is performed often.

```
SELECT * FROM people WHERE (first_name || ' ' || last_name) = 'John Smith';
```

The query might benefit from the following index.

```
CREATE INDEX people_names ON people ((first_name || ' ' || last_name));
```

The syntax of the `CREATE INDEX` command normally requires writing parentheses around index expressions, as shown in the second example. The parentheses can be omitted when the expression is just a function call, as in the first example.

Examining Index Usage

Greenplum Database indexes do not require maintenance and tuning. You can check which indexes are used by the real-life query workload. Use the `EXPLAIN` command to examine index usage for a query.

The query plan shows the steps or *plan nodes* that the database will take to answer a query and time estimates for each plan node. To examine the use of indexes, look for the following query plan node types in your `EXPLAIN` output:

- **Index Scan** - A scan of an index.
- **Bitmap Heap Scan** - Retrieves all
 - from the bitmap generated by `BitmapAnd`, `BitmapOr`, or `BitmapIndexScan` and accesses the heap to retrieve the relevant rows.
- **Bitmap Index Scan** - Compute a bitmap by OR-ing all bitmaps that satisfy the query predicates from the underlying index.

- **BitmapAnd** or **BitmapOr** - Takes the bitmaps generated from multiple BitmapIndexScan nodes, ANDs or ORs them together, and generates a new bitmap as its output.

You have to experiment to determine the indexes to create. Consider the following points.

- Run `ANALYZE` after you create or update an index. `ANALYZE` collects table statistics. The query optimizer uses table statistics to estimate the number of rows returned by a query and to assign realistic costs to each possible query plan.
- Use real data for experimentation. Using test data for setting up indexes tells you what indexes you need for the test data, but that is all.
- Do not use very small test data sets as the results can be unrealistic or skewed.
- Be careful when developing test data. Values that are similar, completely random, or inserted in sorted order will skew the statistics away from the distribution that real data would have.
- You can force the use of indexes for testing purposes by using run-time parameters to turn off specific plan types. For example, turn off sequential scans (`enable_seqscan`) and nested-loop joins (`enable_nestloop`), the most basic plans, to force the system to use a different plan. Time your query with and without indexes and use the `EXPLAIN ANALYZE` command to compare the results.

Managing Indexes

Use the `REINDEX` command to rebuild a poorly-performing index. `REINDEX` rebuilds an index using the data stored in the index's table, replacing the old copy of the index.

To rebuild all indexes on a table

```
REINDEX my_table;
```

```
REINDEX my_index;
```

Dropping an Index

The `DROP INDEX` command removes an index. For example:

```
DROP INDEX title_idx;
```

When loading data, it can be faster to drop all indexes, load, then recreate the indexes.

Creating and Managing Views

Views enable you to save frequently used or complex queries, then access them in a `SELECT` statement as if they were a table. A view is not physically materialized on disk: the query runs as a subquery when you access the view.

These topics describe various aspects of creating and managing views:

- [Best Practices when Creating Views](#) outlines best practices when creating views.
- [Working with View Dependencies](#) contains examples of listing view information and determining what views depend on a certain object.
- [About View Storage in Greenplum Database](#) describes the mechanics behind view

dependencies.

Creating Views

The `CREATE VIEW` command defines a view of a query. For example:

```
CREATE VIEW comedies AS SELECT * FROM films WHERE kind = 'comedy';
```

Views ignore `ORDER BY` and `SORT` operations stored in the view.

Dropping Views

The `DROP VIEW` command removes a view. For example:

```
DROP VIEW topten;
```

The `DROP VIEW...CASCADE` command also removes all dependent objects. As an example, if another view depends on the view which is about to be dropped, the other view will be dropped as well.

Without the `CASCADE` option, the `DROP VIEW` command will fail.

Best Practices when Creating Views

When defining and using a view, remember that a view is just an SQL statement and is replaced by its definition when the query is run.

These are some common uses of views.

- They allow you to have a recurring SQL query or expression in one place for easy reuse.
- They can be used as an interface to abstract from the actual table definitions, so that you can reorganize the tables without having to modify the interface.

If a subquery is associated with a single query, consider using the `WITH` clause of the `SELECT` command instead of creating a seldom-used view.

In general, these uses do not require nesting views, that is, defining views based on other views.

These are two patterns of creating views that tend to be problematic because the view's SQL is used during query execution.

- Defining many layers of views so that your final queries look deceptively simple.
Problems arise when you try to enhance or troubleshoot queries that use the views, for example by examining the execution plan. The query's execution plan tends to be complicated and it is difficult to understand and how to improve it.
- Defining a denormalized "world" view. A view that joins a large number of database tables that is used for a wide variety of queries.
Performance issues can occur for some queries that use the view for some `WHERE` conditions while other `WHERE` conditions work well.

Working with View Dependencies

If there are view dependencies on a table you must use the `CASCADE` keyword to drop it. Also, you cannot alter the table if there are view dependencies on it. This example shows a view dependency on a table.

```
CREATE TABLE t (id integer PRIMARY KEY);
CREATE VIEW v AS SELECT * FROM t;

DROP TABLE t;
ERROR:  cannot drop table t because other objects depend on it
DETAIL:  view v depends on table t
HINT:   Use DROP ... CASCADE to drop the dependent objects too.

ALTER TABLE t DROP id;
ERROR:  cannot drop column id of table t because other objects depend on it
DETAIL:  view v depends on column id of table t
HINT:   Use DROP ... CASCADE to drop the dependent objects too.
```

As the previous example shows, altering a table can be quite a challenge if there is a deep hierarchy of views, because you have to create the views in the correct order. You cannot create a view unless all the objects it requires are present.

You can use view dependency information when you want to alter a table that is referenced by a view. For example, you might want to change a table's column data type from `integer` to `bigint` because you realize you need to store larger numbers. However, you cannot do that if there are views that use the column. You first have to drop those views, then change the column and then run all the `CREATE VIEW` statements to create the views again.

Finding View Dependencies

The following example queries list view information on dependencies on tables and columns.

- [Finding Direct View Dependencies on a Table](#)
- [Finding Direct Dependencies on a Table Column](#)
- [Listing View Schemas](#)
- [Listing View Definitions](#)
- [Listing Nested Views](#)

The example output is based on the [Example Data](#) at the end of this topic.

Also, you can use the first example query [Finding Direct View Dependencies on a Table](#) to find dependencies on user-defined functions (or procedures). The query uses the catalog table `pg_class` that contains information about tables and views. For functions, you can use the catalog table `pg_proc` to get information about functions.

For detailed information about the system catalog tables that store view information, see [About View Storage in Greenplum Database](#).

Finding Direct View Dependencies on a Table

To find out which views directly depend on table `t1`, create a query that performs a join among the catalog tables that contain the dependency information, and qualify the query to return only view dependencies.

```
SELECT v.oid::regclass AS view,
       d.refobjid::regclass AS ref_object    -- name of table
       -- d.refobjid::regproc AS ref_object    -- name of function
FROM pg_depend AS d      -- objects that depend on a table
     JOIN pg_rewrite AS r -- rules depending on a table
       ON r.oid = d.objid
     JOIN pg_class AS v   -- views for the rules
       ON v.oid = r.ev_class
WHERE v.relkind = 'v'     -- filter views only
```

```
-- dependency must be a rule depending on a relation
AND d.classid = 'pg_rewrite'::regclass
AND d.deptype = 'n'           -- normal dependency
-- qualify object
AND d.refclassid = 'pg_class'::regclass -- dependent table
AND d.refobjid = 't1'::regclass
-- AND d.refclassid = 'pg_proc'::regclass -- dependent function
-- AND d.refobjid = 'f'::regproc
;

   view      | ref_object
-----+-----
v1           | t1
v2           | t1
v2           | t1
v3           | t1
mytest.vt1   | t1
mytest.v2a   | t1
mytest.v2a   | t1
(7 rows)
```

The query performs casts to the `regclass` object identifier type. For information about object identifier types, see the PostgreSQL documentation on [Object Identifier Types](#).

In some cases, the views are listed multiple times because the view references multiple table columns. You can remove those duplicates using `DISTINCT`.

You can alter the query to find views with direct dependencies on the function `f`.

- In the `SELECT` clause replace the name of the table `d.refobjid::regclass as ref_object` with the name of the function `d.refobjid::regproc as ref_object`
- In the `WHERE` clause replace the catalog of the referenced object from `d.refclassid = 'pg_class'::regclass` for tables, to `d.refclassid = 'pg_proc'::regclass` for procedures (functions). Also change the object name from `d.refobjid = 't1'::regclass` to `d.refobjid = 'f'::regproc`
- In the `WHERE` clause, replace the name of the table `refobjid = 't1'::regclass` with the name of the function `refobjid = 'f'::regproc`.

In the example query, the changes have been commented out (prefixed with `--`). You can comment out the lines for the table and enable the lines for the function.

Finding Direct Dependencies on a Table Column

You can modify the previous query to find those views that depend on a certain table column, which can be useful if you are planning to drop a column (adding a column to the base table is never a problem). The query uses the table column information in the `pg_attribute` catalog table.

This query finds the views that depend on the column `id` of table `t1`:

```
SELECT v.oid::regclass AS view,
       d.refobjid::regclass AS ref_object, -- name of table
       a.attname AS col_name               -- column name
FROM pg_attribute AS a -- columns for a table
JOIN pg_depend AS d -- objects that depend on a column
  ON d.refobjsubid = a.attnum AND d.refobjid = a.attrelid
JOIN pg_rewrite AS r -- rules depending on the column
  ON r.oid = d.objid
JOIN pg_class AS v -- views for the rules
  ON v.oid = r.ev_class
WHERE v.relkind = 'v' -- filter views only
-- dependency must be a rule depending on a relation
AND d.classid = 'pg_rewrite'::regclass
```

```

AND d.refclassid = 'pg_class'::regclass
AND d.deptype = 'n'      -- normal dependency
AND a.attrelid = 't1'::regclass
AND a.attname = 'id'
;

```

view	ref_object	col_name
v1	t1	id
v2	t1	id
mytest.vt1	t1	id
mytest.v2a	t1	id

(4 rows)

Listing View Schemas

If you have created views in multiple schemas, you can also list views, each view's schema, and the table referenced by the view. The query retrieves the schema from the catalog table `pg_namespace` and excludes the system schemas `pg_catalog`, `information_schema`, and `gp_toolkit`. Also, the query does not list a view if the view refers to itself.

```

SELECT v.oid::regclass AS view,
       ns.nspname AS schema,      -- view schema,
       d.refobjid::regclass AS ref_object -- name of table
FROM pg_depend AS d              -- objects that depend on a table
JOIN pg_rewrite AS r            -- rules depending on a table
  ON r.oid = d.objid
JOIN pg_class AS v              -- views for the rules
  ON v.oid = r.ev_class
JOIN pg_namespace AS ns         -- schema information
  ON ns.oid = v.relnamespace
WHERE v.relkind = 'v'           -- filter views only
      -- dependency must be a rule depending on a relation
      AND d.classid = 'pg_rewrite'::regclass
      AND d.refclassid = 'pg_class'::regclass -- referenced objects in pg_class -- tables
      and views
      AND d.deptype = 'n'        -- normal dependency
      -- qualify object
      AND ns.nspname NOT IN ('pg_catalog', 'information_schema', 'gp_toolkit') -- system s
      chemas
      AND NOT (v.oid = d.refobjid) -- not self-referencing dependency
;

```

view	schema	ref_object
v1	public	t1
v2	public	t1
v2	public	t1
v2	public	v1
v3	public	t1
vm1	public	mytest.tm1
mytest.vm1	mytest	t1
vm2	public	mytest.tm1
mytest.v2a	mytest	t1
mytest.v2a	mytest	t1
mytest.v2a	mytest	v1

(11 rows)

Listing View Definitions

This query lists the views that depend on `t1`, the column referenced, and the view definition. The `CREATE VIEW` command is created by adding the appropriate text to the view definition.

```

SELECT v.relname AS view,

```

```

d.refobjid::regclass as ref_object,
d.refobjsubid as ref_col,
'CREATE VIEW ' || v.relname || ' AS ' || pg_get_viewdef(v.oid) AS view_def
FROM pg_depend AS d
JOIN pg_rewrite AS r
ON r.oid = d.objid
JOIN pg_class AS v
ON v.oid = r.ev_class
WHERE NOT (v.oid = d.refobjid)
AND d.refobjid = 't1'::regclass
ORDER BY d.refobjsubid
;

```

view	ref_object	ref_col	view_def
v1	t1	1	CREATE VIEW v1 AS SELECT max(t1.id) AS id+ FROM t1;
v2a	t1	1	CREATE VIEW v2a AS SELECT t1.val FROM (t1 JOIN v1 USING (id));
vt1	t1	1	CREATE VIEW vt1 AS SELECT t1.id FROM t1 WHERE (t1.id < 3);
v2	t1	1	CREATE VIEW v2 AS SELECT t1.val FROM (t1 JOIN v1 USING (id));
v2a	t1	2	CREATE VIEW v2a AS SELECT t1.val FROM (t1 JOIN v1 USING (id));
v3	t1	2	CREATE VIEW v3 AS SELECT (t1.val f()) FROM t1;
v2	t1	2	CREATE VIEW v2 AS SELECT t1.val FROM (t1 JOIN v1 USING (id));

(7 rows)

Listing Nested Views

This CTE query lists information about views that reference another view.

The **WITH** clause in this CTE query selects all the views in the user schemas. The main **SELECT** statement finds all views that reference another view.

```

WITH views AS ( SELECT v.relname AS view,
d.refobjid AS ref_object,
v.oid AS view_oid,
ns.nspname AS namespace
FROM pg_depend AS d
JOIN pg_rewrite AS r
ON r.oid = d.objid
JOIN pg_class AS v
ON v.oid = r.ev_class
JOIN pg_namespace AS ns
ON ns.oid = v.relnamespace
WHERE v.relkind = 'v'
AND ns.nspname NOT IN ('pg_catalog', 'information_schema', 'gp_toolkit') -- exclude
system schemas
AND d.deptype = 'n' -- normal dependency
AND NOT (v.oid = d.refobjid) -- not a self-referencing dependency
)
SELECT views.view, views.namespace AS schema,
views.ref_object::regclass AS ref_view,
ref_nspace.nspname AS ref_schema
FROM views
JOIN pg_depend as dep

```

```

    ON dep.refobjid = views.view_oid
JOIN pg_class AS class
    ON views.ref_object = class.oid
JOIN pg_namespace AS ref_nspace
    ON class.relnamespace = ref_nspace.oid
WHERE class.relkind = 'v'
    AND dep.deptype = 'n'
;
view | schema | ref_view | ref_schema
-----+-----+-----+-----
v2   | public  | v1       | public
v2a  | mytest  | v1       | public

```

Example Data

The output for the example queries is based on these database objects and data.

```

CREATE TABLE t1 (
    id integer PRIMARY KEY,
    val text NOT NULL
);

INSERT INTO t1 VALUES
    (1, 'one'), (2, 'two'), (3, 'three');

CREATE FUNCTION f() RETURNS text
    LANGUAGE sql AS 'SELECT ''suffix''::text';

CREATE VIEW v1 AS
    SELECT max(id) AS id
    FROM t1;

CREATE VIEW v2 AS
    SELECT t1.val
    FROM t1 JOIN v1 USING (id);

CREATE VIEW v3 AS
    SELECT val || f()
    FROM t1;

CREATE VIEW v5 AS
    SELECT f() ;

CREATE SCHEMA mytest ;

CREATE TABLE mytest.tml (
    id integer PRIMARY KEY,
    val text NOT NULL
);

INSERT INTO mytest.tml VALUES
    (1, 'one'), (2, 'two'), (3, 'three');

CREATE VIEW vm1 AS
    SELECT id FROM mytest.tml WHERE id < 3 ;

CREATE VIEW mytest.vml AS
    SELECT id FROM public.t1 WHERE id < 3 ;

CREATE VIEW vm2 AS
    SELECT max(id) AS id
    FROM mytest.tml;

CREATE VIEW mytest.v2a AS

```

```
SELECT t1.val
FROM public.t1 JOIN public.v1 USING (id);
```

About View Storage in Greenplum Database

A view is similar to a table, both are relations - that is “something with columns” . All such objects are stored in the catalog table `pg_class`. These are the general differences:

- A view has no data files (because it holds no data).
- The value of `pg_class.relkind` for a view is `v` rather than `r`.
- A view has an `ON SELECT` query rewrite rule called `_RETURN`.

The rewrite rule contains the definition of the view and is stored in the `ev_action` column of the `pg_rewrite` catalog table.

For more technical information about views, see the PostgreSQL documentation about [Views and the Rule System](#).

Also, a view definition is *not* stored as a string, but in the form of a query parse tree. Views are parsed when they are created, which has several consequences:

- Object names are resolved during `CREATE VIEW`, so the current setting of `search_path` affects the view definition.
- Objects are referred to by their internal immutable object ID rather than by their name. Consequently, renaming an object or column referenced in a view definition can be performed without dropping the view.
- Greenplum Database can determine exactly which objects are used in the view definition, so it can add dependencies on them.

Note that the way Greenplum Database handles views is quite different from the way Greenplum Database handles functions: function bodies are stored as strings and are not parsed when they are created. Consequently, Greenplum Database does not know on which objects a given function depends.

Where View Dependency Information is Stored

These system catalog tables contain the information used to determine the tables on which a view depends.

- `pg_class` - object information including tables and views. The `relkind` column describes the type of object.
- `pg_depend` - object dependency information for database-specific (non-shared) objects.
- `pg_rewrite` - rewrite rules for tables and views.
- `pg_attribute` - information about table columns.
- `pg_namespace` - information about schemas (namespaces).

It is important to note that there is no direct dependency of a view on the objects it uses: the dependent object is actually the view’s rewrite rule. That adds another layer of indirection to view dependency information.

Creating and Managing Materialized Views

Materialized views are similar to views. A materialized view enables you to save a frequently used or

complex query, then access the query results in a `SELECT` statement as if they were a table. Materialized views persist the query results in a table-like form. While access to the data stored in a materialized view can be much faster than accessing the underlying tables directly or through a view, the data is not always current.

The materialized view data cannot be directly updated. To refresh the materialized view data, use the `REFRESH MATERIALIZED VIEW` command. The query used to create the materialized view is stored in exactly the same way that a view's query is stored. For example, you can create a materialized view that quickly displays a summary of historical sales data for situations where having incomplete data for the current date would be acceptable.

```
CREATE MATERIALIZED VIEW sales_summary AS
  SELECT seller_no, invoice_date, sum(invoice_amt)::numeric(13,2) as sales_amt
  FROM invoice
  WHERE invoice_date < CURRENT_DATE
  GROUP BY seller_no, invoice_date
  ORDER BY seller_no, invoice_date;

CREATE UNIQUE INDEX sales_summary_seller
ON sales_summary (seller_no, invoice_date);
```

The materialized view might be useful for displaying a graph in the dashboard created for sales people. You could schedule a job to update the summary information each night using this command.

```
REFRESH MATERIALIZED VIEW sales_summary;
```

The information about a materialized view in the Greenplum Database system catalogs is exactly the same as it is for a table or view. A materialized view is a relation, just like a table or a view. When a materialized view is referenced in a query, the data is returned directly from the materialized view, just like from a table. The query in the materialized view definition is only used for populating the materialized view.

If you can tolerate periodic updates of materialized view data, the performance benefit can be substantial.

One use of a materialized view is to allow faster access to data brought in from an external data source such as external table or a foreign data wrapper. Also, you can define indexes on a materialized view, whereas foreign data wrappers do not support indexes; this advantage might not apply for other types of external data access.

If a subquery is associated with a single query, consider using the `WITH` clause of the `SELECT` command instead of creating a seldom-used materialized view.

Parent topic: [Defining Database Objects](#)

Creating Materialized Views

The `CREATE MATERIALIZED VIEW` command defines a materialized view based on a query.

```
CREATE MATERIALIZED VIEW us_users AS SELECT u.id, u.name, a.zone FROM users u, address
a WHERE a.country = 'USA';
```

If a materialized view query contains an `ORDER BY` or `SORT` clause, the clause is ignored when a `SELECT` is performed on the materialized query.

Refreshing or Disabling Materialized Views

The `REFRESH MATERIALIZED VIEW` command updates the materialized view data.

```
REFRESH MATERIALIZED VIEW us_users;
```

With the `WITH NO DATA` clause, the current data is removed, no new data is generated, and the materialized view is left in an unscannable state. An error is returned if a query attempts to access an unscannable materialized view.

```
REFRESH MATERIALIZED VIEW us_users WITH NO DATA;
```

Dropping Materialized Views

The `DROP MATERIALIZED VIEW` command removes a materialized view definition and data. For example:

```
DROP MATERIALIZED VIEW us_users;
```

The `DROP MATERIALIZED VIEW ... CASCADE` command also removes all dependent objects. For example, if another materialized view depends on the materialized view which is about to be dropped, the other materialized view will be dropped as well. Without the `CASCADE` option, the `DROP MATERIALIZED VIEW` command fails.

Working with External Data

Both external and foreign tables provide access to data stored in data sources outside of Greenplum Database as if the data were stored in regular database tables. You can read data from and write data to external and foreign tables.

An external table is a Greenplum Database table backed with data that resides outside of the database. You create a readable external table to read data from the external data source and create a writable external table to write data to the external source. You can use external tables in SQL commands just as you would a regular database table. For example, you can `SELECT` (readable external table), `INSERT` (writable external table), and join external tables with other Greenplum tables. External tables are most often used to load and unload database data. Refer to [Defining External Tables](#) for more information about using external tables to access external data.

[Accessing External Data with PXF](#) describes using PXF and external tables to access external data sources.

A foreign table is a different kind of Greenplum Database table backed with data that resides outside of the database. You can both read from and write to the same foreign table. You can similarly use foreign tables in SQL commands as described above for external tables. Refer to [Accessing External Data with Foreign Tables](#) for more information about accessing external data using foreign tables.

Web-based external tables provide access to data served by an HTTP server or an operating system process. See [Creating and Using External Web Tables](#) for more about web-based tables.

- **[Accessing External Data with PXF](#)**
Data managed by your organization may already reside in external sources such as Hadoop, object stores, and other SQL databases. The Greenplum Platform Extension Framework (PXF) provides access to this external data via built-in connectors that map an external data source to a Greenplum Database table definition.
- **[Defining External Tables](#)**
External tables enable accessing external data as if it were a regular database table. They are often used to move data into and out of a Greenplum database.

- [Accessing External Data with Foreign Tables](#)
- [Using the Greenplum Parallel File Server \(gpfdist\)](#)

The gpfdist protocol is used in a `CREATE EXTERNAL TABLE` SQL command to access external data served by the Greenplum Database gpfdist file server utility. When external data is served by gpfdist, all segments in the Greenplum Database system can read or write external table data in parallel.

Parent topic: [Greenplum Database Administrator Guide](#)

Accessing External Data with PXF

Data managed by your organization may already reside in external sources such as Hadoop, object stores, and other SQL databases. The Greenplum Platform Extension Framework (PXF) provides access to this external data via built-in connectors that map an external data source to a Greenplum Database table definition.

PXF is installed with Hadoop and Object Storage connectors. These connectors enable you to read external data stored in text, Avro, JSON, RCFile, Parquet, SequenceFile, and ORC formats. You can use the JDBC connector to access an external SQL database.

Note: In previous versions of Greenplum Database, you may have used the `gphdfs` external table protocol to access data stored in Hadoop. Greenplum Database version 6.0.0 removes the `gphdfs` protocol. Use PXF and the `pxf` external table protocol to access Hadoop in Greenplum Database version 6.x.

The Greenplum Platform Extension Framework includes a C-language extension and a Java service. After you configure and initialize PXF, you start a single PXF JVM process on each Greenplum Database segment host. This long-running process concurrently serves multiple query requests.

For detailed information about the architecture of and using PXF, refer to the [Greenplum Platform Extension Framework \(PXF\)](#) documentation.

Parent topic: [Working with External Data](#)

Parent topic: [Loading and Unloading Data](#)

Defining External Tables

External tables enable accessing external data as if it were a regular database table. They are often used to move data into and out of a Greenplum database.

To create an external table definition, you specify the format of your input files and the location of your external data sources. For information about input file formats, see [Formatting Data Files](#).

Use one of the following protocols to access external table data sources. You cannot mix protocols in `CREATE EXTERNAL TABLE` statements:

- `file://` accesses external data files on segment hosts that the Greenplum Database superuser (`gpadmin`) can access. See [file:// Protocol](#).
- `gpfdist://` points to a directory on the file host and serves external data files to all Greenplum Database segments in parallel. See [gpfdist:// Protocol](#).
- `gpfdists://` is the secure version of `gpfdist`. See [gpfdists:// Protocol](#).
- The `pxf://` protocol accesses object store systems (Azure, Google Cloud Storage, Minio, S3), external Hadoop systems (HDFS, Hive, HBase), and SQL databases using the Greenplum Platform Extension Framework (PXF). See [pxf:// Protocol](#).
- `s3://` accesses files in an Amazon S3 bucket. See [s3:// Protocol](#).

The `pxf://` and `s3://` protocols are custom data access protocols, where the `file://`, `gpfdist://`, and `gpfdists://` protocols are implemented internally in Greenplum Database. The custom and internal protocols differ in these ways:

- `pxf://` and `s3://` are custom protocols that must be registered using the `CREATE EXTENSION` command (`pxf`) or the `CREATE PROTOCOL` command (`s3`). Registering the PXF extension in a database creates the `pxf` protocol. (See [Accessing External Data with PXF](#).) To use the `s3` protocol, you must configure the database and register the `s3` protocol. (See [Configuring the s3 Protocol](#).) Internal protocols are always present and cannot be unregistered.
- When a custom protocol is registered, a row is added to the `pg_extprotocol` catalog table to specify the handler functions that implement the protocol. The protocol's shared libraries must have been installed on all Greenplum Database hosts. The internal protocols are not represented in the `pg_extprotocol` table and have no additional libraries to install.
- To grant users permissions on custom protocols, you use `GRANT [SELECT | INSERT | ALL] ON PROTOCOL`. To allow (or deny) users permissions on the internal protocols, you use `CREATE ROLE` or `ALTER ROLE` to add the `CREATEEXTTABLE` (or `NOCREATEEXTTABLE`) attribute to each user's role.

External tables access external files from within the database as if they are regular database tables. External tables defined with the `gpfdist/gpfdists`, `pxf`, and `s3` protocols utilize Greenplum parallelism by using the resources of all Greenplum Database segments to load or unload data. The `pxf` protocol leverages the parallel architecture of the Hadoop Distributed File System to access files on that system. The `s3` protocol utilizes the Amazon Web Services (AWS) capabilities.

You can query external table data directly and in parallel using SQL commands such as `SELECT`, `JOIN`, or `SORT EXTERNAL TABLE DATA`, and you can create views for external tables.

The steps for using external tables are:

1. Define the external table.

To use the `pxf` or `s3` protocol, you must also configure Greenplum Database and enable the protocol. See [pxf:// Protocol](#) or [s3:// Protocol](#).

2. Do one of the following:
 - Start the Greenplum Database file server(s) when using the `gpfdist` or `gpfdists` protocols.
 - Verify the configuration for the PXF service and start the service.
 - Verify the Greenplum Database configuration for the `s3` protocol.
3. Place the data files in the correct locations.
4. Query the external table with SQL commands.

Greenplum Database provides readable and writable external tables:

- Readable external tables for data loading. Readable external tables support:
 - Basic extraction, transformation, and loading (ETL) tasks common in data warehousing
 - Reading external table data in parallel from multiple Greenplum database segment instances, to optimize large load operations
 - Filter pushdown. If a query contains a `WHERE` clause, it may be passed to the external data source. Refer to the [gp_external_enable_filter_pushdown](#) server configuration parameter discussion for more information. Note that this feature is currently

supported only with the `pxf` protocol (see [pxf:// Protocol](#)). Readable external tables allow only `SELECT` operations.

- Writable external tables for data unloading. Writable external tables support:
 - Selecting data from database tables to insert into the writable external table
 - Sending data to an application as a stream of data. For example, unload data from Greenplum Database and send it to an application that connects to another database or ETL tool to load the data elsewhere
 - Receiving output from Greenplum parallel MapReduce calculations. Writable external tables allow only `INSERT` operations.

External tables can be file-based or web-based. External tables using the `file://` protocol are read-only tables.

- Regular (file-based) external tables access static flat files. Regular external tables are rescannable: the data is static while the query runs.
- Web (web-based) external tables access dynamic data sources, either on a web server with the `http://` protocol or by running OS commands or scripts. External web tables are not rescannable: the data can change while the query runs.

Greenplum Database backup and restore operations back up and restore only external and external web table *definitions*, not the data source data.

- **`file://` Protocol**
The `file://` protocol is used in a URI that specifies the location of an operating system file.
- **`gpfdist://` Protocol**
The `gpfdist://` protocol is used in a URI to reference a running `gpfdist` instance.
- **`gpfdists://` Protocol**
The `gpfdists://` protocol is a secure version of the `gpfdist://` protocol.
- **`pxf://` Protocol**
You can use the Greenplum Platform Extension Framework (PXF) `pxf://` protocol to access data residing in object store systems (Azure, Google Cloud Storage, Minio, S3), external Hadoop systems (HDFS, Hive, HBase), and SQL databases.
- **`s3://` Protocol**
The `s3` protocol is used in a URL that specifies the location of an Amazon S3 bucket and a prefix to use for reading or writing files in the bucket.
- **Using a Custom Protocol**
A custom protocol allows you to connect Greenplum Database to a data source that cannot be accessed with the `file://`, `gpfdist://`, or `pxf://` protocols.
- **Handling Errors in External Table Data**
By default, if external table data contains an error, the command fails and no data loads into the target database table.
- **Creating and Using External Web Tables**
External web tables allow Greenplum Database to treat dynamic data sources like regular database tables. Because web table data can change as a query runs, the data is not rescannable.
- **Examples for Creating External Tables**
These examples show how to define external data with different protocols. Each `CREATE EXTERNAL TABLE` command can contain only one protocol.

Parent topic: [Working with External Data](#)

file:// Protocol

The `file://` protocol is used in a URI that specifies the location of an operating system file.

The URI includes the host name, port, and path to the file. Each file must reside on a segment host in a location accessible by the Greenplum Database superuser (`gpadmin`). The host name used in the URI must match a segment host name registered in the `gp_segment_configuration` system catalog table.

The `LOCATION` clause can have multiple URIs, as shown in this example:

```
CREATE EXTERNAL TABLE ext_expenses (
  name text, date date, amount float4, category text, desc1 text )
LOCATION ( 'file://host1:5432/data/expense/*.csv',
         'file://host2:5432/data/expense/*.csv',
         'file://host3:5432/data/expense/*.csv' )
FORMAT 'CSV' (HEADER);
```

The number of URIs you specify in the `LOCATION` clause is the number of segment instances that will work in parallel to access the external table. For each URI, Greenplum assigns a primary segment on the specified host to the file. For maximum parallelism when loading data, divide the data into as many equally sized files as you have primary segments. This ensures that all segments participate in the load. The number of external files per segment host cannot exceed the number of primary segment instances on that host. For example, if your array has four primary segment instances per segment host, you can place four external files on each segment host. Tables based on the `file://` protocol can only be readable tables.

The system view `pg_max_external_files` shows how many external table files are permitted per external table. This view lists the available file slots per segment host when using the `file://` protocol. The view is only applicable for the `file://` protocol. For example:

```
SELECT * FROM pg_max_external_files;
```

Parent topic: [Defining External Tables](#)

gpfdist:// Protocol

The `gpfdist://` protocol is used in a URI to reference a running `gpfdist` instance.

The `gpfdist` utility serves external data files from a directory on a file host to all Greenplum Database segments in parallel.

`gpfdist` is located in the `$GPHOME/bin` directory on your Greenplum Database master host and on each segment host.

Run `gpfdist` on the host where the external data files reside. For readable external tables, `gpfdist` uncompresses `gzip` (`.gz`) and `bzip2` (`.bz2`) files automatically. For writable external tables, data is compressed using `gzip` if the target file has a `.gz` extension. You can use the wildcard character (*) or other C-style pattern matching to denote multiple files to read. The files specified are assumed to be relative to the directory that you specified when you started the `gpfdist` instance.

Note: Compression is not supported for readable and writeable external tables when the `gpfdist` utility runs on Windows platforms.

All primary segments access the external file(s) in parallel, subject to the number of segments set in the `gp_external_max_segments` server configuration parameter. Use multiple `gpfdist` data sources in a `CREATE EXTERNAL TABLE` statement to scale the external table's scan performance.

`gpfdist` supports data transformations. You can write a transformation process to convert external data from or to a format that is not directly supported with Greenplum Database external tables.

For more information about configuring `gpfdist`, see [Using the Greenplum Parallel File Server \(gpfdist\)](#).

See the `gpfdist` reference documentation for more information about using `gpfdist` with external tables.

Parent topic: [Defining External Tables](#)

gpfdists:// Protocol

The `gpfdists://` protocol is a secure version of the `gpfdist://` protocol.

To use it, you run the `gpfdist` utility with the `--ssl` option. When specified in a URI, the `gpfdists://` protocol enables encrypted communication and secure identification of the file server and the Greenplum Database to protect against attacks such as eavesdropping and man-in-the-middle attacks.

`gpfdists` implements SSL security in a client/server scheme with the following attributes and limitations:

- Client certificates are required.
- Multilingual certificates are not supported.
- A Certificate Revocation List (CRL) is not supported.
- The `TLSv1` protocol is used with the `TLS_RSA_WITH_AES_128_CBC_SHA` encryption algorithm.
- SSL parameters cannot be changed.
- SSL renegotiation is supported.
- The SSL ignore host mismatch parameter is set to `false`.
- Private keys containing a passphrase are not supported for the `gpfdist` file server (server.key) and for the Greenplum Database (client.key).
- Issuing certificates that are appropriate for the operating system in use is the user's responsibility. Generally, converting certificates as shown in <https://www.sslshopper.com/ssl-converter.html> is supported.

Note: A server started with the `gpfdist --ssl` option can only communicate with the `gpfdists` protocol. A server that was started with `gpfdist` without the `--ssl` option can only communicate with the `gpfdist` protocol.

- The client certificate file, `client.crt`
- The client private key file, `client.key`

Use one of the following methods to invoke the `gpfdists` protocol.

- Run `gpfdist` with the `--ssl` option and then use the `gpfdists` protocol in the `LOCATION` clause of a `CREATE EXTERNAL TABLE` statement.
- Use a `gpload` YAML control file with the `SSL` option set to true. Running `gpload` starts the `gpfdist` server with the `--ssl` option, then uses the `gpfdists` protocol.

Using `gpfdists` requires that the following client certificates reside in the `$PGDATA/gpfdists` directory on each segment.

- The client certificate file, `client.crt`

- The client private key file, `client.key`
- The trusted certificate authorities, `root.crt`

For an example of loading data into an external table security, see [Example 3—Multiple gpfdists instances](#).

The server configuration parameter `verify_gpfdists_cert` controls whether SSL certificate authentication is enabled when Greenplum Database communicates with the `gpfdist` utility to either read data from or write data to an external data source. You can set the parameter value to `false` to disable authentication when testing the communication between the Greenplum Database external table and the `gpfdist` utility that is serving the external data. If the value is `false`, these SSL exceptions are ignored:

- The self-signed SSL certificate that is used by `gpfdist` is not trusted by Greenplum Database.
- The host name contained in the SSL certificate does not match the host name that is running `gpfdist`.

Warning: Disabling SSL certificate authentication exposes a security risk by not validating the `gpfdists` SSL certificate.

Parent topic: [Defining External Tables](#)

pxf:// Protocol

You can use the Greenplum Platform Extension Framework (PXF) `pxf://` protocol to access data residing in object store systems (Azure, Google Cloud Storage, Minio, S3), external Hadoop systems (HDFS, Hive, HBase), and SQL databases.

The PXF `pxf` protocol is packaged as a Greenplum Database extension. The `pxf` protocol supports reading from external data stores. You can also write text, binary, and parquet-format data with the `pxf` protocol.

When you use the `pxf` protocol to query an external data store, you specify the directory, file, or table that you want to access. PXF requests the data from the data store and delivers the relevant portions in parallel to each Greenplum Database segment instance serving the query.

You must explicitly initialize and start PXF before you can use the `pxf` protocol to read or write external data. You must also enable PXF in each database in which you want to allow users to create external tables to access external data, and grant permissions on the `pxf` protocol to those Greenplum Database users.

For detailed information about configuring and using PXF and the `pxf` protocol, refer to [Accessing External Data with PXF](#).

Parent topic: [Defining External Tables](#)

s3:// Protocol

The `s3` protocol is used in a URL that specifies the location of an Amazon S3 bucket and a prefix to use for reading or writing files in the bucket.

Amazon Simple Storage Service (Amazon S3) provides secure, durable, highly-scalable object storage. For information about Amazon S3, see [Amazon S3](#).

You can define read-only external tables that use existing data files in the S3 bucket for table data, or writable external tables that store the data from INSERT operations to files in the S3 bucket. Greenplum Database uses the S3 URL and prefix specified in the protocol URL either to select one or more files for a read-only table, or to define the location and filename format to use when

uploading S3 files for `INSERT` operations to writable tables.

The `s3` protocol also supports [Dell EMC Elastic Cloud Storage \(ECS\)](#), an Amazon S3 compatible service.

Note: The `pxf` protocol can access data in S3 and other object store systems such as Azure, Google Cloud Storage, and Minio. The `pxf` protocol can also access data in external Hadoop systems (HDFS, Hive, HBase), and SQL databases. See [pxf:// Protocol](#).

This topic contains the sections:

- [Configuring the s3 Protocol](#)
- [Using s3 External Tables](#)
- [About the s3 Protocol LOCATION URL](#)
- [About Reading and Writing S3 Data Files](#)
- [s3 Protocol AWS Server-Side Encryption Support](#)

- [About the s3 Protocol Configuration File](#)
- [About Specifying the Configuration File Location](#)
- [s3 Protocol Limitations](#)
- [Using the gpcheckcloud Utility](#)

Configuring the s3 Protocol

You must configure the `s3` protocol before you can use it. Perform these steps in each database in which you want to use the protocol:

1. Create the read and write functions for the `s3` protocol library:

```
CREATE OR REPLACE FUNCTION write_to_s3() RETURNS integer AS
'$libdir/gps3ext.so', 's3_export' LANGUAGE C STABLE;
```

```
CREATE OR REPLACE FUNCTION read_from_s3() RETURNS integer AS
'$libdir/gps3ext.so', 's3_import' LANGUAGE C STABLE;
```

2. Declare the `s3` protocol and specify the read and write functions you created in the previous step:

```
CREATE PROTOCOL s3 (writefunc = write_to_s3, readfunc = read_from_s3);
```

Note: The protocol name `s3` must be the same as the protocol of the URL specified for the external table that you create to access an S3 resource.

The corresponding function is called by every Greenplum Database segment instance.

Using s3 External Tables

Follow these basic steps to use the `s3` protocol with Greenplum Database external tables. Each step includes links to relevant topics from which you can obtain more information. See also [s3 Protocol Limitations](#) to better understand the capabilities and limitations of s3 external tables:

1. [Configure the s3 Protocol](#).
2. Create the `s3` protocol configuration file:

1. Create a template `s3` protocol configuration file using the `gpcheckcloud` utility:

```
gpcheckcloud -t > ./mytest_s3.config
```

2. Edit the template file to specify the `accessid` and `secret` required to connect to the S3 location. See [About the s3 Protocol Configuration File](#) for information about other `s3` protocol configuration parameters.
3. Greenplum Database can access an `s3` protocol configuration file when the file is located on each segment host or when the file is served up by an `http/https` server. Identify where you plan to locate the configuration file, and note the location and configuration option (if applicable). Refer to [About Specifying the Configuration File Location](#) for more information about the location options for the file.
4. Use the `gpcheckcloud` utility to validate connectivity to the S3 bucket. You must specify the S3 endpoint name and bucket that you want to check.

For example, if the `s3` protocol configuration file resides in the default location, you would run the following command:

```
gpcheckcloud -c "s3://<s3-endpoint>/<s3-bucket>"
```

`gpcheckcloud` attempts to connect to the S3 endpoint and lists any files in the S3 bucket, if available. A successful connection ends with the message:

```
Your configuration works well.
```

You can optionally use `gpcheckcloud` to validate uploading to and downloading from the S3 bucket. Refer to [Using the gpcheckcloud Utility](#) for information about this utility and other usage examples.

5. Create an `s3` external table by specifying an `s3` protocol URL in the `CREATE EXTERNAL TABLE` command, `LOCATION` clause.

For read-only `s3` tables, the URL defines the location and prefix used to select existing data files that comprise the `s3` table. For example:

```
CREATE READABLE EXTERNAL TABLE S3TBL (date text, time text, amt int)
  LOCATION ('s3://s3-us-west-2.amazonaws.com/s3test.example.com/dataset1/normal
/ config=/home/gpadmin/aws_s3/s3.conf')
  FORMAT 'csv';
```

For writable `s3` tables, the protocol URL defines the S3 location in which Greenplum Database writes the data files that back the table for `INSERT` operations. You can also specify a prefix that Greenplum will add to the files that it creates. For example:

```
CREATE WRITABLE EXTERNAL TABLE S3WRIT (LIKE S3TBL)
  LOCATION ('s3://s3-us-west-2.amazonaws.com/s3test.example.com/dataset1/normal
/ config=/home/gpadmin/aws_s3/s3.conf')
  FORMAT 'csv';
```

Refer to [About the s3 Protocol LOCATION URL](#) for more information about the `s3` protocol URL.

About the s3 Protocol LOCATION URL

When you use the `s3` protocol, you specify an S3 file location and optional configuration file location and region parameters in the `LOCATION` clause of the `CREATE EXTERNAL TABLE` command. The syntax

follows:

```
's3://<S3_endpoint>[:<port>]/<bucket_name>/[<S3_prefix>] [region=<S3_region>] [config=
<config_file_location> | config_server=<url>]'
```

The `s3` protocol requires that you specify the S3 endpoint and S3 bucket name. Each Greenplum Database segment host must have access to the S3 location. The optional `S3_prefix` value is used to select files for read-only S3 tables, or as a filename prefix to use when uploading files for s3 writable tables.

Note: The Greenplum Database `s3` protocol URL must include the S3 endpoint hostname.

To specify an ECS endpoint (an Amazon S3 compatible service) in the `LOCATION` clause, you must set the `s3` protocol configuration file parameter `version` to 2. The `version` parameter controls whether the `region` parameter is used in the `LOCATION` clause. You can also specify an Amazon S3 location when the `version` parameter is 2. For information about the `version` parameter, see [About the s3 Protocol Configuration File](#).

Note: Although the `S3_prefix` is an optional part of the syntax, you should always include an S3 prefix for both writable and read-only s3 tables to separate datasets as part of the `CREATE EXTERNAL TABLE` syntax.

For writable s3 tables, the `s3` protocol URL specifies the endpoint and bucket name where Greenplum Database uploads data files for the table. The S3 file prefix is used for each new file uploaded to the S3 location as a result of inserting data to the table. See [About Reading and Writing S3 Data Files](#).

For read-only s3 tables, the S3 file prefix is optional. If you specify an `S3_prefix`, then the `s3` protocol selects all files that start with the specified prefix as data files for the external table. The `s3` protocol does not use the slash character (/) as a delimiter, so a slash character following a prefix is treated as part of the prefix itself.

For example, consider the following 5 files that each have the `S3_endpoint` named `s3-us-west-2.amazonaws.com` and the `bucket_name` `test1`:

```
s3://s3-us-west-2.amazonaws.com/test1/abc
s3://s3-us-west-2.amazonaws.com/test1/abc/
s3://s3-us-west-2.amazonaws.com/test1/abc/xx
s3://s3-us-west-2.amazonaws.com/test1/abcdef
s3://s3-us-west-2.amazonaws.com/test1/abcdefff
```

- If the S3 URL is provided as `s3://s3-us-west-2.amazonaws.com/test1/abc`, then the `abc` prefix selects all 5 files.
- If the S3 URL is provided as `s3://s3-us-west-2.amazonaws.com/test1/abc/`, then the `abc/` prefix selects the files `s3://s3-us-west-2.amazonaws.com/test1/abc/` and `s3://s3-us-west-2.amazonaws.com/test1/abc/xx`.
- If the S3 URL is provided as `s3://s3-us-west-2.amazonaws.com/test1/abcd`, then the `abcd` prefix selects the files `s3://s3-us-west-2.amazonaws.com/test1/abcdef` and `s3://s3-us-west-2.amazonaws.com/test1/abcdefff`

Wildcard characters are not supported in an `S3_prefix`; however, the S3 prefix functions as if a wildcard character immediately followed the prefix itself.

All of the files selected by the S3 URL (`S3_endpoint/bucket_name/S3_prefix`) are used as the source for the external table, so they must have the same format. Each file must also contain complete data rows. A data row cannot be split between files.

For information about the Amazon S3 endpoints see

http://docs.aws.amazon.com/general/latest/gr/rande.html#s3_region. For information about S3 buckets and folders, see the Amazon S3 documentation <https://aws.amazon.com/documentation/s3/>. For information about the S3 file prefix, see the Amazon S3 documentation [Listing Keys Hierarchically Using a Prefix and Delimiter](#).

You use the `config` or `config_server` parameter to specify the location of the required `s3` protocol configuration file that contains AWS connection credentials and communication parameters as described in [About Specifying the Configuration File Location](#).

About Reading and Writing S3 Data Files

You can use the `s3` protocol to read and write data files on Amazon S3.

Reading S3 Files

The S3 permissions on any file that you read must include `Open/Download` and `View` for the S3 user ID that accesses the files.

For read-only S3 tables, all of the files specified by the S3 file location (`S3_endpoint/bucket_name/S3_prefix`) are used as the source for the external table and must have the same format. Each file must also contain complete data rows. If the files contain an optional header row, the column names in the header row cannot contain a newline character (`\n`) or a carriage return (`\r`). Also, the column delimiter cannot be a newline character (`\n`) or a carriage return character (`\r`).

The `s3` protocol recognizes gzip and deflate compressed files and automatically decompresses the files. For gzip compression, the protocol recognizes the format of a gzip compressed file. For deflate compression, the protocol assumes a file with the `.deflate` suffix is a deflate compressed file.

Each Greenplum Database segment can download one file at a time from the S3 location using several threads. To take advantage of the parallel processing performed by the Greenplum Database segments, the files in the S3 location should be similar in size and the number of files should allow for multiple segments to download the data from the S3 location. For example, if the Greenplum Database system consists of 16 segments and there was sufficient network bandwidth, creating 16 files in the S3 location allows each segment to download a file from the S3 location. In contrast, if the location contained only 1 or 2 files, only 1 or 2 segments download data.

Writing S3 Files

Writing a file to S3 requires that the S3 user ID have `Upload/Delete` permissions.

When you initiate an `INSERT` operation on a writable S3 table, each Greenplum Database segment uploads a single file to the configured S3 bucket using the filename format `<prefix><segment_id><random>.<extension>[.gz]` where:

- `<prefix>` is the prefix specified in the S3 URL.
- `<segment_id>` is the Greenplum Database segment ID.
- `<random>` is a random number that is used to ensure that the filename is unique.
- `<extension>` describes the file type (`.txt` or `.csv`, depending on the value you provide in the `FORMAT` clause of `CREATE WRITABLE EXTERNAL TABLE`). Files created by the `gpcheckcloud` utility always uses the extension `.data`.
- `.gz` is appended to the filename if compression is enabled for S3 writable tables (the default).

You can configure the buffer size and the number of threads that segments use for uploading files. See [About the S3 Protocol Configuration File](#).

s3 Protocol AWS Server-Side Encryption Support

Greenplum Database supports server-side encryption using Amazon S3-managed keys (SSE-S3) for AWS S3 files you access with readable and writable external tables created using the `s3` protocol. SSE-S3 encrypts your object data as it writes to disk, and transparently decrypts the data for you when you access it.

Note: The `s3` protocol supports SSE-S3 only for Amazon Web Services S3 files. SSE-SE is not supported when accessing files in S3 compatible services.

Your S3 `accessid` and `secret` permissions govern your access to all S3 bucket objects, whether the data is encrypted or not. However, you must configure your client to use S3-managed keys for accessing encrypted data.

Refer to [Protecting Data Using Server-Side Encryption](#) in the AWS documentation for additional information about AWS Server-Side Encryption.

Configuring S3 Server-Side Encryption

`s3` protocol server-side encryption is disabled by default. To take advantage of server-side encryption on AWS S3 objects you write using the Greenplum Database `s3` protocol, you must set the `server_side_encryption` configuration parameter in your `s3` protocol configuration file to the value `sse-s3`:

```
server_side_encryption = sse-s3
```

When the configuration file you provide to a `CREATE WRITABLE EXTERNAL TABLE` call using the `s3` protocol includes the `server_side_encryption = sse-s3` setting, Greenplum Database applies encryption headers for you on all `INSERT` operations on that external table. S3 then encrypts on write the object(s) identified by the URI you provided in the `LOCATION` clause.

S3 transparently decrypts data during read operations of encrypted files accessed via readable external tables you create using the `s3` protocol. No additional configuration is required.

For further encryption configuration granularity, you may consider creating Amazon Web Services S3 *Bucket Policy*(s), identifying the objects you want to encrypt and the write actions on those objects as described in the [Protecting Data Using Server-Side Encryption with Amazon S3-Managed Encryption Keys \(SSE-S3\)](#) AWS documentation.

s3 Protocol Proxy Support

You can specify a URL that is the proxy that S3 uses to connect to a data source. S3 supports these protocols: HTTP and HTTPS. You can specify a proxy with the `s3` protocol configuration parameter `proxy` or an environment variable. If the configuration parameter is set, the environment variables are ignored.

To specify proxy with an environment variable, you set the environment variable based on the protocol: `http_proxy` or `https_proxy`. You can specify a different URL for each protocol by setting the appropriate environment variable. S3 supports these environment variables.

- `all_proxy` specifies the proxy URL that is used if an environment variable for a specific protocol is not set.
- `no_proxy` specifies a comma-separated list of hosts names that do not use the proxy specified by an environment variable.

The environment variables must be set and must be accessible to Greenplum Database on all

Greenplum Database hosts.

For information about the configuration parameter `proxy`, see [About the s3 Protocol Configuration File](#).

About the s3 Protocol Configuration File

An `s3` protocol configuration file contains Amazon Web Services (AWS) connection credentials and communication parameters. This file is required to use the `s3` protocol.

The `s3` protocol configuration file is a text file that contains a `[default]` section and parameters. An example configuration file follows:

```
[default]
secret = "secret"
accessid = "user access id"
threadnum = 3
chunksize = 67108864
```

You can use the Greenplum Database `gpcheckcloud` utility to test the `s3` protocol configuration file. See [Using the gpcheckcloud Utility](#).

s3 Configuration File Parameters

`accessid`

Required. AWS S3 ID to access the S3 bucket.

`secret`

Required. AWS S3 passcode for the S3 ID to access the S3 bucket.

`autocompress`

For writable `s3` external tables, this parameter specifies whether to compress files (using `gzip`) before uploading to S3. Files are compressed by default if you do not specify this parameter.

`chunksize`

The buffer size that each segment thread uses for reading from or writing to the S3 server. The default is 64 MB. The minimum is 8MB and the maximum is 128MB.

When inserting data to a writable `s3` table, each Greenplum Database segment writes the data into its buffer (using multiple threads up to the `threadnum` value) until it is full, after which it writes the buffer to a file in the S3 bucket. This process is then repeated as necessary on each segment until the insert operation completes.

Because Amazon S3 allows a maximum of 10,000 parts for multipart uploads, the minimum `chunksize` value of 8MB supports a maximum insert size of 80GB per Greenplum database segment. The maximum `chunksize` value of 128MB supports a maximum insert size 1.28TB per segment. For writable `s3` tables, you must ensure that the `chunksize` setting can support the anticipated table size of your table. See [Multipart Upload Overview](#) in the S3 documentation for more information about uploads to S3.

`encryption`

Use connections that are secured with Secure Sockets Layer (SSL). Default value is `true`. The values `true`, `t`, `on`, `yes`, and `y` (case insensitive) are treated as `true`. Any other value is treated as `false`.

If the port is not specified in the URL in the `LOCATION` clause of the `CREATE EXTERNAL TABLE` command, the configuration file `encryption` parameter affects the port used by the `s3` protocol (port 80 for HTTP or port 443 for HTTPS). If the port is specified, that port is used regardless of the encryption setting.

gpcheckcloud_newline

When downloading files from an S3 location, the `gpcheckcloud` utility appends a new line character to last line of a file if the last line of a file does not have an EOL (end of line) character. The default character is `\n` (newline). The value can be `\n`, `\r` (carriage return), or `\n\r` (newline/carriage return).

Adding an EOL character prevents the last line of one file from being concatenated with the first line of next file.

low_speed_limit

The upload/download speed lower limit, in bytes per second. The default speed is 10240 (10K). If the upload or download speed is slower than the limit for longer than the time specified by `low_speed_time`, then the connection is stopped and retried. After 3 retries, the `s3` protocol returns an error. A value of 0 specifies no lower limit.

low_speed_time

When the connection speed is less than `low_speed_limit`, this parameter specified the amount of time, in seconds, to wait before cancelling an upload to or a download from the S3 bucket. The default is 60 seconds. A value of 0 specifies no time limit.

proxy

Specify a URL that is the proxy that S3 uses to connect to a data source. S3 supports these protocols: HTTP and HTTPS. This is the format for the parameter.

```
proxy = <protocol>://[<user>:<password>@]<proxyhost>[:<port>]
```

If this parameter is not set or is an empty string (`proxy = ""`), S3 uses the proxy specified by the environment variable `http_proxy` or `https_proxy` (and the environment variables `all_proxy` and `no_proxy`). The environment variable that S3 uses depends on the protocol. For information about the environment variables, see [S3 Protocol Proxy Support](#).

There can be at most one `proxy` parameter in the configuration file. The URL specified by the parameter is the proxy for all supported protocols.

server_side_encryption

The S3 server-side encryption method that has been configured for the bucket. Greenplum Database supports only server-side encryption with Amazon S3-managed keys, identified by the configuration parameter value `sse-s3`. Server-side encryption is disabled (`none`) by default.

threadnum

The maximum number of concurrent threads a segment can create when uploading data to or downloading data from the S3 bucket. The default is 4. The minimum is 1 and the maximum is 8.

verifycert

Controls how the `s3` protocol handles authentication when establishing encrypted communication between a client and an S3 data source over HTTPS. The value is either `true` or `false`. The default value is `true`.

- `verifycert=false` - Ignores authentication errors and allows encrypted communication over HTTPS.
- `verifycert=true` - Requires valid authentication (a proper certificate) for encrypted communication over HTTPS.

Setting the value to `false` can be useful in testing and development environments to allow communication without changing certificates.

Warning: Setting the value to `false` exposes a security risk by ignoring invalid credentials when establishing communication between a client and a S3 data store.

version

Specifies the version of the information specified in the **LOCATION** clause of the **CREATE EXTERNAL TABLE** command. The value is either 1 or 2. The default value is 1.

If the value is 1, the **LOCATION** clause supports an Amazon S3 URL, and does not contain the **region** parameter. If the value is 2, the **LOCATION** clause supports S3 compatible services and must include the **region** parameter. The **region** parameter specifies the S3 data source region. For this S3 URL `s3://s3-us-west-2.amazonaws.com/s3test.example.com/dataset1/normal/`, the AWS S3 region is `us-west-2`.

If **version** is 1 or is not specified, this is an example of the **LOCATION** clause of the **CREATE EXTERNAL TABLE** command that specifies an Amazon S3 endpoint.

```
LOCATION ('s3://s3-us-west-2.amazonaws.com/s3test.example.com/dataset1/normal/ config=
/home/gpadmin/aws_s3/s3.conf')
```

If **version** is 2, this is an example **LOCATION** clause with the **region** parameter for an AWS S3 compatible service.

```
LOCATION ('s3://test.company.com/s3test.company/test1/normal/ region=local-test config
=/home/gpadmin/aws_s3/s3.conf')
```

If **version** is 2, the **LOCATION** clause can also specify an Amazon S3 endpoint. This example specifies an Amazon S3 endpoint that uses the **region** parameter.

```
LOCATION ('s3://s3-us-west-2.amazonaws.com/s3test.example.com/dataset1/normal/ region=
us-west-2 config=/home/gpadmin/aws_s3/s3.conf')
```

Note: Greenplum Database can require up to `threadnum * chunksize` memory on each segment host when uploading or downloading S3 files. Consider this `s3` protocol memory requirement when you configure overall Greenplum Database memory.

About Specifying the Configuration File Location

The default location of the `s3` protocol configuration file is a file named `s3.conf` that resides in the data directory of each Greenplum Database segment instance:

```
<gpseg_data_dir>/<gpseg_prefix><N>/s3/s3.conf
```

The `gpseg_data_dir` is the path to the Greenplum Database segment data directory, the `gpseg_prefix` is the segment prefix, and `N` is the segment ID. The segment data directory, prefix, and ID are set when you initialize a Greenplum Database system.

You may choose an alternate location for the `s3` protocol configuration file by specifying the optional `config` or `config_server` parameters in the **LOCATION** URL:

- You can simplify the configuration by using a single configuration file that resides in the same file system location on each segment host. In this scenario, you specify the `config` parameter in the **LOCATION** clause to identify the absolute path to the file. The following example specifies a location in the `gpadmin` home directory:

```
LOCATION ('s3://s3-us-west-2.amazonaws.com/test/my_data config=/home/gpadmin/s3
.conf')
```

The `/home/gpadmin/s3.conf` file must reside on each segment host, and all segment

instances on a host use the file.

- You also have the option to use an [http/https](#) server to serve up the configuration file. In this scenario, you specify an [http/https](#) server URL in the `config_server` parameter. You are responsible for configuring and starting the server, and each Greenplum Database segment host must be able to access the server. The following example specifies an IP address and port for an [https](#) server:

```
LOCATION ('s3://s3-us-west-2.amazonaws.com/test/my_data config_server=https://203.0.113.0:8553')
```

s3 Protocol Limitations

These are `s3` protocol limitations:

- Only the S3 path-style URL is supported.

```
s3://<S3_endpoint>/<bucketname>/[<S3_prefix>]
```

- Only the S3 endpoint is supported. The protocol does not support virtual hosting of S3 buckets (binding a domain name to an S3 bucket).
- AWS signature version 4 signing process is supported.

For information about the S3 endpoints supported by each signing process, see http://docs.aws.amazon.com/general/latest/gr/rande.html#s3_region.

- Only a single URL and optional configuration file location and region parameters is supported in the `LOCATION` clause of the `CREATE EXTERNAL TABLE` command.
- If the `NEWLINE` parameter is not specified in the `CREATE EXTERNAL TABLE` command, the newline character must be identical in all data files for specific prefix. If the newline character is different in some data files with the same prefix, read operations on the files might fail.
- For writable s3 external tables, only the `INSERT` operation is supported. `UPDATE`, `DELETE`, and `TRUNCATE` operations are not supported.
- Because Amazon S3 allows a maximum of 10,000 parts for multipart uploads, the maximum `chunksize` value of 128MB supports a maximum insert size of 1.28TB per Greenplum database segment for writable s3 tables. You must ensure that the `chunksize` setting can support the anticipated table size of your table. See [Multipart Upload Overview](#) in the S3 documentation for more information about uploads to S3.
- To take advantage of the parallel processing performed by the Greenplum Database segment instances, the files in the S3 location for read-only s3 tables should be similar in size and the number of files should allow for multiple segments to download the data from the S3 location. For example, if the Greenplum Database system consists of 16 segments and there was sufficient network bandwidth, creating 16 files in the S3 location allows each segment to download a file from the S3 location. In contrast, if the location contained only 1 or 2 files, only 1 or 2 segments download data.

Using the gpcheckcloud Utility

The Greenplum Database utility `gpcheckcloud` helps users create an `s3` protocol configuration file and test a configuration file. You can specify options to test the ability to access an S3 bucket with a configuration file, and optionally upload data to or download data from files in the bucket.

If you run the utility without any options, it sends a template configuration file to `STDOUT`. You can

capture the output and create an `s3` configuration file to connect to Amazon S3.

The utility is installed in the Greenplum Database `$GPHOME/bin` directory.

Syntax

```
gpcheckcloud {-c | -d} "s3://<S3_endpoint>/<bucketname>/[<S3_prefix>] [config=<path_to_config_file>]"

gpcheckcloud -u <file_to_upload> "s3://<S3_endpoint>/<bucketname>/[<S3_prefix>] [config=<path_to_config_file>]"
gpcheckcloud -t
gpcheckcloud -h
```

Options

`-c`

Connect to the specified S3 location with the configuration specified in the `s3` protocol URL and return information about the files in the S3 location.

If the connection fails, the utility displays information about failures such as invalid credentials, prefix, or server address (DNS error), or server not available.

`-d`

Download data from the specified S3 location with the configuration specified in the `s3` protocol URL and send the output to `STDOUT`.

If files are gzip compressed or have a `.deflate` suffix to indicate deflate compression, the uncompressed data is sent to `STDOUT`.

`-u`

Upload a file to the S3 bucket specified in the `s3` protocol URL using the specified configuration file if available. Use this option to test compression and `chunksize` and `autocompress` settings for your configuration.

`-t`

Sends a template configuration file to `STDOUT`. You can capture the output and create an `s3` configuration file to connect to Amazon S3.

`-h`

Display `gpcheckcloud` help.

Examples

This example runs the utility without options to create a template `s3` configuration file `mytest_s3.config` in the current directory.

```
gpcheckcloud -t > ./mytest_s3.config
```

This example attempts to upload a local file, `test-data.csv` to an S3 bucket location using the `s3` configuration file `s3.mytestconf`:

```
gpcheckcloud -u ./test-data.csv "s3://s3-us-west-2.amazonaws.com/test1/abc config=s3.mytestconf"
```

A successful upload results in one or more files placed in the S3 bucket using the filename format `abc<segment_id><random>.data[.gz]`. See [About Reading and Writing S3 Data Files](#).

This example attempts to connect to an S3 bucket location with the `s3` protocol configuration file `s3.mytestconf`.

```
gpcheckcloud -c "s3://s3-us-west-2.amazonaws.com/test1/abc config=s3.mytestconf"
```

This example attempts to connect to an S3 bucket location using the default location for the `s3` protocol configuration file (`s3/s3.conf` in segment data directories):

```
gpcheckcloud -c "s3://s3-us-west-2.amazonaws.com/test1/abc"
```

Download all files from the S3 bucket location and send the output to `STDOUT`.

```
gpcheckcloud -d "s3://s3-us-west-2.amazonaws.com/test1/abc config=s3.mytestconf"
```

Using a Custom Protocol

A custom protocol allows you to connect Greenplum Database to a data source that cannot be accessed with the `file://`, `gpfdist://`, or `pxf://` protocols.

Creating a custom protocol requires that you implement a set of C functions with specified interfaces, declare the functions in Greenplum Database, and then use the `CREATE TRUSTED PROTOCOL` command to enable the protocol in the database.

See [Example Custom Data Access Protocol](#) for an example.

Parent topic: [Defining External Tables](#)

Handling Errors in External Table Data

By default, if external table data contains an error, the command fails and no data loads into the target database table.

Define the external table with single row error handling to enable loading correctly formatted rows and to isolate data errors in external table data. See [Handling Load Errors](#).

The `gpfdist` file server uses the `HTTP` protocol. External table queries that use `LIMIT` end the connection after retrieving the rows, causing an HTTP socket error. If you use `LIMIT` in queries of external tables that use the `gpfdist://` or `http://` protocols, ignore these errors – data is returned to the database as expected.

Parent topic: [Defining External Tables](#)

Creating and Using External Web Tables

External web tables allow Greenplum Database to treat dynamic data sources like regular database tables. Because web table data can change as a query runs, the data is not rescannable.

`CREATE EXTERNAL WEB TABLE` creates a web table definition. You can define command-based or URL-based external web tables. The definition forms are distinct: you cannot mix command-based and URL-based definitions.

Parent topic: [Defining External Tables](#)

Command-based External Web Tables

The output of a shell command or script defines command-based web table data. Specify the command in the `EXECUTE` clause of `CREATE EXTERNAL WEB TABLE`. The data is current as of the time the command runs. The `EXECUTE` clause runs the shell command or script on the specified master,

and/or segment host or hosts. The command or script must reside on the hosts corresponding to the host(s) defined in the `EXECUTE` clause.

By default, the command is run on segment hosts when active segments have output rows to process. For example, if each segment host runs four primary segment instances that have output rows to process, the command runs four times per segment host. You can optionally limit the number of segment instances that run the web table command. All segments included in the web table definition in the `ON` clause run the command in parallel.

The command that you specify in the external table definition is run from the database and cannot access environment variables from `.bashrc` or `.profile`. Set environment variables in the `EXECUTE` clause. For example:

```
=# CREATE EXTERNAL WEB TABLE output (output text)
  EXECUTE 'PATH=/home/gpadmin/programs; export PATH; myprogram.sh'
  FORMAT 'TEXT';
```

Scripts must be executable by the `gpadmin` user and reside in the same location on the master or segment hosts.

The following command defines a web table that runs a script. The script runs on each segment host where a segment has output rows to process.

```
=# CREATE EXTERNAL WEB TABLE log_output
  (linenum int, message text)
  EXECUTE '/var/load_scripts/get_log_data.sh' ON HOST
  FORMAT 'TEXT' (DELIMITER '|');
```

URL-based External Web Tables

A URL-based web table accesses data from a web server using the HTTP protocol. Web table data is dynamic; the data is not rescannable.

Specify the `LOCATION` of files on a web server using `http://`. The web data file(s) must reside on a web server that Greenplum segment hosts can access. The number of URLs specified corresponds to the number of segment instances that work in parallel to access the web table. For example, if you specify two external files to a Greenplum Database system with eight primary segments, two of the eight segments access the web table in parallel at query runtime.

The following sample command defines a web table that gets data from several URLs.

```
=# CREATE EXTERNAL WEB TABLE ext_expenses (name text,
  date date, amount float4, category text, description text)
  LOCATION (
    'http://intranet.company.com/expenses/sales/file.csv',
    'http://intranet.company.com/expenses/exec/file.csv',
    'http://intranet.company.com/expenses/finance/file.csv',
    'http://intranet.company.com/expenses/ops/file.csv',
    'http://intranet.company.com/expenses/marketing/file.csv',
    'http://intranet.company.com/expenses/eng/file.csv'
  )
  FORMAT 'CSV' ( HEADER );
```

Examples for Creating External Tables

These examples show how to define external data with different protocols. Each `CREATE EXTERNAL TABLE` command can contain only one protocol.

Note: When using IPv6, always enclose the numeric IP addresses in square brackets.

Start `gpfdist` before you create external tables with the `gpfdist` protocol. The following code starts the `gpfdist` file server program in the background on port `8081` serving files from directory `/var/data/staging`. The logs are saved in `/home/gpadmin/log`.

```
gpfdist -p 8081 -d /var/data/staging -l /home/gpadmin/log &
```

- [Example 2—Multiple gpfdist instances](#)
- [Example 3—Multiple gpfdists instances](#)
- [Example 4—Single gpfdist instance with error logging](#)
- [Example 5—TEXT Format on a Hadoop Distributed File Server](#)
- [Example 6—Multiple files in CSV format with header rows](#)
- [Example 7—Readable External Web Table with Script](#)
- [Example 8—Writable External Table with gpfdist](#)
- [Example 9—Writable External Web Table with Script](#)
- [Example 10—Readable and Writable External Tables with XML Transformations](#)

Parent topic: [Defining External Tables](#)

Example 1—Single gpfdist instance on single-NIC machine

Creates a readable external table, `ext_expenses`, using the `gpfdist` protocol. The files are formatted with a pipe (`|`) as the column delimiter.

```
=# CREATE EXTERNAL TABLE ext_expenses ( name text,
    date date, amount float4, category text, desc1 text )
    LOCATION ('gpfdist://etlhost-1:8081/*')
    FORMAT 'TEXT' (DELIMITER '|');
```

Parent topic: [Examples for Creating External Tables](#)

Example 2—Multiple gpfdist instances

Creates a readable external table, `ext_expenses`, using the `gpfdist` protocol from all files with the `txt` extension. The column delimiter is a pipe (`|`) and `NULL` (`' '`) is a space.

```
=# CREATE EXTERNAL TABLE ext_expenses ( name text,
    date date, amount float4, category text, desc1 text )
    LOCATION ('gpfdist://etlhost-1:8081/*.txt',
        'gpfdist://etlhost-2:8081/*.txt')
    FORMAT 'TEXT' ( DELIMITER '|' NULL ' ');
```

Parent topic: [Examples for Creating External Tables](#)

Example 3—Multiple gpfdists instances

Creates a readable external table, `ext_expenses`, from all files with the `txt` extension using the `gpfdists` protocol. The column delimiter is a pipe (`|`) and NULL (`' '`) is a space. For information about the location of security certificates, see [gpfdists:// Protocol](#).

1. Run `gpfdist` with the `--ssl` option.
2. Run the following command.

```
=# CREATE EXTERNAL TABLE ext_expenses ( name text,
    date date, amount float4, category text, desc1 text )
LOCATION ('gpfdists://etlhost-1:8081/*.txt',
        'gpfdists://etlhost-2:8082/*.txt')
FORMAT 'TEXT' ( DELIMITER '|' NULL ' ' ) ;
```

Parent topic: [Examples for Creating External Tables](#)

Example 4—Single gpfdist instance with error logging

Uses the `gpfdist` protocol to create a readable external table, `ext_expenses`, from all files with the `txt` extension. The column delimiter is a pipe (`|`) and NULL (`' '`) is a space.

Access to the external table is single row error isolation mode. Input data formatting errors are captured internally in Greenplum Database with a description of the error. See [Viewing Bad Rows in the Error Log](#) for information about investigating error rows. You can view the errors, fix the issues, and then reload the rejected data. If the error count on a segment is greater than five (the `SEGMENT REJECT LIMIT` value), the entire external table operation fails and no rows are processed.

```
=# CREATE EXTERNAL TABLE ext_expenses ( name text,
    date date, amount float4, category text, desc1 text )
LOCATION ('gpfdist://etlhost-1:8081/*.txt',
        'gpfdist://etlhost-2:8082/*.txt')
FORMAT 'TEXT' ( DELIMITER '|' NULL ' ' )
LOG ERRORS SEGMENT REJECT LIMIT 5;
```

To create the readable `ext_expenses` table from CSV-formatted text files:

```
=# CREATE EXTERNAL TABLE ext_expenses ( name text,
    date date, amount float4, category text, desc1 text )
LOCATION ('gpfdist://etlhost-1:8081/*.txt',
        'gpfdist://etlhost-2:8082/*.txt')
FORMAT 'CSV' ( DELIMITER ',' )
LOG ERRORS SEGMENT REJECT LIMIT 5;
```

Parent topic: [Examples for Creating External Tables](#)

Example 5—TEXT Format on a Hadoop Distributed File Server

Creates a readable external table, `ext_expenses`, using the `pxf` protocol. The column delimiter is a pipe (`|`).

```
=# CREATE EXTERNAL TABLE ext_expenses ( name text,
    date date, amount float4, category text, desc1 text )
LOCATION ('pxf://dir/data/filename.txt?PROFILE=hdfs:text')
FORMAT 'TEXT' (DELIMITER '|');
```

Refer to [Accessing External Data with PXF](#) for information about using the Greenplum Platform Extension Framework (PXF) to access data on a Hadoop Distributed File System.

Parent topic: [Examples for Creating External Tables](#)

Example 6—Multiple files in CSV format with header rows

Creates a readable external table, *ext_expenses*, using the *file* protocol. The files are *csv* format and have a header row.

```
=# CREATE EXTERNAL TABLE ext_expenses ( name text,
    date date, amount float4, category text, desc1 text )
    LOCATION ('file://filehost/data/international/*',
              'file://filehost/data/regional/*',
              'file://filehost/data/supplement/*.csv')
    FORMAT 'CSV' (HEADER);
```

Parent topic: [Examples for Creating External Tables](#)

Example 7—Readable External Web Table with Script

Creates a readable external web table that runs a script once per segment host:

```
=# CREATE EXTERNAL WEB TABLE log_output (linenum int,
    message text)
    EXECUTE '/var/load_scripts/get_log_data.sh' ON HOST
    FORMAT 'TEXT' (DELIMITER '|');
```

Parent topic: [Examples for Creating External Tables](#)

Example 8—Writable External Table with gpfdist

Creates a writable external table, *sales_out*, that uses *gpfdist* to write output data to the file *sales.out*. The column delimiter is a pipe (|) and NULL () is a space. The file will be created in the directory specified when you started the *gpfdist* file server.

```
=# CREATE WRITABLE EXTERNAL TABLE sales_out (LIKE sales)
    LOCATION ('gpfdist://etl1:8081/sales.out')
    FORMAT 'TEXT' ( DELIMITER '|' NULL ' ')
    DISTRIBUTED BY (txn_id);
```

Parent topic: [Examples for Creating External Tables](#)

Example 9—Writable External Web Table with Script

Creates a writable external web table, *campaign_out*, that pipes output data received by the segments to an executable script, *to_adreport_etl.sh*:

```
=# CREATE WRITABLE EXTERNAL WEB TABLE campaign_out
    (LIKE campaign)
    EXECUTE '/var/unload_scripts/to_adreport_etl.sh'
    FORMAT 'TEXT' (DELIMITER '|');
```

Parent topic: [Examples for Creating External Tables](#)

Example 10—Readable and Writable External Tables with XML Transformations

Greenplum Database can read and write XML data to and from external tables with gpfdist. For information about setting up an XML transform, see [Transforming External Data with gpfdist and gpload](#).

Parent topic: [Examples for Creating External Tables](#)

Accessing External Data with Foreign Tables

Greenplum Database implements portions of the SQL/MED specification, allowing you to access data that resides outside of Greenplum using regular SQL queries. Such data is referred to as *foreign* or external data.

You can access foreign data with help from a *foreign-data wrapper*. A foreign-data wrapper is a library that communicates with a remote data source. This library hides the source-specific connection and data access details.

The Greenplum Database distribution includes the [postgres_fdw](#) foreign data wrapper.

If none of the existing PostgreSQL or Greenplum Database foreign-data wrappers suit your needs, you can write your own as described in [Writing a Foreign Data Wrapper](#).

To access foreign data, you create a *foreign server* object, which defines how to connect to a particular remote data source according to the set of options used by its supporting foreign-data wrapper. Then you create one or more *foreign tables*, which define the structure of the remote data. A foreign table can be used in queries just like a normal table, but a foreign table has no storage in the Greenplum Database server. Whenever a foreign table is accessed, Greenplum Database asks the foreign-data wrapper to fetch data from, or update data in (if supported by the wrapper), the remote source.

Note: GPORCA does not support foreign tables, a query on a foreign table always falls back to the Postgres Planner.

Accessing remote data may require authenticating to the remote data source. This information can be provided by a *user mapping*, which can provide additional data such as a user name and password based on the current Greenplum Database role.

For additional information, refer to the [CREATE FOREIGN DATA WRAPPER](#), [CREATE SERVER](#), [CREATE USER MAPPING](#), and [CREATE FOREIGN TABLE](#) SQL reference pages.

Using Foreign-Data Wrappers with Greenplum Database

Most PostgreSQL foreign-data wrappers should work with Greenplum Database. However, PostgreSQL foreign-data wrappers connect only through the Greenplum Database master by default and do not access the Greenplum Database segment instances directly.

Greenplum Database adds an `mpp_execute` option to FDW-related SQL commands. If the foreign-data wrapper supports it, you can specify `mpp_execute '*value*'` in the `OPTIONS` clause when you create the FDW, server, or foreign table to identify the Greenplum host from which the foreign-data wrapper reads or writes data. Valid **value*s* are:

- `master` (the default)—Read or write data from the master host.
- `any`—Read data from either the master host or any one segment, depending on which path costs less.
- `all segments`—Read or write data from all segments. If a foreign-data wrapper supports this

value, for correct results it should have a policy that matches segments to data.

(A PostgreSQL foreign-data wrapper may work with the various `mpp_execute` option settings, but the results are not guaranteed to be correct. For example, a segment may not be able to connect to the foreign server, or segments may receive overlapping results resulting in duplicate rows.)

Note: GPORCA does not support foreign tables, a query on a foreign table always falls back to the Postgres Planner.

Parent topic: [Working with External Data](#)

Writing a Foreign Data Wrapper

This chapter outlines how to write a new foreign-data wrapper.

All operations on a foreign table are handled through its foreign-data wrapper (FDW), a library that consists of a set of functions that the core Greenplum Database server calls. The foreign-data wrapper is responsible for fetching data from the remote data store and returning it to the Greenplum Database executor. If updating foreign-data is supported, the wrapper must handle that, too.

The foreign-data wrappers included in the Greenplum Database open source github repository are good references when trying to write your own. You may want to examine the source code for the `file_fdw` and `postgres_fdw` modules in the `contrib/` directory. The [CREATE FOREIGN DATA WRAPPER](#) reference page also provides some useful details.

Note: The SQL standard specifies an interface for writing foreign-data wrappers. Greenplum Database does not implement that API, however, because the effort to accommodate it into Greenplum would be large, and the standard API hasn't yet gained wide adoption.

This topic includes the following sections:

- [Requirements](#)
- [Known Issues and Limitations](#)
- [Header Files](#)
- [Foreign Data Wrapper Functions](#)
- [Foreign Data Wrapper Callback Functions](#)
- [Foreign Data Wrapper Helper Functions](#)
- [Greenplum Database Considerations](#)
- [Building a Foreign Data Wrapper Extension with PGXS](#)
- [Deployment Considerations](#)

Parent topic: [Accessing External Data with Foreign Tables](#)

Requirements

When you develop with the Greenplum Database foreign-data wrapper API:

- You must develop your code on a system with the same hardware and software architecture as that of your Greenplum Database hosts.
- Your code must be written in a compiled language such as C, using the version-1 interface. For details on C language calling conventions and dynamic loading, refer to [C Language Functions](#) in the PostgreSQL documentation.
- Symbol names in your object files must not conflict with each other nor with symbols defined

in the Greenplum Database server. You must rename your functions or variables if you get error messages to this effect.

- Review the foreign table introduction described in [Accessing External Data with Foreign Tables](#).

Known Issues and Limitations

The Greenplum Database 6 foreign-data wrapper implementation has the following known issues and limitations:

- Greenplum Database supports all values of the `mpp_execute` option value for foreign table scans only. Greenplum supports parallel write operations only when `mpp_execute` is set to `'all_segments'`; Greenplum initiates write operations through the master for all other `mpp_execute` settings. See [Greenplum Database Considerations](#).

Header Files

The Greenplum Database header files that you may use when you develop a foreign-data wrapper are located in the `greenplum-db/src/include/` directory (when developing against the Greenplum Database open source github repository), or installed in the `$GPHOME/include/postgresql/server/` directory (when developing against a Greenplum installation):

- `foreign/fdwapi.h` - FDW API structures and callback function signatures
- `foreign/foreign.h` - foreign-data wrapper helper structs and functions
- `catalog/pg_foreign_table.h` - foreign table definition
- `catalog/pg_foreign_server.h` - foreign server definition

Your FDW code may also be dependent on header files and libraries required to access the remote data store.

Foreign Data Wrapper Functions

The developer of a foreign-data wrapper must implement an SQL-invokable *handler* function, and optionally an SQL-invokable *validator* function. Both functions must be written in a compiled language such as C, using the version-1 interface.

The *handler* function simply returns a struct of function pointers to callback functions that will be called by the Greenplum Database planner, executor, and various maintenance commands. The *handler* function must be registered with Greenplum Database as taking no arguments and returning the special pseudo-type `fdw_handler`. For example:

```
CREATE FUNCTION NEW_fdw_handler()
  RETURNS fdw_handler
  AS 'MODULE_PATHNAME'
  LANGUAGE C STRICT;
```

Most of the effort in writing a foreign-data wrapper is in implementing the callback functions. The FDW API callback functions, plain C functions that are not visible or callable at the SQL level, are described in [Foreign Data Wrapper Callback Functions](#).

The *validator* function is responsible for validating options provided in `CREATE` and `ALTER` commands for its foreign-data wrapper, as well as foreign servers, user mappings, and foreign tables using the wrapper. The *validator* function must be registered as taking two arguments, a text array containing the options to be validated, and an OID representing the type of object with which the options are associated. For example:

```
CREATE FUNCTION NEW_fdw_validator( text[], oid )
  RETURNS void
  AS 'MODULE_PATHNAME'
  LANGUAGE C STRICT;
```

The OID argument reflects the type of the system catalog that the object would be stored in, one of `ForeignDataWrapperRelationId`, `ForeignServerRelationId`, `UserMappingRelationId`, or `ForeignTableRelationId`. If no *validator* function is supplied by a foreign data wrapper, Greenplum Database does not check option validity at object creation time or object alteration time.

Foreign Data Wrapper Callback Functions

The foreign-data wrapper API defines callback functions that Greenplum Database invokes when scanning and updating foreign tables. The API also includes callbacks for performing explain and analyze operations on a foreign table.

The *handler* function of a foreign-data wrapper returns a `palloc`'d `FdwRoutine` struct containing pointers to callback functions described below. The `FdwRoutine` struct is located in the `foreign/fdwapi.h` header file, and is defined as follows:

```
/*
 * FdwRoutine is the struct returned by a foreign-data wrapper's handler
 * function. It provides pointers to the callback functions needed by the
 * planner and executor.
 *
 * More function pointers are likely to be added in the future. Therefore
 * it's recommended that the handler initialize the struct with
 * makeNode(FdwRoutine) so that all fields are set to NULL. This will
 * ensure that no fields are accidentally left undefined.
 */
typedef struct FdwRoutine
{
    NodeTag      type;

    /* Functions for scanning foreign tables */
    GetForeignRelSize_function GetForeignRelSize;
    GetForeignPaths_function GetForeignPaths;
    GetForeignPlan_function GetForeignPlan;
    BeginForeignScan_function BeginForeignScan;
    IterateForeignScan_function IterateForeignScan;
    ReScanForeignScan_function ReScanForeignScan;
    EndForeignScan_function EndForeignScan;

    /
    *
    * Remaining functions are optional. Set the pointer to NULL for any that
    * are not provided.
    * /

    /* Functions for updating foreign tables */
    AddForeignUpdateTargets_function AddForeignUpdateTargets;
    PlanForeignModify_function PlanForeignModify;
    BeginForeignModify_function BeginForeignModify;
    ExecForeignInsert_function ExecForeignInsert;
    ExecForeignUpdate_function ExecForeignUpdate;
    ExecForeignDelete_function ExecForeignDelete;
    EndForeignModify_function EndForeignModify;
    IsForeignRelUpdatable_function IsForeignRelUpdatable;

    /* Support functions for EXPLAIN */
    ExplainForeignScan_function ExplainForeignScan;
    ExplainForeignModify_function ExplainForeignModify;
```

```
/* Support functions for ANALYZE */
AnalyzeForeignTable_function AnalyzeForeignTable;
} FdwRoutine;
```

You must implement the scan-related functions in your foreign-data wrapper; implementing the other callback functions is optional.

Scan-related callback functions include:

Callback Signature	Description
<pre>void GetForeignRelSize (PlannerInfo *root, RelOptInfo *baserel, Oid foreigntableid)</pre>	Obtain relation size estimates for a foreign table. Called at the beginning of planning for a query on a foreign table.
<pre>void GetForeignPaths (PlannerInfo *root, RelOptInfo *baserel, Oid foreigntableid)</pre>	Create possible access paths for a scan on a foreign table. Called during query planning. Note: A Greenplum Database-compatible FDW must call <code>create_foreignscan_path()</code> in its <code>GetForeignPaths()</code> callback function.
<pre>ForeignScan * GetForeignPlan (PlannerInfo *root, RelOptInfo *baserel, Oid foreigntableid, ForeignPath *best_path, List *tlist, List *scan_clauses)</pre>	Create a <code>ForeignScan</code> plan node from the selected foreign access path. Called at the end of query planning.
<pre>void BeginForeignScan (ForeignScanState *node, int eflags)</pre>	Begin running a foreign scan. Called during executor startup.
<pre>TupleTableSlot * IterateForeignScan (ForeignScanState *node)</pre>	Fetch one row from the foreign source, returning it in a tuple table slot; return NULL if no more rows are available.
<pre>void ReScanForeignScan (ForeignScanState *node)</pre>	Restart the scan from the beginning.
<pre>void EndForeignScan (ForeignScanState *node)</pre>	End the scan and release resources.

If a foreign data wrapper supports writable foreign tables, it should provide the update-related callback functions that are required by the capabilities of the FDW. Update-related callback functions include:

Callback Signature	Description
<pre>void AddForeignUpdateTargets (Query *parsetree, RangeTblEntry *target_rte, Relation target_relation)</pre>	Add additional information in the foreign table that will be retrieved during an update or delete operation to identify the exact row on which to operate.

Callback Signature	Description
<pre>List * PlanForeignModify (P lannerInfo *root, ModifyTab le *plan, Index resultRelat ion, int subplan_index)</pre>	Perform additional planning actions required for an insert, update, or delete operation on a foreign table, and return the information generated.
<pre>void BeginForeignModify (Mo difyTableState *mtstate, Re sultRelInfo *rinfo, List *f dw_private, int subplan_ind ex, int eflags)</pre>	Begin executing a modify operation on a foreign table. Called during executor startup.
<pre>TupleTableSlot * ExecForeig nInsert (EState *estate, Re sultRelInfo *rinfo, TupleTa bleSlot *slot, TupleTableSl ot *planSlot)</pre>	Insert a single tuple into the foreign table. Return a slot containing the data that was actually inserted, or NULL if no row was inserted.
<pre>TupleTableSlot * ExecForeig nUpdate (EState *estate, Re sultRelInfo *rinfo, TupleTa bleSlot *slot, TupleTableSl ot *planSlot)</pre>	Update a single tuple in the foreign table. Return a slot containing the row as it was actually updated, or NULL if no row was updated.
<pre>TupleTableSlot * ExecForeig nDelete (EState *estate, Re sultRelInfo *rinfo, TupleTa bleSlot *slot, TupleTableSl ot *planSlot)</pre>	Delete a single tuple from the foreign table. Return a slot containing the row that was deleted, or NULL if no row was deleted.
<pre>void EndForeignModify (ES tate *estate, ResultRelInfo * rinfo)</pre>	End the update and release resources.
<pre>int IsForeignRelUpdatable (Relation rel)</pre>	Report the update operations supported by the specified foreign table.

Refer to [Foreign Data Wrapper Callback Routines](#) in the PostgreSQL documentation for detailed information about the inputs and outputs of the FDW callback functions.

Foreign Data Wrapper Helper Functions

The FDW API exports several helper functions from the Greenplum Database core server so that authors of foreign-data wrappers have easy access to attributes of FDW-related objects, such as options provided when the user creates or alters the foreign-data wrapper, server, or foreign table. To use these helper functions, you must include `foreign.h` header file in your source file:

```
#include "foreign/foreign.h"
```

The FDW API includes the helper functions listed in the table below. Refer to [Foreign Data Wrapper Helper Functions](#) in the PostgreSQL documentation for more information about these functions.

Helper Signature	Description
<pre>ForeignDataWrapper * GetForeignDataWrapper(Oid fdwid);</pre>	Returns the <code>ForeignDataWrapper</code> object for the foreign-data wrapper with the given OID.
<pre>ForeignDataWrapper * GetForeignDataWrapperByName(const char *name, bool missing_ok);</pre>	Returns the <code>ForeignDataWrapper</code> object for the foreign-data wrapper with the given name.
<pre>ForeignServer * GetForeignServer(Oid serverid);</pre>	Returns the <code>ForeignServer</code> object for the foreign server with the given OID.
<pre>ForeignServer * GetForeignServerByName(const char *name, bool missing_ok);</pre>	Returns the <code>ForeignServer</code> object for the foreign server with the given name.
<pre>UserMapping * GetUserMapping(Oid userid, Oid serverid);</pre>	Returns the <code>UserMapping</code> object for the user mapping of the given role on the given server.
<pre>ForeignTable * GetForeignTable(Oid relid);</pre>	Returns the <code>ForeignTable</code> object for the foreign table with the given OID.
<pre>List * GetForeignColumnOptions(Oid relid, AttrNumber attrnum);</pre>	Returns the per-column FDW options for the column with the given foreign table OID and attribute number.

Greenplum Database Considerations

A Greenplum Database user can specify the `mpp_execute` option when they create or alter a foreign table, foreign server, or foreign data wrapper. A Greenplum Database-compatible foreign-data wrapper examines the `mpp_execute` option value and uses it to determine where to request or send data - from the `master` (the default), `any` (master or any one segment), or `all segments` (parallel read/write).

Greenplum Database supports all `mpp_execute` settings for a scan.

Greenplum Database supports parallel write when `mpp_execute 'all segments'` is set. For all other `mpp_execute` settings, Greenplum Database executes write/update operations initiated by a foreign data wrapper on the Greenplum master node.

Note: When `mpp_execute 'all segments'` is set, Greenplum Database creates the foreign table with a random partition policy. This enables a foreign data wrapper to write to a foreign table from all segments.

The following scan code snippet probes the `mpp_execute` value associated with a foreign table:

```
ForeignTable *table = GetForeignTable(foreigntableid);
if (table->exec_location == FTEXECLOCATION_ALL_SEGMENTS)
{
```

```

    ...
}
else if (table->exec_location == FTEXECLOCATION_ANY)
{
    ...
}
else if (table->exec_location == FTEXECLOCATION_MASTER)
{
    ...
}

```

If the foreign table was not created with an `mpp_execute` option setting, the `mpp_execute` setting of the foreign server, and then the foreign data wrapper, is probed and used. If none of the foreign-data-related objects has an `mpp_execute` setting, the default setting is `master`.

If a foreign-data wrapper supports `mpp_execute 'all'`, it will implement a policy that matches Greenplum segments to data. So as not to duplicate data retrieved from the remote, the FDW on each segment must be able to establish which portion of the data is their responsibility. An FDW may use the segment identifier and the number of segments to help make this determination. The following code snippet demonstrates how a foreign-data wrapper may retrieve the segment number and total number of segments:

```

int segmentNumber = GpIdentity.segindex;
int totalNumberOfSegments = getgpsegmentCount();

```

Building a Foreign Data Wrapper Extension with PGXS

You compile the foreign-data wrapper functions that you write with the FDW API into one or more shared libraries that the Greenplum Database server loads on demand.

You can use the PostgreSQL build extension infrastructure (PGXS) to build the source code for your foreign-data wrapper against a Greenplum Database installation. This framework automates common build rules for simple modules. If you have a more complicated use case, you will need to write your own build system.

To use the PGXS infrastructure to generate a shared library for your FDW, create a simple `Makefile` that sets PGXS-specific variables.

Note: Refer to [Extension Building Infrastructure](#) in the PostgreSQL documentation for information about the `Makefile` variables supported by PGXS.

For example, the following `Makefile` generates a shared library in the current working directory named `base_fdw.so` from two C source files, `base_fdw_1.c` and `base_fdw_2.c`:

```

MODULE_big = base_fdw
OBJS = base_fdw_1.o base_fdw_2.o

PG_CONFIG = pg_config
PGXS := $(shell $(PG_CONFIG) --pgxs)

PG_CPPFLAGS = -I$(shell $(PG_CONFIG) --includedir)
SHLIB_LINK = -L$(shell $(PG_CONFIG) --libdir)
include $(PGXS)

```

A description of the directives used in this `Makefile` follows:

- `MODULE_big` - identifies the base name of the shared library generated by the `Makefile`
- `PG_CPPFLAGS` - adds the Greenplum Database installation `include/` directory to the compiler

header file search path

- `SHLIB_LINK` adds the Greenplum Database installation library directory (`$GPHOME/lib/`) to the linker search path
- The `PG_CONFIG` and `PGXS` variable settings and the `include` statement are required and typically reside in the last three lines of the `Makefile`.

To package the foreign-data wrapper as a Greenplum Database extension, you create script (`newfdw--version.sql`) and control (`newfdw.control`) files that register the FDW *handler* and *validator* functions, create the foreign data wrapper, and identify the characteristics of the FDW shared library file.

Note: [Packaging Related Objects into an Extension](#) in the PostgreSQL documentation describes how to package an extension.

Example foreign-data wrapper extension script file named `base_fdw--1.0.sql`:

```
CREATE FUNCTION base_fdw_handler()
  RETURNS fdw_handler
  AS 'MODULE_PATHNAME'
LANGUAGE C STRICT;

CREATE FUNCTION base_fdw_validator(text[], oid)
  RETURNS void
  AS 'MODULE_PATHNAME'
LANGUAGE C STRICT;

CREATE FOREIGN DATA WRAPPER base_fdw
  HANDLER base_fdw_handler
  VALIDATOR base_fdw_validator;
```

Example FDW control file named `base_fdw.control`:

```
# base_fdw FDW extension
comment = 'base foreign-data wrapper implementation; does not do much'
default_version = '1.0'
module_pathname = '$libdir/base_fdw'
relocatable = true
```

When you add the following directives to the `Makefile`, you identify the FDW extension control file base name (`EXTENSION`) and SQL script (`DATA`):

```
EXTENSION = base_fdw
DATA = base_fdw--1.0.sql
```

Running `make install` with these directives in the `Makefile` copies the shared library and FDW SQL and control files into the specified or default locations in your Greenplum Database installation (`$GPHOME`).

Deployment Considerations

You must package the FDW shared library and extension files in a form suitable for deployment in a Greenplum Database cluster. When you construct and deploy the package, take into consideration the following:

- The FDW shared library must be installed to the same file system location on the master host and on every segment host in the Greenplum Database cluster. You specify this location in the `.control` file. This location is typically the `$GPHOME/lib/postgresql/` directory.
- The FDW `.sql` and `.control` files must be installed to the

`$GPHOME/share/postgresql/extension/` directory on the master host and on every segment host in the Greenplum Database cluster.

- The `gpadmin` user must have permission to traverse the complete file system path to the FDW shared library file and extension files.

Using the Greenplum Parallel File Server (gpfdist)

The `gpfdist` protocol is used in a `CREATE EXTERNAL TABLE` SQL command to access external data served by the Greenplum Database `gpfdist` file server utility. When external data is served by `gpfdist`, all segments in the Greenplum Database system can read or write external table data in parallel.

This topic describes the setup and management tasks for using `gpfdist` with external tables.

- [About gpfdist and External Tables](#)
- [About gpfdist Setup and Performance](#)
- [Controlling Segment Parallelism](#)
- [Installing gpfdist](#)
- [Starting and Stopping gpfdist](#)
- [Troubleshooting gpfdist](#)

Parent topic: [Working with External Data](#)

About gpfdist and External Tables

The `gpfdist` file server utility is located in the `$GPHOME/bin` directory on your Greenplum Database master host and on each segment host. When you start a `gpfdist` instance you specify a listen port and the path to a directory containing files to read or where files are to be written. For example, this command runs `gpfdist` in the background, listening on port 8801, and serving files in the `/home/gpadmin/external_files` directory:

```
$ gpfdist -p 8801 -d /home/gpadmin/external_files &
```

The `CREATE EXTERNAL TABLE` command `LOCATION` clause connects an external table definition to one or more `gpfdist` instances. If the external table is readable, the `gpfdist` server reads data records from files from in specified directory, packs them into a block, and sends the block in a response to a Greenplum Database segment's request. The segments unpack rows they receive and distribute them according to the external table's distribution policy. If the external table is a writable table, segments send blocks of rows in a request to `gpfdist` and `gpfdist` writes them to the external file.

External data files can contain rows in CSV format or any delimited text format supported by the `FORMAT` clause of the `CREATE EXTERNAL TABLE` command. In addition, `gpfdist` can be configured with a YAML-formatted file to transform external data files between a supported text format and another format, for example XML or JSON. See <ref> for an example that shows how to use `gpfdist` to read external XML files into a Greenplum Database readable external table.

For readable external tables, `gpfdist` uncompresses `gzip` (`.gz`) and `bzip2` (`.bz2`) files automatically. You can use the wildcard character (*) or other C-style pattern matching to denote multiple files to read. External files are assumed to be relative to the directory specified when you started the `gpfdist` instance.

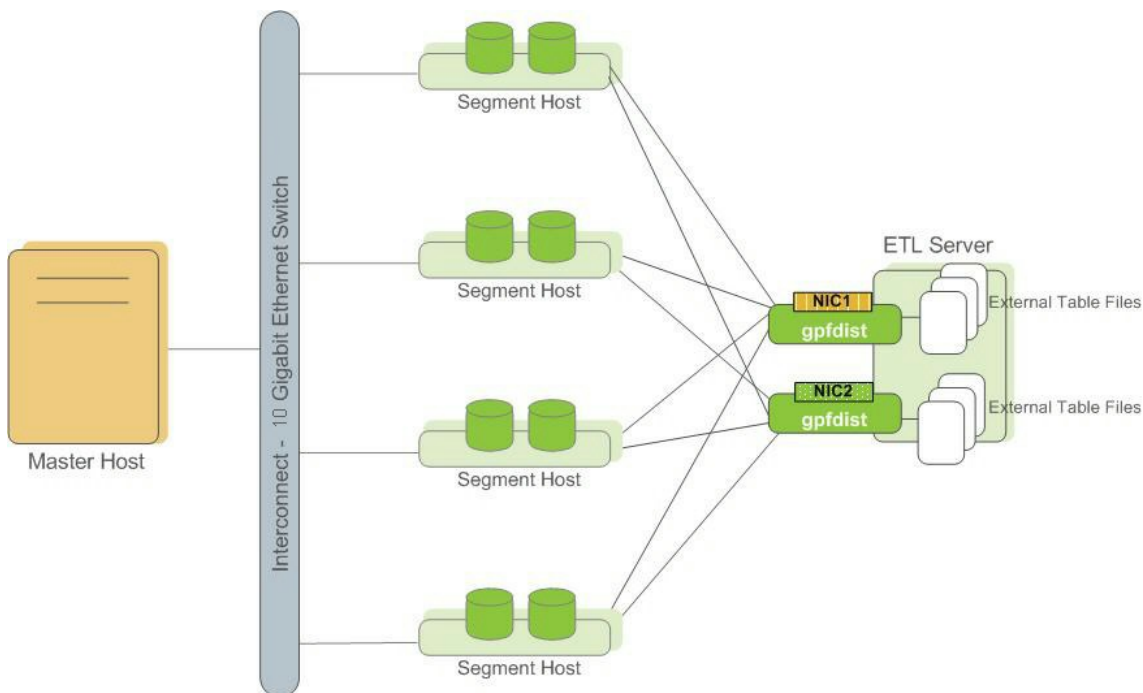

About gpfdist Setup and Performance

You can run `gpfdist` instances on multiple hosts and you can run multiple `gpfdist` instances on each host. This allows you to deploy `gpfdist` servers strategically so that you can attain fast data load and unload rates by utilizing all of the available network bandwidth and Greenplum Database's parallelism.

- Allow network traffic to use all ETL host network interfaces simultaneously. Run one instance of `gpfdist` for each interface on the ETL host, then declare the host name of each NIC in the `LOCATION` clause of your external table definition (see [Examples for Creating External Tables](#)).

- Divide external table data equally among multiple `gpfdist` instances on the ETL host. For example, on an ETL system with two NICs, run two `gpfdist` instances (one on each NIC) to optimize data load performance and divide the external table data files evenly between the two `gpfdist` servers.

Note: Use pipes (|) to separate formatted text when you submit files to `gpfdist`. Greenplum Database encloses comma-separated text strings in single or double quotes. `gpfdist` has to remove the quotes

to parse the strings. Using pipes to separate formatted text avoids the extra step and improves performance.

Controlling Segment Parallelism

The `gp_external_max_segs` server configuration parameter controls the number of segment instances that can access a single gpfdist instance simultaneously. 64 is the default. You can set the number of segments such that some segments process external data files and some perform other database processing. Set this parameter in the `postgresql.conf` file of your master instance.

Installing gpfdist

gpfdist is installed in `$GPHOME/bin` of your Greenplum Database master host installation. Run gpfdist on a machine other than the Greenplum Database master or standby master, such as on a machine devoted to ETL processing. Running gpfdist on the master or standby master can have a performance impact on query execution. To install gpfdist on your ETL server, get it from the *Greenplum Clients* package and follow its installation instructions.

Starting and Stopping gpfdist

You can start gpfdist in your current directory location or in any directory that you specify. The default port is 8080.

From your current directory, type:

```
gpfdist &
```

From a different directory, specify the directory from which to serve files, and optionally, the HTTP port to run on.

To start gpfdist in the background and log output messages and errors to a log file:

```
$ gpfdist -d /var/load_files -p 8081 -l /home/`gpadmin`/log &
```

For multiple gpfdist instances on the same ETL host (see [Figure 1](#)), use a different base directory and port for each instance. For example:

```
$ gpfdist -d /var/load_files1 -p 8081 -l /home/`gpadmin`/log1 &
$ gpfdist -d /var/load_files2 -p 8082 -l /home/`gpadmin`/log2 &
```

To stop gpfdist when it is running in the background:

First find its process id:

```
$ ps -ef | grep gpfdist
```

Then stop the process, for example (where 3456 is the process ID in this example):

```
$ kill 3456
```

Troubleshooting gpfdist

The segments access gpfdist at runtime. Ensure that the Greenplum segment hosts have network

access to gpfdist. gpfdist is a web server: test connectivity by running the following command from each host in the Greenplum array (segments and master):

```
$ wget http://<gpfdist_hostname>:<port>/<filename>
```

The `CREATE EXTERNAL TABLE` definition must have the correct host name, port, and file names for gpfdist. Specify file names and paths relative to the directory from which gpfdist serves files (the directory path specified when gpfdist started). See [Examples for Creating External Tables](#).

If you start gpfdist on your system and IPv6 networking is disabled, gpfdist displays this warning message when testing for an IPv6 port.

```
[WRN gpfdist.c:2050] Creating the socket failed
```

If the corresponding IPv4 port is available, gpfdist uses that port and the warning for IPv6 port can be ignored. To see information about the ports that gpfdist tests, use the `-v` option.

For information about IPv6 and IPv4 networking, see your operating system documentation.

When reading or writing data with the `gpfdist` or `gfdists` protocol, the `gpfdist` utility rejects HTTP requests that do not include `X-GP-PROTO` in the request header. If `X-GP-PROTO` is not detected in the header request `gpfdist` returns a 400 error in the status line of the HTTP response header: `400 invalid request (no gp-PROTO)`.

Greenplum Database includes `X-GP-PROTO` in the HTTP request header to indicate that the request is from Greenplum Database.

If the `gpfdist` utility hangs with no read or write activity occurring, you can generate a core dump the next time a hang occurs to help debug the issue. Set the environment variable `GPFDIST_WATCHDOG_TIMER` to the number of seconds of no activity to wait before `gpfdist` is forced to exit. When the environment variable is set and `gpfdist` hangs, the utility stops after the specified number of seconds, creates a core dump, and sends relevant information to the log file.

This example sets the environment variable on a Linux system so that `gpfdist` exits after 300 seconds (5 minutes) of no activity.

```
export GPFDIST_WATCHDOG_TIMER=300
```

Loading and Unloading Data

The topics in this section describe methods for loading and writing data into and out of a Greenplum Database, and how to format data files.

Greenplum Database supports high-performance parallel data loading and unloading, and for smaller amounts of data, single file, non-parallel data import and export.

Greenplum Database can read from and write to several types of external data sources, including text files, Hadoop file systems, Amazon S3, and web servers.

- The `COPY` SQL command transfers data between an external text file on the master host, or multiple text files on segment hosts, and a Greenplum Database table.
- Readable external tables allow you to query data outside of the database directly and in parallel using SQL commands such as `SELECT`, `JOIN`, or `SORT EXTERNAL TABLE DATA`, and you can create views for external tables. External tables are often used to load external data into a regular database table using a command such as `CREATE TABLE table AS SELECT * FROM ext_table`.

- External web tables provide access to dynamic data. They can be backed with data from URLs accessed using the HTTP protocol or by the output of an OS script running on one or more segments.
- The `gpfdist` utility is the Greenplum Database parallel file distribution program. It is an HTTP server that is used with external tables to allow Greenplum Database segments to load external data in parallel, from multiple file systems. You can run multiple instances of `gpfdist` on different hosts and network interfaces and access them in parallel.
- The `gpload` utility automates the steps of a load task using `gpfdist` and a YAML-formatted control file.
- You can create readable and writable external tables with the Greenplum Platform Extension Framework (PXF), and use these tables to load data into, or offload data from, Greenplum Database. For information about using PXF, refer to [Accessing External Data with PXF](#).
- The Greenplum Streaming Server is an ETL tool and API that you can use to load data into Greenplum Database. For information about using this tool, refer to the [Greenplum Streaming Server](#) documentation.
- The Greenplum Streaming Server Kafka integration provides high-speed, parallel data transfer from Kafka to Greenplum Database. For more information, refer to the [Greenplum Streaming Server](#) documentation.
- The Greenplum Connector for Apache Spark provides high speed, parallel data transfer between Tanzu Greenplum and Apache Spark. For information about using the Connector, refer to the documentation at <https://docs.vmware.com/en/VMware-Tanzu-Greenplum-Connector-for-Apache-Spark/index.html>.
- The Greenplum Connector for Informatica provides high speed data transfer from an Informatica PowerCenter cluster to a Tanzu Greenplum cluster for batch and streaming ETL operations. For information about using the Connector, refer to the documentation at <https://docs.vmware.com/en/VMware-Tanzu-Greenplum-Connector-for-Informatica/index.html>.
- The Greenplum Connector for Apache NiFi enables you to create data ingestion pipelines that load record-oriented data into Tanzu Greenplum. For information about using this Connector, refer to the [Connector documentation](#).

The method you choose to load data depends on the characteristics of the source data—its location, size, format, and any transformations required.

In the simplest case, the `COPY` SQL command loads data into a table from a text file that is accessible to the Greenplum Database master instance. This requires no setup and provides good performance for smaller amounts of data. With the `COPY` command, the data copied into or out of the database passes between a single file on the master host and the database. This limits the total size of the dataset to the capacity of the file system where the external file resides and limits the data transfer to a single file write stream.

More efficient data loading options for large datasets take advantage of the Greenplum Database MPP architecture, using the Greenplum Database segments to load data in parallel. These methods allow data to load simultaneously from multiple file systems, through multiple NICs, on multiple hosts, achieving very high data transfer rates. External tables allow you to access external files from within the database as if they are regular database tables. When used with `gpfdist`, the Greenplum Database parallel file distribution program, external tables provide full parallelism by using the resources of all Greenplum Database segments to load or unload data.

Greenplum Database leverages the parallel architecture of the Hadoop Distributed File System to access files on that system.

Greenplum Client and Loader Tools Package

This documentation describes the contents of, and how to install, configure, and use the Greenplum client and loader utility programs for UNIX and Windows systems.

Key topics in the documentation include:

- [About the Tools Package](#)
- [Installing the Client and Loader Tools Package](#)
- [Configuring Greenplum Database for Remote Client Access](#)
- [Configuring a Client System for Kerberos Authentication](#)
- [Using the Client and Loader Tools](#)
- [Client and Loader Utility Reference](#)

About the Tools Package

The Greenplum client and loader tools package provides utility programs that you can install and run on a host outside of your Greenplum Database cluster. The package is available on [VMware Tanzu Network](#).

Greenplum utility programs provided in the client and loader tools package include:

Program	Description
createdb	Create a Greenplum database. Requires superuser or specially-granted Greenplum Database privileges.
createuser	Register a Greenplum user. Requires superuser or specially-granted Greenplum Database privileges.
dropdb	Drop a Greenplum database. Requires superuser or specially-granted Greenplum Database privileges.
dropuser	Remove a Greenplum user. Requires superuser or specially-granted Greenplum Database privileges.
gpfdist	Greenplum parallel file distribution program.
gpkafka	Load Kafka data into Greenplum Database using the VMware Tanzu Greenplum Streaming Server.
gpload	Greenplum data loading utility.
gpss	Start a VMware Tanzu Greenplum Streaming Server instance.
gpsscli	VMware Tanzu Greenplum Streaming Server client program.
pg_dump	Dump the contents of a Greenplum database to a file.
pg_dumpall	Dump the contents of all Greenplum databases to a file.
psql	PostgreSQL interactive command-line interface for Greenplum Database.

Note: The Windows Greenplum client and loader tools package provides additional libraries and programs, including `kinit`, `kdestroy`, and `klist`. The Windows package does **not** include the `gpkafka`, `gpsscli`, and `gpss` programs.

The `gpload` program provided in the Windows package is backwards-compatible with Greenplum Database 5.

Installing the Client and Loader Tools Package

This section provides the information required to download and install the tools on your client

machine.

Supported Platforms

You can select a client and loader tools package to install on any of the following systems:

- CentOS 6.x
- CentOS 7.x
- CentOS 8.x
- SUSE Linux Enterprise Server x86_64 12 (SLES 12)
- Ubuntu 18.04
- Windows 7 SP1 or later
- Windows Server 2012 or later

Installation Procedure

Perform the following procedure to install the Greenplum Database client tools on your system:

1. Download the appropriate installer package for your platform from [VMware Tanzu Network](#). For example, to download the CentOS 7.x package, click to select the **Greenplum Clients->Greenplum Clients for RHEL 7** package.

The naming format of a UNIX package file is `greenplum-db-clients-<version>-<platform>.<filetype>`.

The naming format of a Windows package file is `greenplum-db-clients-<version>-x86_64.msi`.
2. *Note the file system location of the downloaded file.*
3. Follow the instructions in [Verifying the Greenplum Database Software Download](#) to verify the integrity of the **Greenplum Clients** software.
4. If you are installing the package on a system running the CentOS, Ubuntu, or SLES operating systems, follow the instructions in [Running the UNIX Tools Installer](#).
5. If you are installing the package on a Windows system, follow the instructions in [Running the Windows Tools Installer](#).

About Your Installation

Your Greenplum Database client and loader tools installation includes the following files and directories:

File/Directory	Description
bin/	client and loader tool utility programs
ext/ (UNIX only)	Python runtime components required by the UNIX utilities
greenplum_clients_path.<ext>	environment set up script or batch file; the file extension (<ext>) is operating system- or shell-dependent
lib/	libraries required by the utilities
LICENSE (UNIX)	license notices for the utilities
'Pivotal License' (Windows)	

File/Directory	Description
NOTICE (UNIX)	attribution notices for the utilities
'Thirdparty Notice' (Windows)	
'GPDB Clients Version' (Windows only)	file identifying the Windows package version

Running the UNIX Tools Installer

This section describes the client and loader tool package installation procedure for CentOS, Ubuntu, and SLES systems.

Prerequisites

You must have operating system superuser privileges to install the tools package.

Note: Installing the client tools package automatically installs dependent packages not already installed on the system.

Procedure

Perform the following procedure to install the client and loader tools package on a CentOS or Ubuntu system.

1. Locate the installer file that you downloaded from VMware Tanzu Network. The naming format of the file is `greenplum-db-clients-<version>-<platform>.<file_type>`.
2. Install the package using your package management utility. You must be the superuser or have `sudo` access to install packages. For example:

- To install the tools on a host running CentOS 7.x:

```
root@clientsys$ yum install greenplum-db-clients-6.14.0-rhel7-x86_64.rpm
```

- To install the tools on a host running SLES 12:

```
root@clientsys$ zypper install greenplum-db-clients-6.14.0-sles12-x86_64.rpm
```

- To install the tools on a host running Ubuntu 18.04:

```
root@clientsys$ apt install greenplum-db-clients-6.14.0-ubuntu18.04-amd64.deb
```

The client tools are installed into the `/usr/local/greenplum-db-clients-<version>/` directory. The installation process creates a symbolic link from `/usr/local/greenplum-db-clients` to the install directory.

Running the Windows Tools Installer

This section describes the client and loader tool package installation procedure for Windows systems.

Prerequisites

You must have operating system superuser privileges to install the tools package.

Procedure

Perform the following procedure to install the client and loader tools package on a Windows system.

1. The Greenplum Database client and loader tools for Windows require a recent Microsoft Visual C++ Redistributable for Visual Studio 2017. You must download and install an update as described in the Microsoft support article titled [The latest supported Visual C++ downloads](#).
2. If you plan to use the `gpload.bat` Greenplum Database loader program for Windows:
 1. Ensure that a 64-bit version of Python 2.7 is installed on your system. Refer to [Python 2.7.16](#) or the source of your choice for Python download and install instructions.
 2. You must also add the Python directory to your `PATH`.
3. Locate the installer `.msi` file that you downloaded from VMware Tanzu Network in a previous step. The naming format of the Windows installer file is `greenplum-db-clients-<version>-x86_64.msi`.
4. Double-click on the `greenplum-db-clients-<version>-x86_64.msi` file to launch the installer.
5. Click **Next** on the **Greenplum Clients Setup Wizard** Welcome screen.
6. Read through the **End-User License Agreement**, and click **I Agree** to accept the terms of the license.
7. By default, the Greenplum Database client and load tools are installed into the following directory:

```
C:\Program Files\Greenplum\greenplum-clients\
```

Click **Browse** on the **Custom Setup** screen to choose another location.

8. Click **Next** when you have chosen the desired install path.
9. Click **Install** to begin the installation.
10. Click **Finish** to exit the Windows client and load tools installer.

Configuring Greenplum Database for Remote Client Access

Greenplum Database does not, by default, accept remote client connections. You must configure Greenplum Database to accept remote connections. This configuration involves identifying each client host system and Greenplum Database role combination to which you want to provide access, and then adding access rules to the `pg_hba.conf` client authentication configuration file. Refer to [Allowing Connections to Greenplum Database](#) for detailed information about configuring remote client access.

Note: Ensure that the authentication method that you configure for a role is supported by the Greenplum Database client program(s) that the role will execute.

In addition to configuring remote client access, you must also ensure that each Greenplum role that you are allowing to connect to the master exists in the cluster, and that the role has the correct privileges to database objects. [Managing Roles and Privileges](#) describes configuring Greenplum Database users and granting privileges.

Configuring a Client System for Kerberos Authentication

If your Greenplum Database cluster employs Kerberos user authentication, your client host must be configured to access Greenplum with Kerberos. Refer to the following documentation for instructions on configuring Kerberos authentication on a client system:

- UNIX client hosts - [Configuring Kerberos for Linux Clients](#)
- Windows client hosts - [Configuring Kerberos for Windows Clients](#)

If your Greenplum Database cluster is not using Kerberos for user authentication, then this configuration is not required.

Using the Client and Loader Tools

This section provides the information required to set up your Greenplum Database client runtime environment and use the client and loader tools. Topics include:

- [Prerequisites](#)
- [Setting Up Your Greenplum Database Clients Runtime Environment](#)
- [Running the Client and Loader Programs](#)
- [Greenplum Database Documentation References](#)
- [Windows Considerations](#)

Prerequisites

Before using the client and loader tools, ensure that:

- Your Greenplum Database cluster is up and running, and you can identify the master host and port number, if the master server process is not running on the default port (5432).
- Network connectivity exists between the client machine and the Greenplum Database master host. If you are using the `gpfdist`, `gpload`, or `gpss` utility programs, network connectivity must also exist between the client machine and all Greenplum Database segment hosts.
- You have installed and configured the tools and any dependent components on your client machine as described in [Installing the Client and Loader Tools Package](#).
- You can identify your Greenplum Database user/role name and password.
- You have created or can identify the Greenplum database, schema, and table objects of interest.

Contact your Greenplum Database administrator if you do not meet the prerequisites mentioned above.

Setting Up Your Greenplum Database Clients Runtime Environment

The client and loader tools package installs a file that you use to set up your Greenplum Database client and loader environment. This script or batch file, named `greenplum_clients_path.<ext>` (where the file extension `<ext>` is operating system- or shell-dependent) is located in the client tools root install directory.

`greenplum_clients_path.<ext>:`

- Sets the runtime environment variables that are required by the utilities.

- Sets the `$GPHOME_CLIENTS` environment variable to point to the root directory of the client and loader tools installation.
- Updates your `$PATH` to include `$GPHOME_CLIENTS/bin`.

You must source or run `greenplum_clients_path.<ext>` before you invoke any of the client or loader programs. For example, run the following command on a CentOS or Ubuntu system to source the file:

```
user@clientsys$ . /usr/local/greenplum-db-clients/greenplum_clients_path.sh
```

Note: Consider adding the command to source or run `greenplum_clients_path.<ext>` to your shell or equivalent initialization file.

Running the Client and Loader Programs

Clients always connect to Greenplum Database through the master host. In order for the client or loader program to establish a connection to the master host, you provide the following connection parameters to the program via options, a configuration file, or environment variables:

Connection Parameter	Description	Environment Variable Name
Database name	The name of the database to which you want to connect.	PGDATABASE
Host name	The host name of the Greenplum Database master. The default host is the local host.	PGHOST
Port	The port number on which the Greenplum Database master server instance is running. The default port is 5432.	PGPORT
User name	The Greenplum Database user (role) name. This name may not necessarily be the same as your operating system user name.	PGUSER

Note: Refer to the [Client and Loader Utility Reference](#) for the client or load command to determine tool support for specifying these connection parameters via options, configuration property names, and/or environment variables.

Greenplum Database Documentation References

The following Greenplum Database documentation topics provide additional information about using selected client and loader tools:

- [gpfdist](#) - [Using the Greenplum Parallel File Server \(gpfdist\)](#)
- [gpkafka](#) - [Loading from a Kafka data source](#) in the VMware Tanzu Greenplum Streaming Server documentation
- [gpload](#) - [Loading Data with gpload](#)
- [gpss](#), [gpsscli](#) - [VMware Tanzu Greenplum Streaming Server](#) documentation
- [psql](#) - [Connecting with psql](#)

Windows Considerations

Keep in mind these additional considerations when you use the Windows client and load programs:

- You must ensure that any ports that you identify in a `gpload` control file are unblocked by any firewall running on the Windows client system.

- By default, `gpload.bat` attempts to create a directory named `gpAdminLog` in the directory from which you execute the program, and writes its log files there. This operation will fail if you do not have write permission to the current working directory. Run `gpload.bat` with the `-l` option to direct the log output to a different location.
- Review the Greenplum [Character Encoding](#) and [Formatting Rows](#) documentation for Windows-specific considerations for the tools.

Client and Loader Utility Reference

The Greenplum client and loader tools package includes the following utilities:

- `createdb`
- `createuser`
- `dropdb`
- `dropuser`
- `gpfdist`
- `gpkafka`
- `gpload`
- `gpss`
- `gpsscli`
- `pg_dump`
- `pg_dumpall`
- `psql`

Note: The Windows Greenplum client and loader tools package provides additional libraries and programs, including `kinit`, `kdestroy`, and `klist`. The Windows package does **not** include the `gpkafka`, `gpsscli`, and `gpss` programs.

The `gpload` program provided in the Windows package is backwards-compatible with Greenplum Database 5.

createdb

Creates a new database.

Synopsis

```
createdb [<connection-option> ...] [<option> ...] [<dbname> ['<description>']]

createdb -? | --help

createdb -V | --version
```

Description

`createdb` creates a new database in a Greenplum Database system.

Normally, the database user who runs this command becomes the owner of the new database. However, a different owner can be specified via the `-o` option, if the executing user has appropriate privileges.

`createdb` is a wrapper around the SQL command `CREATE DATABASE`.

Options

dbname

The name of the database to be created. The name must be unique among all other databases in the Greenplum system. If not specified, reads from the environment variable `PGDATABASE`, then `PGUSER` or defaults to the current system user.

description

A comment to be associated with the newly created database. Descriptions containing white space must be enclosed in quotes.

-D tablespace | --tablespace=tablespace

Specifies the default tablespace for the database. (This name is processed as a double-quoted identifier.)

-e echo

Echo the commands that `createdb` generates and sends to the server.

-E encoding | --encoding encoding

Character set encoding to use in the new database. Specify a string constant (such as `'UTF8'`), an integer encoding number, or `DEFAULT` to use the default encoding. See the Greenplum Database Reference Guide for information about supported character sets.

-l locale | --locale locale

Specifies the locale to be used in this database. This is equivalent to specifying both `--lc-collate` and `--lc-ctype`.

--lc-collate locale

Specifies the `LC_COLLATE` setting to be used in this database.

--lc-ctype locale

Specifies the `LC_CTYPE` setting to be used in this database.

-O owner | --owner=owner

The name of the database user who will own the new database. Defaults to the user running this command. (This name is processed as a double-quoted identifier.)

-T template | --template=template

The name of the template from which to create the new database. Defaults to `template1`. (This name is processed as a double-quoted identifier.)

-V | --version

Print the `createdb` version and exit.

-? | --help

Show help about `createdb` command line arguments, and exit.

The options `-D`, `-l`, `-E`, `-O`, and `-T` correspond to options of the underlying SQL command `CREATE DATABASE`; see `CREATE DATABASE` in the *Greenplum Database Reference Guide* for more information about them.

Connection Options

-h host | --host=host

The host name of the machine on which the Greenplum master database server is running. If not specified, reads from the environment variable `PGHOST` or defaults to `localhost`.

-p port | --port=port

The TCP port on which the Greenplum master database server is listening for connections. If not specified, reads from the environment variable `PGPORT` or defaults to 5432.

-U username | --username=username

The database role name to connect as. If not specified, reads from the environment variable

`PGUSER` or defaults to the current system role name.

`-w` | `-no-password`

Never issue a password prompt. If the server requires password authentication and a password is not available by other means such as a `.pgpass` file, the connection attempt will fail. This option can be useful in batch jobs and scripts where no user is present to enter a password.

`-W` | `-password`

Force a password prompt.

`-maintenance-db=dbname`

Specifies the name of the database to connect to when creating the new database. If not specified, the `postgres` database will be used; if that does not exist (or if it is the name of the new database being created), `template1` will be used.

Examples

To create the database `test` using the default options:

```
createdb test
```

To create the database `demo` using the Greenplum master on host `gpmaster`, port `54321`, using the `LATIN1` encoding scheme:

```
createdb -p 54321 -h gpmaster -E LATIN1 demo
```

[CREATE DATABASE](#), [dropdb](#)

createuser

Creates a new database role.

Synopsis

```
createuser [<connection-option> ...] [<role_attribute> ...] [-e] <role_name>

createuser -? | --help

createuser -V | --version
```

Description

`createuser` creates a new Greenplum Database role. You must be a superuser or have the `CREATEROLE` privilege to create new roles. You must connect to the database as a superuser to create new superusers.

Superusers can bypass all access permission checks within the database, so superuser privileges should not be granted lightly.

`createuser` is a wrapper around the SQL command `CREATE ROLE`.

Options

role_name

The name of the role to be created. This name must be different from all existing roles in this Greenplum Database installation.

-c number | -connection-limit=number

Set a maximum number of connections for the new role. The default is to set no limit.

-d | -createdb

The new role will be allowed to create databases.

-D | -no-createdb

The new role will not be allowed to create databases. This is the default.

-e | -echo

Echo the commands that `createuser` generates and sends to the server.

-E | -encrypted

Encrypts the role's password stored in the database. If not specified, the default password behavior is used.

-i | -inherit

The new role will automatically inherit privileges of roles it is a member of. This is the default.

-I | -no-inherit

The new role will not automatically inherit privileges of roles it is a member of.

-interactive

Prompt for the user name if none is specified on the command line, and also prompt for whichever of the options `-d/-D`, `-r/-R`, `-s/-S` is not specified on the command line.

-l | -login

The new role will be allowed to log in to Greenplum Database. This is the default.

-L | -no-login

The new role will not be allowed to log in (a group-level role).

-N | -unencrypted

Does not encrypt the role's password stored in the database. If not specified, the default password behavior is used.

-P | -pwprompt

If given, `createuser` will issue a prompt for the password of the new role. This is not necessary if you do not plan on using password authentication.

-r | -createrole

The new role will be allowed to create new roles (`CREATEROLE` privilege).

-R | -no-createrole

The new role will not be allowed to create new roles. This is the default.

-s | -superuser

The new role will be a superuser.

-S | -no-superuser

The new role will not be a superuser. This is the default.

-V | -version

Print the `createuser` version and exit.

-replication

The new user will have the `REPLICATION` privilege, which is described more fully in the documentation for `CREATE ROLE`.

-no-replication

The new user will not have the `REPLICATION` privilege, which is described more fully in the documentation for `CREATE ROLE`.

-? | -help

Show help about `createuser` command line arguments, and exit.

Connection Options**-h host | -host=host**

The host name of the machine on which the Greenplum master database server is running. If not specified, reads from the environment variable `PGHOST` or defaults to `localhost`.

`-p port | -port=port`

The TCP port on which the Greenplum master database server is listening for connections. If not specified, reads from the environment variable `PGPORT` or defaults to 5432.

`-U username | -username=username`

The database role name to connect as. If not specified, reads from the environment variable `PGUSER` or defaults to the current system role name.

`-w | -no-password`

Never issue a password prompt. If the server requires password authentication and a password is not available by other means such as a `.pgpass` file, the connection attempt will fail. This option can be useful in batch jobs and scripts where no user is present to enter a password.

`-W | -password`

Force a password prompt.

Examples

To create a role `joe` on the default database server:

```
$ createuser joe
```

To create a role `joe` on the default database server with prompting for some additional attributes:

```
$ createuser --interactive joe
Shall the new role be a superuser? (y/n) **n**
Shall the new role be allowed to create databases? (y/n) **n**
Shall the new role be allowed to create more new roles? (y/n) **n**
CREATE ROLE
```

To create the same role `joe` using connection options, with attributes explicitly specified, and taking a look at the underlying command:

```
createuser -h masterhost -p 54321 -S -D -R -e joe
CREATE ROLE joe NOSUPERUSER NOCREATEDB NOCREATEROLE INHERIT
LOGIN;
CREATE ROLE
```

To create the role `joe` as a superuser, and assign password `admin123` immediately:

```
createuser -P -s -e joe
Enter password for new role: admin123
Enter it again: admin123
CREATE ROLE joe PASSWORD 'admin123' SUPERUSER CREATEDB
CREATEROLE INHERIT LOGIN;
CREATE ROLE
```

In the above example, the new password is not actually echoed when typed, but we show what was typed for clarity. However the password will appear in the echoed command, as illustrated if the `-e` option is used.

[CREATE ROLE](#), [dropuser](#)

dropdb

Removes a database.

Synopsis

```
dropdb [<connection-option> ...] [-e] [-i] <dbname>

dropdb -? | --help

dropdb -V | --version
```

Description

`dropdb` destroys an existing database. The user who runs this command must be a superuser or the owner of the database being dropped.

`dropdb` is a wrapper around the SQL command `DROP DATABASE`. See the *Greenplum Database Reference Guide* for information about `DROP DATABASE`.

Options

`dbname`

The name of the database to be removed.

`-e` | `-echo`

Echo the commands that `dropdb` generates and sends to the server.

`-i` | `-interactive`

Issues a verification prompt before doing anything destructive.

`-V` | `-version`

Print the `dropdb` version and exit.

`-if-exists`

Do not throw an error if the database does not exist. A notice is issued in this case.

`-?` | `-help`

Show help about `dropdb` command line arguments, and exit.

Connection Options

`-h host` | `-host=host`

The host name of the machine on which the Greenplum master database server is running. If not specified, reads from the environment variable `PGHOST` or defaults to `localhost`.

`-p port` | `-port=port`

The TCP port on which the Greenplum master database server is listening for connections. If not specified, reads from the environment variable `PGPORT` or defaults to 5432.

`-U username` | `-username=username`

The database role name to connect as. If not specified, reads from the environment variable `PGUSER` or defaults to the current system role name.

`-w` | `-no-password`

Never issue a password prompt. If the server requires password authentication and a password is not available by other means such as a `.pgpass` file, the connection attempt will fail. This option can be useful in batch jobs and scripts where no user is present to enter a password.

`-W` | `-password`

Force a password prompt.

`-maintenance-db=dbname`

Specifies the name of the database to connect to in order to drop the target database. If not

specified, the `postgres` database will be used; if that does not exist (or if it is the name of the database being dropped), `template1` will be used.

Examples

To destroy the database named `demo` using default connection parameters:

```
dropdb demo
```

To destroy the database named `demo` using connection options, with verification, and a peek at the underlying command:

```
dropdb -p 54321 -h masterhost -i -e demo
Database "demo" will be permanently deleted.
Are you sure? (y/n) y
DROP DATABASE "demo"
DROP DATABASE
```

[createdb](#), [DROP DATABASE](#)

dropuser

Removes a database role.

Synopsis

```
dropuser [<connection-option> ...] [-e] [-i] <role_name>

dropuser -? | --help

dropuser -V | --version
```

Description

`dropuser` removes an existing role from Greenplum Database. Only superusers and users with the `CREATEROLE` privilege can remove roles. To remove a superuser role, you must yourself be a superuser.

`dropuser` is a wrapper around the SQL command `DROP ROLE`.

Options

`role_name`

The name of the role to be removed. You will be prompted for a name if not specified on the command line and the `-i/--interactive` option is used.

`-e | -echo`

Echo the commands that `dropuser` generates and sends to the server.

`-i | -interactive`

Prompt for confirmation before actually removing the role, and prompt for the role name if none is specified on the command line.

`-if-exists`

Do not throw an error if the user does not exist. A notice is issued in this case.

-V | -version

Print the `dropuser` version and exit.

-? | -help

Show help about `dropuser` command line arguments, and exit.

Connection Options

-h host | -host=host

The host name of the machine on which the Greenplum master database server is running. If not specified, reads from the environment variable `PGHOST` or defaults to `localhost`.

-p port | -port=port

The TCP port on which the Greenplum master database server is listening for connections. If not specified, reads from the environment variable `PGPORT` or defaults to 5432.

-U username | -username=username

The database role name to connect as. If not specified, reads from the environment variable `PGUSER` or defaults to the current system role name.

-w | -no-password

Never issue a password prompt. If the server requires password authentication and a password is not available by other means such as a `.pgpass` file, the connection attempt will fail. This option can be useful in batch jobs and scripts where no user is present to enter a password.

-W | -password

Force a password prompt.

Examples

To remove the role `joe` using default connection options:

```
dropuser joe
DROP ROLE
```

To remove the role `joe` using connection options, with verification, and a peek at the underlying command:

```
dropuser -p 54321 -h masterhost -i -e joe
Role "joe" will be permanently removed.
Are you sure? (y/n) y
DROP ROLE "joe"
DROP ROLE
```

[createuser](#), [DROP ROLE](#)

gpfdist

Serves data files to or writes data files out from Greenplum Database segments.

Synopsis

```
gpfdist [-d <directory>] [-p <http_port>] [-P <last_http_port>] [-l <log_file>]
        [-t <timeout>] [-S] [-w <time>] [-v | -V] [-s] [-m <max_length>]
        [--ssl <certificate_path> [--sslclean <wait_time>] ]
```

```
[-c <config.yml>]

gpfdist -? | --help

gpfdist --version
```

Description

`gpfdist` is Greenplum Database parallel file distribution program. It is used by readable external tables and `gpload` to serve external table files to all Greenplum Database segments in parallel. It is used by writable external tables to accept output streams from Greenplum Database segments in parallel and write them out to a file.

Note: `gpfdist` and `gpload` are compatible only with the Greenplum Database major version in which they are shipped. For example, a `gpfdist` utility that is installed with Greenplum Database 4.x cannot be used with Greenplum Database 5.x or 6.x.

In order for `gpfdist` to be used by an external table, the `LOCATION` clause of the external table definition must specify the external table data using the `gpfdist://` protocol (see the Greenplum Database command `CREATE EXTERNAL TABLE`).

Note: If the `--ssl` option is specified to enable SSL security, create the external table with the `gpfdists://` protocol.

The benefit of using `gpfdist` is that you are guaranteed maximum parallelism while reading from or writing to external tables, thereby offering the best performance as well as easier administration of external tables.

For readable external tables, `gpfdist` parses and serves data files evenly to all the segment instances in the Greenplum Database system when users `SELECT` from the external table. For writable external tables, `gpfdist` accepts parallel output streams from the segments when users `INSERT` into the external table, and writes to an output file.

Note: When `gpfdist` reads data and encounters a data formatting error, the error message includes a row number indicating the location of the formatting error. `gpfdist` attempts to capture the row that contains the error. However, `gpfdist` might not capture the exact row for some formatting errors.

For readable external tables, if load files are compressed using `gzip` or `bzip2` (have a `.gz` or `.bz2` file extension), `gpfdist` uncompresses the data while loading the data (on the fly). For writable external tables, `gpfdist` compresses the data using `gzip` if the target file has a `.gz` extension.

Note: Compression is not supported for readable and writeable external tables when the `gpfdist` utility runs on Windows platforms.

When reading or writing data with the `gpfdist` or `gpfdists` protocol, Greenplum Database includes `X-GP-PROTO` in the HTTP request header to indicate that the request is from Greenplum Database. The utility rejects HTTP requests that do not include `X-GP-PROTO` in the request header.

Most likely, you will want to run `gpfdist` on your ETL machines rather than the hosts where Greenplum Database is installed. To install `gpfdist` on another host, simply copy the utility over to that host and add `gpfdist` to your `$PATH`.

Note: When using IPv6, always enclose the numeric IP address in brackets.

Options

`-d` directory

The directory from which `gpfdist` will serve files for readable external tables or create output files for writable external tables. If not specified, defaults to the current directory.

`-l log_file`

The fully qualified path and log file name where standard output messages are to be logged.

`-p http_port`

The HTTP port on which `gpfdist` will serve files. Defaults to 8080.

`-P last_http_port`

The last port number in a range of HTTP port numbers (`http_port` to `last_http_port`, inclusive) on which `gpfdist` will attempt to serve files. `gpfdist` serves the files on the first port number in the range to which it successfully binds.

`-t timeout`

Sets the time allowed for Greenplum Database to establish a connection to a `gpfdist` process. Default is 5 seconds. Allowed values are 2 to 7200 seconds (2 hours). May need to be increased on systems with a lot of network traffic.

`-m max_length`

Sets the maximum allowed data row length in bytes. Default is 32768. Should be used when user data includes very wide rows (or when `line too long` error message occurs). Should not be used otherwise as it increases resource allocation. Valid range is 32K to 256MB. (The upper limit is 1MB on Windows systems.)

Note: Memory issues might occur if you specify a large maximum row length and run a large number of `gpfdist` concurrent connections. For example, setting this value to the maximum of 256MB with 96 concurrent `gpfdist` processes requires approximately 24GB of memory ($(96 + 1) \times 246\text{MB}$).

`-s`

Enables simplified logging. When this option is specified, only messages with `WARN` level and higher are written to the `gpfdist` log file. `INFO` level messages are not written to the log file. If this option is not specified, all `gpfdist` messages are written to the log file.

You can specify this option to reduce the information written to the log file.

`-S (use O_SYNC)`

Opens the file for synchronous I/O with the `O_SYNC` flag. Any writes to the resulting file descriptor block `gpfdist` until the data is physically written to the underlying hardware.

`-w time`

Sets the number of seconds that Greenplum Database delays before closing a target file such as a named pipe. The default value is 0, no delay. The maximum value is 7200 seconds (2 hours).

For a Greenplum Database with multiple segments, there might be a delay between segments when writing data from different segments to the file. You can specify a time to wait before Greenplum Database closes the file to ensure all the data is written to the file.

`-ssl certificate_path`

Adds SSL encryption to data transferred with `gpfdist`. After running `gpfdist` with the `--ssl certificate_path` option, the only way to load data from this file server is with the `gpfdist://` protocol. For information on the `gpfdist://` protocol, see “Loading and Unloading Data” in the *Greenplum Database Administrator Guide*.

The location specified in `certificate_path` must contain the following files:

- The server certificate file, `server.crt`
- The server private key file, `server.key`
- The trusted certificate authorities, `root.crt`

The root directory (/) cannot be specified as `certificate_path`.

– `sslclean wait_time`

When the utility is run with the `--ssl` option, sets the number of seconds that the utility delays before closing an SSL session and cleaning up the SSL resources after it completes writing data to or from a Greenplum Database segment. The default value is 0, no delay. The maximum value is 500 seconds. If the delay is increased, the transfer speed decreases.

In some cases, this error might occur when copying large amounts of data: `gpfdist server closed connection`. To avoid the error, you can add a delay, for example `--sslclean 5`.

– `config.yaml`

Specifies rules that `gpfdist` uses to select a transform to apply when loading or extracting data. The `gpfdist` configuration file is a YAML 1.1 document.

For information about the file format, see [Configuration File Format](#) in the *Greenplum Database Administrator Guide*. For information about configuring data transformation with `gpfdist`, see [Transforming External Data with gpfdist and gpload](#) in the *Greenplum Database Administrator Guide*.

This option is not available on Windows platforms.

– `v` (verbose)

Verbose mode shows progress and status messages.

– `V` (very verbose)

Verbose mode shows all output messages generated by this utility.

– `?` (help)

Displays the online help.

– `version`

Displays the version of this utility.

Notes

The server configuration parameter `verify_gpfdists_cert` controls whether SSL certificate authentication is enabled when Greenplum Database communicates with the `gpfdist` utility to either read data from or write data to an external data source. You can set the parameter value to `false` to disable authentication when testing the communication between the Greenplum Database external table and the `gpfdist` utility that is serving the external data. If the value is `false`, these SSL exceptions are ignored:

- The self-signed SSL certificate that is used by `gpfdist` is not trusted by Greenplum Database.
- The host name contained in the SSL certificate does not match the host name that is running `gpfdist`.

Warning: Disabling SSL certificate authentication exposes a security risk by not validating the `gpfdists` SSL certificate.

You can set the server configuration parameter `gpfdist_retry_timeout` to control the time that Greenplum Database waits before returning an error when a `gpfdist` server does not respond while Greenplum Database is attempting to write data to `gpfdist`. The default is 300 seconds (5 minutes).

If the `gpfdist` utility hangs with no read or write activity occurring, you can generate a core dump the next time a hang occurs to help debug the issue. Set the environment variable `GPFDIST_WATCHDOG_TIMER` to the number of seconds of no activity to wait before `gpfdist` is forced to exit. When the environment variable is set and `gpfdist` hangs, the utility is stopped after the specified number of seconds, creates a core dump, and sends relevant information to the log file.

This example sets the environment variable on a Linux system so that `gpfdist` exits after 300

seconds (5 minutes) of no activity.

```
export GPFDIST_WATCHDOG_TIMER=300
```

Examples

To serve files from a specified directory using port 8081 (and start `gpfdist` in the background):

```
gpfdist -d /var/load_files -p 8081 &
```

To start `gpfdist` in the background and redirect output and errors to a log file:

```
gpfdist -d /var/load_files -p 8081 -l /home/gpadmin/log &
```

To stop `gpfdist` when it is running in the background:

– First find its process id:

```
ps ax | grep gpfdist
```

– Then stop the process, for example:

```
kill 3456
```

See Also

[gpload](#), [CREATE EXTERNAL TABLE](#)

gpload

Runs a load job as defined in a YAML formatted control file.

Synopsis

```
gpload -f <control_file> [-l <log_file>] [-h <hostname>] [-p <port>]
    [-U <username>] [-d <database>] [-W] [--gpfdist_timeout <seconds>]
    [--no_auto_trans] [--max_retries <retry_times>] [[-v | -V] [-q]] [-D]

gpload -?

gpload --version
```

Requirements

The client machine where `gpload` is run must have the following:

- The `gpfdist` parallel file distribution program installed and in your `$PATH`. This program is located in `$GPHOME/bin` of your Greenplum Database server installation.
- Network access to and from all hosts in your Greenplum Database array (master and segments).
- Network access to and from the hosts where the data to be loaded resides (ETL servers).

Description

`gpload` is a data loading utility that acts as an interface to the Greenplum Database external table parallel loading feature. Using a load specification defined in a YAML formatted control file, `gpload` runs a load by invoking the Greenplum Database parallel file server (`gpfdist`), creating an external table definition based on the source data defined, and running an `INSERT`, `UPDATE` or `MERGE` operation to load the source data into the target table in the database.

Note: `gpfdist` is compatible only with the Greenplum Database major version in which it is shipped. For example, a `gpfdist` utility that is installed with Greenplum Database 4.x cannot be used with Greenplum Database 5.x or 6.x.

Note: The Greenplum Database 5.22 and later `gpload` for Linux is compatible with Greenplum Database 6.x. The Greenplum Database 6.x `gpload` for both Linux and Windows is compatible with Greenplum 5.x.

Note: `MERGE` and `UPDATE` operations are not supported if the target table column name is a reserved keyword, has capital letters, or includes any character that requires quotes (" ") to identify the column.

The operation, including any SQL commands specified in the `SQL` collection of the YAML control file (see [Control File Format](#)), are performed as a single transaction to prevent inconsistent data when performing multiple, simultaneous load operations on a target table.

Options

`-f control_file`

Required. A YAML file that contains the load specification details. See [Control File Format](#).

`- gpfdist_timeout seconds`

Sets the timeout for the `gpfdist` parallel file distribution program to send a response. Enter a value from 0 to 30 seconds (entering "0" to disables timeouts). Note that you might need to increase this value when operating on high-traffic networks.

`-l log_file`

Specifies where to write the log file. Defaults to `~/gpAdminLogs/gpload_YYYYMMDD`. For more information about the log file, see [Log File Format](#).

`- no_auto_trans`

Specify `--no_auto_trans` to disable processing the load operation as a single transaction if you are performing a single load operation on the target table.

By default, `gpload` processes each load operation as a single transaction to prevent inconsistent data when performing multiple, simultaneous operations on a target table.

`-q` (no screen output)

Run in quiet mode. Command output is not displayed on the screen, but is still written to the log file.

`-D` (debug mode)

Check for error conditions, but do not run the load.

`-v` (verbose mode)

Show verbose output of the load steps as they are run.

`-V` (very verbose mode)

Shows very verbose output.

`-?` (show help)

Show help, then exit.

`- version`

Show the version of this utility, then exit.

Connection Options

-d database

The database to load into. If not specified, reads from the load control file, the environment variable `$PGDATABASE` or defaults to the current system user name.

-h hostname

Specifies the host name of the machine on which the Greenplum Database master database server is running. If not specified, reads from the load control file, the environment variable `$PGHOST` or defaults to `localhost`.

-p port

Specifies the TCP port on which the Greenplum Database master database server is listening for connections. If not specified, reads from the load control file, the environment variable `$PGPORT` or defaults to 5432.

- max_retries retry_times

Specifies the maximum number of times `gpload` attempts to connect to Greenplum Database after a connection timeout. The default value is 0, do not attempt to connect after a connection timeout. A negative integer, such as `-1`, specifies an unlimited number of attempts.

-U username

The database role name to connect as. If not specified, reads from the load control file, the environment variable `$PGUSER` or defaults to the current system user name.

-W (force password prompt)

Force a password prompt. If not specified, reads the password from the environment variable `$PGPASSWORD` or from a password file specified by `$PGPASSFILE` or in `~/.pgpass`. If these are not set, then `gpload` will prompt for a password even if `-w` is not supplied.

Control File Format

The `gpload` control file uses the [YAML 1.1](#) document format and then implements its own schema for defining the various steps of a Greenplum Database load operation. The control file must be a valid YAML document.

The `gpload` program processes the control file document in order and uses indentation (spaces) to determine the document hierarchy and the relationships of the sections to one another. The use of white space is significant. White space should not be used simply for formatting purposes, and tabs should not be used at all.

The basic structure of a load control file is:

```
---
[VERSION] (#cfversion): 1.0.0.1
[DATABASE] (#cfdatabase): <db_name>
[USER] (#cfuser): <db_username>
[HOST] (#cfhost): <master_hostname>
[PORT] (#cfport): <master_port>
[GPLOAD] (#cfgpload):
  [INPUT] (#cfinput):
    - [SOURCE] (#cfsource):
        [LOCAL\_HOSTNAME] (#cfsourcelocalname):
          - <hostname_or_ip>
        [PORT] (#cfsourceport): <http_port>
      | [PORT\_RANGE] (#cfversion): [<start_port_range>, <end_port_range>]
        [FILE] (#cfsourcefile):
          - </path/to/input_file>
        [SSL] (#cfsourcessl): true | false
        [CERTIFICATES\_PATH] (#cfsourcecertificatespath): </path/to/certificates>
    - [FULLY\_QUALIFIED\_DOMAIN\_NAME] (#fqdn): true | false
    - [COLUMNS] (#cfcolumns):
        - <field_name>: <data_type>
```

```

- [TRANSFORM] (#cftransform): '<transformation>'
- [TRANSFORM\_CONFIG] (#cftransformconfig): '<configuration-file-path>'
- [MAX\_LINE\_LENGTH] (#cfmaxlinelength): <integer>
- [FORMAT] (#cfformat): text | csv
- [DELIMITER] (#cfdelimiter): '<delimiter_character>'
- [ESCAPE] (#cfescape): '<escape_character>' | 'OFF'
- [NEWLINE] (#newline): 'LF' | 'CR' | 'CRLF'
- [NULL\_AS] (#cfnullas): '<null_string>'
- [FILL\_MISSING\_FIELDS] (#cfllfields): true | false
- [FORCE\_NOT\_NULL] (#cfforcenotnull): true | false

  - [AFTER] (#cfafter): "<sql_command>"

```

VERSION

Optional. The version of the `gpload` control file schema. The current version is 1.0.0.1.

DATABASE

Optional. Specifies which database in the Greenplum Database system to connect to. If not specified, defaults to `$PGDATABASE` if set or the current system user name. You can also specify the database on the command line using the `-d` option.

USER

Optional. Specifies which database role to use to connect. If not specified, defaults to the current user or `$PGUSER` if set. You can also specify the database role on the command line using the `-U` option.

If the user running `gpload` is not a Greenplum Database superuser, then the appropriate rights must be granted to the user for the load to be processed. See the *Greenplum Database Reference Guide* for more information.

HOST

Optional. Specifies Greenplum Database master host name. If not specified, defaults to localhost or `$PGHOST` if set. You can also specify the master host name on the command line using the `-h` option.

PORT

Optional. Specifies Greenplum Database master port. If not specified, defaults to 5432 or `$PGPORT` if set. You can also specify the master port on the command line using the `-p` option.

GPLOAD

Required. Begins the load specification section. A `GPLOAD` specification must have an `INPUT`

and an `OUTPUT` section defined.

INPUT

Required. Defines the location and the format of the input data to be loaded. `gpload` will start one or more instances of the `gpfdist` file distribution program on the current host and create the required external table definition(s) in Greenplum Database that point to the source data. Note that the host from which you run `gpload` must be accessible over the network by all Greenplum Database hosts (master and segments).

SOURCE

Required. The `SOURCE` block of an `INPUT` specification defines the location of a source file. An `INPUT` section can have more than one `SOURCE` block defined. Each `SOURCE` block defined corresponds to one instance of the `gpfdist` file distribution program that will be started on the local machine. Each `SOURCE` block defined must have a `FILE` specification.

For more information about using the `gpfdist` parallel file server and single and multiple `gpfdist` instances, see [Loading and Unloading Data](#).

LOCAL_HOSTNAME

Optional. Specifies the host name or IP address of the local machine on which `gpload` is running. If this machine is configured with multiple network interface cards (NICs), you can specify the host name or IP of each individual NIC to allow network traffic to use all NICs simultaneously. The default is to use the local machine's primary host name or IP only.

PORT

Optional. Specifies the specific port number that the `gpfdist` file distribution program should use. You can also supply a `PORT_RANGE` to select an available port from the specified range. If both `PORT` and `PORT_RANGE` are defined, then `PORT` takes precedence. If neither `PORT` or `PORT_RANGE` are defined, the default is to select an available port between 8000 and 9000.

If multiple host names are declared in `LOCAL_HOSTNAME`, this port number is used for all hosts. This configuration is desired if you want to use all NICs to load the same file or set of files in a given directory location.

PORT_RANGE

Optional. Can be used instead of `PORT` to supply a range of port numbers from which `gpload` can choose an available port for this instance of the `gpfdist` file distribution program.

FILE

Required. Specifies the location of a file, named pipe, or directory location on the local file system that contains data to be loaded. You can declare more than one file so long as the data is of the same format in all files specified.

If the files are compressed using `gzip` or `bzip2` (have a `.gz` or `.bz2` file extension), the files will be uncompressed automatically (provided that `gunzip` or `bunzip2` is in your path).

When specifying which source files to load, you can use the wildcard character (*) or other C-style pattern matching to denote multiple files. The files specified are assumed to be relative to the current directory from which `gpload` is run (or you can declare an absolute path).

SSL

Optional. Specifies usage of SSL encryption. If `SSL` is set to true, `gpload` starts the `gpfdist` server with the `--ssl` option and uses the `gpfdists://` protocol.

CERTIFICATES_PATH

Required when SSL is `true`; cannot be specified when SSL is `false` or unspecified. The location specified in `CERTIFICATES_PATH` must contain the following files:

- The server certificate file, `server.crt`
- The server private key file, `server.key`
- The trusted certificate authorities, `root.crt`

The root directory (`/`) cannot be specified as `CERTIFICATES_PATH`.

FULLY_QUALIFIED_DOMAIN_NAME

Optional. Specifies whether `gpload` resolve hostnames to the fully qualified domain name (FQDN) or the local hostname. If the value is set to `true`, names are resolved to the FQDN. If the value is set to `false`, resolution is to the local hostname. The default is `false`.

A fully qualified domain name might be required in some situations. For example, if the Greenplum Database system is in a different domain than an ETL application that is being accessed by `gpload`.

COLUMNS

Optional. Specifies the schema of the source data file(s) in the format of `field_name:data_type`. The `DELIMITER` character in the source file is what separates two data value fields (columns). A row is determined by a line feed character (`0x0a`).

If the input `COLUMNS` are not specified, then the schema of the output `TABLE` is implied, meaning that the source data must have the same column order, number of columns, and data format as the target table.

The default source-to-target mapping is based on a match of column names as defined in this section and the column names in the target `TABLE`. This default mapping can be overridden using the `MAPPING` section.

TRANSFORM

Optional. Specifies the name of the input transformation passed to `gpload`. For information about XML transformations, see “Loading and Unloading Data” in the *Greenplum Database Administrator Guide*.

TRANSFORM_CONFIG

Required when `TRANSFORM` is specified. Specifies the location of the transformation configuration file that is specified in the `TRANSFORM` parameter, above.

MAX_LINE_LENGTH

Optional. An integer that specifies the maximum length of a line in the XML transformation data passed to `gpload`.

FORMAT

Optional. Specifies the format of the source data file(s) - either plain text (`TEXT`) or comma separated values (`CSV`) format. Defaults to `TEXT` if not specified. For more information about the format of the source data, see [Loading and Unloading Data](#).

DELIMITER

Optional. Specifies a single ASCII character that separates columns within each row (line) of data. The default is a tab character in `TEXT` mode, a comma in `CSV` mode. You can also specify a non- printable ASCII character or a non-printable unicode character, for example: `"\x1B"` or `"\u001B"`. The escape string syntax, `E'<character-code>'`, is also supported for non-printable characters. The ASCII or unicode character must be enclosed in single quotes. For example: `E'\x1B'` or `E'\u001B'`.

ESCAPE

Specifies the single character that is used for C escape sequences (such as `\n`, `\t`, `\100`, and so on) and for escaping data characters that might otherwise be taken as row or column delimiters. Make sure to choose an escape character that is not used anywhere in your actual column data. The default escape character is a `\` (backslash) for text-formatted files and a `"` (double quote) for csv-formatted files, however it is possible to specify another character to represent an escape. It is also possible to disable escaping in text-formatted files by specifying the value `'OFF'` as the escape value. This is very useful for data such as text-formatted web log data that has many embedded backslashes that are not intended to be escapes.

NEWLINE

Specifies the type of newline used in your data files, one of:

- LF (Line feed, 0x0A)
- CR (Carriage return, 0x0D)
- CRLF (Carriage return plus line feed, 0x0D 0x0A).

If not specified, Greenplum Database detects the newline type by examining the first row of data that it receives, and uses the first newline type that it encounters.

NULL_AS

Optional. Specifies the string that represents a null value. The default is `\N` (backslash-N) in `TEXT` mode, and an empty value with no quotations in `CSV` mode. You might prefer an empty string even in `TEXT` mode for cases where you do not want to distinguish nulls from empty strings. Any source data item that matches this string will be considered a null value.

FILL_MISSING_FIELDS

Optional. The default value is `false`. When reading a row of data that has missing trailing field values (the row of data has missing data fields at the end of a line or row), Greenplum Database returns an error.

If the value is `true`, when reading a row of data that has missing trailing field values, the values are set to `NULL`. Blank rows, fields with a `NOT NULL` constraint, and trailing delimiters on a line will still report an error.

See the `FILL MISSING FIELDS` clause of the `CREATE EXTERNAL TABLE` command.

FORCE_NOT_NULL

Optional. In `CSV` mode, processes each specified column as though it were quoted and hence not a `NULL` value. For the default null string in `CSV` mode (nothing between two delimiters), this causes missing values to be evaluated as zero-length strings.

QUOTE

Required when `FORMAT` is `CSV`. Specifies the quotation character for `CSV` mode. The default is double-quote (`"`).

HEADER

Optional. Specifies that the first line in the data file(s) is a header row (contains the names of the columns) and should not be included as data to be loaded. If using multiple data source files, all files must have a header row. The default is to assume that the input files do not have a header row.

ENCODING

Optional. Character set encoding of the source data. Specify a string constant (such as `'SQL_ASCII'`), an integer encoding number, or `'DEFAULT'` to use the default client encoding. If not specified, the default client encoding is used. For information about supported character sets, see the *Greenplum Database Reference Guide*.

Note: If you *change* the `ENCODING` value in an existing `gpload` control file, you must manually drop any external tables that were creating using the previous `ENCODING` configuration. `gpload` does not drop and recreate external tables to use the new `ENCODING` if `REUSE_TABLES` is set to `true`.

ERROR_LIMIT

Optional. Enables single row error isolation mode for this load operation. When enabled, input rows that have format errors will be discarded provided that the error limit count is not reached on any Greenplum Database segment instance during input processing. If the error limit is not reached, all good rows will be loaded and any error rows will either be discarded or captured as part of error log information. The default is to cancel the load operation on the first error encountered. Note that single row error isolation only applies to data rows with format errors; for example, extra or missing attributes, attributes of a wrong data type, or invalid client encoding sequences. Constraint errors, such as primary key violations, will still cause the load operation to be cancelled if encountered. For information about handling load errors, see [Loading and Unloading Data](#).

LOG_ERRORS

Optional when `ERROR_LIMIT` is declared. Value is either `true` or `false`. The default value is `false`. If the value is `true`, rows with formatting errors are logged internally when running in single row error isolation mode. You can examine formatting errors with the Greenplum Database built-in SQL function `gp_read_error_log('<table_name>')`. If formatting errors are detected when loading data, `gpload` generates a warning message with the name of the table that contains the error information similar to this message.

```
<timestamp>|WARN|1 bad row, please use GPDB built-in function gp_read_error_log('
table-name')
to access the detailed error row
```

If `LOG_ERRORS: true` is specified, `REUSE_TABLES: true` must be specified to retain the formatting errors in Greenplum Database error logs. If `REUSE_TABLES: true` is not specified, the error information is deleted after the `gpload` operation. Only summary information about formatting errors is returned. You can delete the formatting errors from the error logs with the Greenplum Database function `gp_truncate_error_log()`.

Note: When `gpfdist` reads data and encounters a data formatting error, the error message includes a row number indicating the location of the formatting error. `gpfdist` attempts to capture the row that contains the error. However, `gpfdist` might not capture the exact row for some formatting errors.

For more information about handling load errors, see “Loading and Unloading Data” in the *Greenplum Database Administrator Guide*. For information about the `gp_read_error_log()` function, see the [CREATE EXTERNAL TABLE](#) command.

EXTERNAL

Optional. Defines the schema of the external table database objects created by `gpload`. The default is to use the Greenplum Database `search_path`.

SCHEMA

Required when `EXTERNAL` is declared. The name of the schema of the external table. If the schema does not exist, an error is returned.

If `%` (percent character) is specified, the schema of the table name specified by `TABLE` in the `OUTPUT` section is used. If the table name does not specify a schema, the default schema is

used.

OUTPUT

Required. Defines the target table and final data column values that are to be loaded into the database.

TABLE

Required. The name of the target table to load into.

MODE

Optional. Defaults to `INSERT` if not specified. There are three available load modes:

INSERT - Loads data into the target table using the following method:

```
INSERT INTO <target_table> SELECT * FROM <input_data>;
```

UPDATE - Updates the `UPDATE_COLUMNS` of the target table where the rows have `MATCH_COLUMNS` attribute values equal to those of the input data, and the optional `UPDATE_CONDITION` is true. `UPDATE` is not supported if the target table column name is a reserved keyword, has capital letters, or includes any character that requires quotes (" ") to identify the column.

MERGE - Inserts new rows and updates the `UPDATE_COLUMNS` of existing rows where `FOOBAR` attribute values are equal to those of the input data, and the optional `MATCH_COLUMNS` is true. New rows are identified when the `MATCH_COLUMNS` value in the source data does not have a corresponding value in the existing data of the target table. In those cases, the **entire row** from the source file is inserted, not only the `MATCH` and `UPDATE` columns. If there are multiple new `MATCH_COLUMNS` values that are the same, only one new row for that value will be inserted. Use `UPDATE_CONDITION` to filter out the rows to discard. `MERGE` is not supported if the target table column name is a reserved keyword, has capital letters, or includes any character that requires quotes (" ") to identify the column.

MATCH_COLUMNS

Required if `MODE` is `UPDATE` or `MERGE`. Specifies the column(s) to use as the join condition for the update. The attribute value in the specified target column(s) must be equal to that of the corresponding source data column(s) in order for the row to be updated in the target table.

UPDATE_COLUMNS

Required if `MODE` is `UPDATE` or `MERGE`. Specifies the column(s) to update for the rows that meet the `MATCH_COLUMNS` criteria and the optional `UPDATE_CONDITION`.

UPDATE_CONDITION

Optional. Specifies a Boolean condition (similar to what you would declare in a `WHERE` clause) that must be met in order for a row in the target table to be updated.

MAPPING

Optional. If a mapping is specified, it overrides the default source-to-target column mapping. The default source-to-target mapping is based on a match of column names as defined in the source `COLUMNS` section and the column names of the target `TABLE`. A mapping is specified as either:

```
<target_column_name>: <source_column_name>
```

or

```
<target_column_name>: '<expression>'
```

Where `<expression>` is any expression that you would specify in the `SELECT` list of a query, such as a constant value, a column reference, an operator invocation, a function call, and so on.

PRELOAD

Optional. Specifies operations to run prior to the load operation. Right now the only preload operation is `TRUNCATE`.

TRUNCATE

Optional. If set to true, `gpload` will remove all rows in the target table prior to loading it. Default is false.

REUSE_TABLES

Optional. If set to true, `gpload` will not drop the external table objects and staging table objects it creates. These objects will be reused for future load operations that use the same load specifications. This improves performance of trickle loads (ongoing small loads to the same target table).

If `LOG_ERRORS: true` is specified, `REUSE_TABLES: true` must be specified to retain the formatting errors in Greenplum Database error logs. If `REUSE_TABLES: true` is not specified, formatting error information is deleted after the `gpload` operation.

If the `<external_table_name>` exists, the utility uses the existing table. The utility returns an error if the table schema does not match the `OUTPUT` table schema.

STAGING_TABLE

Optional. Specify the name of the temporary external table that is created during a `gpload` operation. The external table is used by `gpfdist`. `REUSE_TABLES: true` must also be specified. If `REUSE_TABLES` is false or not specified, `STAGING_TABLE` is ignored. By default, `gpload` creates a temporary external table with a randomly generated name.

If `external_table_name` contains a period (`.`), `gpload` returns an error. If the table exists, the utility uses the table. The utility returns an error if the existing table schema does not match the `OUTPUT` table schema.

The utility uses the value of `SCHEMA` in the `EXTERNAL` section as the schema for `<external_table_name>`. If the `SCHEMA` value is `%`, the schema for `<external_table_name>` is the same as the schema of the target table, the schema of `TABLE` in the `OUTPUT` section.

If `SCHEMA` is not set, the utility searches for the table (using the schemas in the database `search_path`). If the table is not found, `external_table_name` is created in the default `PUBLIC` schema.

`gpload` creates the staging table using the distribution key(s) of the target table as the distribution key(s) for the staging table. If the target table was created `DISTRIBUTED RANDOMLY`, `gpload` uses `MATCH_COLUMNS` as the staging table's distribution key(s).

FAST_MATCH

Optional. If set to true, `gpload` only searches the database for matching external table objects when reusing external tables. The utility does not check the external table column names and column types in the catalog table `pg_attribute` to ensure that the table can be used for a `gpload` operation. Set the value to true to improve `gpload` performance when reusing external table objects and the database catalog table `pg_attribute` contains a large number of rows. The utility returns an error and quits if the column definitions are not compatible.

The default value is false, the utility checks the external table definition column names and column types.

`REUSE_TABLES: true` must also be specified. If `REUSE_TABLES` is false or not specified and `FAST_MATCH: true` is specified, `gpload` returns a warning message.

SQL

Optional. Defines SQL commands to run before and/or after the load operation. You can specify multiple **BEFORE** and/or **AFTER** commands. List commands in the order of desired execution.

BEFORE

Optional. An SQL command to run before the load operation starts. Enclose commands in quotes.

AFTER

Optional. An SQL command to run after the load operation completes. Enclose commands in quotes.

Log File Format

Log files output by **gpload** have the following format:

```
<timestamp>|<level>|<message>
```

Where **<timestamp>** takes the form: **YYYY-MM-DD HH:MM:SS**, level is one of **DEBUG**, **LOG**, **INFO**, **ERROR**, and message is a normal text message.

Some **INFO** messages that may be of interest in the log files are (where **#** corresponds to the actual number of seconds, units of data, or failed rows):

```
INFO|running time: <#.##> seconds
INFO|transferred <#.##> kB of <#.##> kB.
INFO|gpload succeeded
INFO|gpload succeeded with warnings
INFO|gpload failed
INFO|1 bad row
INFO|<#> bad rows
```

Notes

If your database object names were created using a double-quoted identifier (delimited identifier), you must specify the delimited name within single quotes in the **gpload** control file. For example, if you create a table as follows:

```
CREATE TABLE "MyTable" ("MyColumn" text);
```

Your YAML-formatted **gpload** control file would refer to the above table and column names as follows:

```
- COLUMNS:
  - '"MyColumn"': text
OUTPUT:
  - TABLE: public.'"MyTable"'
```

If the YAML control file contains the **ERROR_TABLE** element that was available in Greenplum Database 4.3.x, **gpload** logs a warning stating that **ERROR_TABLE** is not supported, and load errors are handled as if the **LOG_ERRORS** and **REUSE_TABLE** elements were set to **true**. Rows with formatting errors are logged internally when running in single row error isolation mode.

Examples

Run a load job as defined in `my_load.yml`:

```
gpload -f my_load.yml
```

Example load control file:

```
---
VERSION: 1.0.0.1
DATABASE: ops
USER: gpadmin
HOST: mdw-1
PORT: 5432
GLOAD:
  INPUT:
    - SOURCE:
        LOCAL_HOSTNAME:
          - etl1-1
          - etl1-2
          - etl1-3
          - etl1-4
        PORT: 8081
        FILE:
          - /var/load/data/*
    - COLUMNS:
        - name: text
        - amount: float4
        - category: text
        - descr: text
        - date: date
    - FORMAT: text
    - DELIMITER: '|'
    - ERROR_LIMIT: 25
    - LOG_ERRORS: true
  OUTPUT:
    - TABLE: payables.expenses
    - MODE: INSERT
  PRELOAD:
    - REUSE_TABLES: true
  SQL:
    - BEFORE: "INSERT INTO audit VALUES('start', current_timestamp)"
    - AFTER: "INSERT INTO audit VALUES('end', current_timestamp)"
```

[gpfdist](#), [CREATE EXTERNAL TABLE](#)

pg_dump

Extracts a database into a single script file or other archive file.

Synopsis

```
pg_dump [<connection-option> ...] [<dump_option> ...] [<dbname>]

pg_dump -? | --help

pg_dump -V | --version
```

Description

`pg_dump` is a standard PostgreSQL utility for backing up a database, and is also supported in Greenplum Database. It creates a single (non-parallel) dump file. For routine backups of Greenplum Database, it is better to use the Greenplum Database backup utility, `gpbackup`, for the best performance.

Use `pg_dump` if you are migrating your data to another database vendor's system, or to another Greenplum Database system with a different segment configuration (for example, if the system you are migrating to has greater or fewer segment instances). To restore, you must use the corresponding `pg_restore` utility (if the dump file is in archive format), or you can use a client program such as `psql` (if the dump file is in plain text format).

Since `pg_dump` is compatible with regular PostgreSQL, it can be used to migrate data into Greenplum Database. The `pg_dump` utility in Greenplum Database is very similar to the PostgreSQL `pg_dump` utility, with the following exceptions and limitations:

- If using `pg_dump` to backup a Greenplum Database database, keep in mind that the dump operation can take a long time (several hours) for very large databases. Also, you must make sure you have sufficient disk space to create the dump file.
- If you are migrating data from one Greenplum Database system to another, use the `--gp-syntax` command-line option to include the `DISTRIBUTED BY` clause in `CREATE TABLE` statements. This ensures that Greenplum Database table data is distributed with the correct distribution key columns upon restore.

`pg_dump` makes consistent backups even if the database is being used concurrently. `pg_dump` does not block other users accessing the database (readers or writers).

When used with one of the archive file formats and combined with `pg_restore`, `pg_dump` provides a flexible archival and transfer mechanism. `pg_dump` can be used to backup an entire database, then `pg_restore` can be used to examine the archive and/or select which parts of the database are to be restored. The most flexible output file formats are the custom format (`-Fc`) and the directory format (`-Fd`). They allow for selection and reordering of all archived items, support parallel restoration, and are compressed by default. The directory format is the only format that supports parallel dumps.

Options

dbname

Specifies the name of the database to be dumped. If this is not specified, the environment variable `PGDATABASE` is used. If that is not set, the user name specified for the connection is used.

Dump Options

-a | -data-only

Dump only the data, not the schema (data definitions). Table data and sequence values are dumped.

This option is similar to, but for historical reasons not identical to, specifying `--section=data`.

-b | -blobs

Include large objects in the dump. This is the default behavior except when `--schema`, `--table`, or `--schema-only` is specified. The `-b` switch is only useful add large objects to dumps where a specific schema or table has been requested. Note that blobs are considered data and therefore will be included when `--data-only` is used, but not when `--schema-only` is.

Note: Greenplum Database does not support the PostgreSQL [large object facility](#) for streaming user data that is stored in large-object structures.

-c | --clean

Adds commands to the text output file to clean (drop) database objects prior to outputting the commands for creating them. (Restore might generate some harmless error messages, if any objects were not present in the destination database.) Note that objects are not dropped before the dump operation begins, but `DROP` commands are added to the DDL dump output files so that when you use those files to do a restore, the `DROP` commands are run prior to the `CREATE` commands. This option is only meaningful for the plain-text format. For the archive formats, you may specify the option when you call `pg_restore`.

-C | --create

Begin the output with a command to create the database itself and reconnect to the created database. (With a script of this form, it doesn't matter which database in the destination installation you connect to before running the script.) If `--clean` is also specified, the script drops and recreates the target database before reconnecting to it. This option is only meaningful for the plain-text format. For the archive formats, you may specify the option when you call `pg_restore`.

-E encoding | --encoding=encoding

Create the dump in the specified character set encoding. By default, the dump is created in the database encoding. (Another way to get the same result is to set the `PGCLIENTENCODING` environment variable to the desired dump encoding.)

-f file | --file=file

Send output to the specified file. This parameter can be omitted for file-based output formats, in which case the standard output is used. It must be given for the directory output format however, where it specifies the target directory instead of a file. In this case the directory is created by `pg_dump` and must not exist before.

-F plclldlt | --format=plain|custom|directory|tar

Selects the format of the output. format can be one of the following:

`p | plain` — Output a plain-text SQL script file (the default).

`c | custom` — Output a custom archive suitable for input into `pg_restore`. Together with the directory output format, this is the most flexible output format in that it allows manual selection and reordering of archived items during restore. This format is compressed by default and also supports parallel dumps.

`d | directory` — Output a directory-format archive suitable for input into `pg_restore`. This will create a directory with one file for each table and blob being dumped, plus a so-called Table of Contents file describing the dumped objects in a machine-readable format that `pg_restore` can read. A directory format archive can be manipulated with standard Unix tools; for example, files in an uncompressed archive can be compressed with the `gzip` tool. This format is compressed by default.

`t | tar` — Output a tar-format archive suitable for input into `pg_restore`. The tar format is compatible with the directory format; extracting a tar-format archive produces a valid directory-format archive. However, the tar format does not support compression. Also, when using tar format the relative order of table data items cannot be changed during restore.

-j njobs | --jobs=njobs

Run the dump in parallel by dumping njobs tables simultaneously. This option reduces the time of the dump but it also increases the load on the database server. You can only use this option with the directory output format because this is the only output format where multiple processes can write their data at the same time.

Note: Parallel dumps using `pg_dump` are parallelized only on the query dispatcher (master) node, not across the query executor (segment) nodes as is the case when you use `gpbackup`.

`pg_dump` will open njobs + 1 connections to the database, so make sure your `max_connections`

setting is high enough to accommodate all connections.

Requesting exclusive locks on database objects while running a parallel dump could cause the dump to fail. The reason is that the `pg_dump` master process requests shared locks on the objects that the worker processes are going to dump later in order to make sure that nobody deletes them and makes them go away while the dump is running. If another client then requests an exclusive lock on a table, that lock will not be granted but will be queued waiting for the shared lock of the master process to be released. Consequently, any other access to the table will not be granted either and will queue after the exclusive lock request. This includes the worker process trying to dump the table. Without any precautions this would be a classic deadlock situation. To detect this conflict, the `pg_dump` worker process requests another shared lock using the `NOWAIT` option. If the worker process is not granted this shared lock, somebody else must have requested an exclusive lock in the meantime and there is no way to continue with the dump, so `pg_dump` has no choice but to cancel the dump.

For a consistent backup, the database server needs to support synchronized snapshots, a feature that was introduced in Greenplum Database 6.0. With this feature, database clients can ensure they see the same data set even though they use different connections. `pg_dump -j` uses multiple database connections; it connects to the database once with the master process and once again for each worker job. Without the synchronized snapshot feature, the different worker jobs wouldn't be guaranteed to see the same data in each connection, which could lead to an inconsistent backup.

If you want to run a parallel dump of a pre-6.0 server, you need to make sure that the database content doesn't change from between the time the master connects to the database until the last worker job has connected to the database. The easiest way to do this is to halt any data modifying processes (DDL and DML) accessing the database before starting the backup. You also need to specify the `--no-synchronized-snapshots` parameter when running `pg_dump -j` against a pre-6.0 Greenplum Database server.

`-n schema | --schema=schema`

Dump only schemas matching the schema pattern; this selects both the schema itself, and all its contained objects. When this option is not specified, all non-system schemas in the target database will be dumped. Multiple schemas can be selected by writing multiple `-n` switches. Also, the schema parameter is interpreted as a pattern according to the same rules used by `psql's \d` commands, so multiple schemas can also be selected by writing wildcard characters in the pattern. When using wildcards, be careful to quote the pattern if needed to prevent the shell from expanding the wildcards.

Note: When `-n` is specified, `pg_dump` makes no attempt to dump any other database objects that the selected schema(s) may depend upon. Therefore, there is no guarantee that the results of a specific-schema dump can be successfully restored by themselves into a clean database.

Note: Non-schema objects such as blobs are not dumped when `-n` is specified. You can add blobs back to the dump with the `--blobs` switch.

`-N schema | --exclude-schema=schema`

Do not dump any schemas matching the schema pattern. The pattern is interpreted according to the same rules as for `-n`. `-N` can be given more than once to exclude schemas matching any of several patterns. When both `-n` and `-N` are given, the behavior is to dump just the schemas that match at least one `-n` switch but no `-N` switches. If `-N` appears without `-n`, then schemas matching `-N` are excluded from what is otherwise a normal dump.

`-o | --oids`

Dump object identifiers (OIDs) as part of the data for every table. Use of this option is not recommended for files that are intended to be restored into Greenplum Database.

-O | -no-owner

Do not output commands to set ownership of objects to match the original database. By default, `pg_dump` issues `ALTER OWNER` or `SET SESSION AUTHORIZATION` statements to set ownership of created database objects. These statements will fail when the script is run unless it is started by a superuser (or the same user that owns all of the objects in the script). To make a script that can be restored by any user, but will give that user ownership of all the objects, specify `-O`. This option is only meaningful for the plain-text format. For the archive formats, you may specify the option when you call `pg_restore`.

-s | -schema-only

Dump only the object definitions (schema), not data.

This option is the inverse of `--data-only`. It is similar to, but for historical reasons not identical to, specifying `--section=pre-data --section=post-data`.

(Do not confuse this with the `--schema` option, which uses the word “schema” in a different meaning.)

To exclude table data for only a subset of tables in the database, see `--exclude-table-data`.

-S username | -superuser=username

Specify the superuser user name to use when disabling triggers. This is relevant only if `--disable-triggers` is used. It is better to leave this out, and instead start the resulting script as a superuser.

Note: Greenplum Database does not support user-defined triggers.

-t table | -table=table

Dump only tables (or views or sequences or foreign tables) matching the table pattern. Specify the table in the format `schema.table`.

Multiple tables can be selected by writing multiple `-t` switches. Also, the table parameter is interpreted as a pattern according to the same rules used by `psql's \d` commands, so multiple tables can also be selected by writing wildcard characters in the pattern. When using wildcards, be careful to quote the pattern if needed to prevent the shell from expanding the wildcards. The `-n` and `-N` switches have no effect when `-t` is used, because tables selected by `-t` will be dumped regardless of those switches, and non-table objects will not be dumped.

Note: When `-t` is specified, `pg_dump` makes no attempt to dump any other database objects that the selected table(s) may depend upon. Therefore, there is no guarantee that the results of a specific-table dump can be successfully restored by themselves into a clean database.

Also, `-t` cannot be used to specify a child table partition. To dump a partitioned table, you must specify the parent table name.

-T table | -exclude-table=table

Do not dump any tables matching the table pattern. The pattern is interpreted according to the same rules as for `-t`. `-T` can be given more than once to exclude tables matching any of several patterns. When both `-t` and `-T` are given, the behavior is to dump just the tables that match at least one `-t` switch but no `-T` switches. If `-T` appears without `-t`, then tables matching `-T` are excluded from what is otherwise a normal dump.

-v | -verbose

Specifies verbose mode. This will cause `pg_dump` to output detailed object comments and start/stop times to the dump file, and progress messages to standard error.

-V | -version

Print the `pg_dump` version and exit.

-x | -no-privileges | -no-acl

Prevent dumping of access privileges (`GRANT/REVOKE` commands).

-Z 0..9 | –compress=0..9

Specify the compression level to use. Zero means no compression. For the custom archive format, this specifies compression of individual table-data segments, and the default is to compress at a moderate level.

For plain text output, setting a non-zero compression level causes the entire output file to be compressed, as though it had been fed through `gzip`; but the default is not to compress. The tar archive format currently does not support compression at all.

–binary-upgrade

This option is for use by in-place upgrade utilities. Its use for other purposes is not recommended or supported. The behavior of the option may change in future releases without notice.

–column-inserts | –attribute-inserts

Dump data as `INSERT` commands with explicit column names (`INSERT INTO table (column, ...) VALUES ...`). This will make restoration very slow; it is mainly useful for making dumps that can be loaded into non-PostgreSQL-based databases. However, since this option generates a separate command for each row, an error in reloading a row causes only that row to be lost rather than the entire table contents.

–disable-dollar-quoting

This option disables the use of dollar quoting for function bodies, and forces them to be quoted using SQL standard string syntax.

–disable-triggers

This option is relevant only when creating a data-only dump. It instructs `pg_dump` to include commands to temporarily disable triggers on the target tables while the data is reloaded. Use this if you have triggers on the tables that you do not want to invoke during data reload. The commands emitted for `--disable-triggers` must be done as superuser. So, you should also specify a superuser name with `-s`, or preferably be careful to start the resulting script as a superuser. This option is only meaningful for the plain-text format. For the archive formats, you may specify the option when you call `pg_restore`.

Note: Greenplum Database does not support user-defined triggers.

`--exclude-table-data=table`

Do not dump data for any tables matching the table pattern. The pattern is interpreted according to the same rules as for `-t`. `--exclude-table-data` can be given more than once to exclude tables matching any of several patterns. This option is useful when you need the definition of a particular table even though you do not need the data in it.

To exclude data for all tables in the database, see `--schema-only`.

`--if-exists`

Use conditional commands (i.e. add an `IF EXISTS` clause) when cleaning database objects.

This option is not valid unless `--clean` is also specified.

–inserts

Dump data as `INSERT` commands (rather than `COPY`). This will make restoration very slow; it is mainly useful for making dumps that can be loaded into non-PostgreSQL-based databases. However, since this option generates a separate command for each row, an error in reloading a row causes only that row to be lost rather than the entire table contents. Note that the restore may fail altogether if you have rearranged column order. The `--column-inserts` option is safe against column order changes, though even slower.

–lock-wait-timeout=timeout

Do not wait forever to acquire shared table locks at the beginning of the dump. Instead, fail if unable to lock a table within the specified timeout. Specify timeout as a number of milliseconds.

- no-security-labels
Do not dump security labels.
- no-synchronized-snapshots
This option allows running `pg_dump -j` against a pre-6.0 Greenplum Database server; see the documentation of the `-j` parameter for more details.
- no-tablespaces
Do not output commands to select tablespaces. With this option, all objects will be created in whichever tablespace is the default during restore.

This option is only meaningful for the plain-text format. For the archive formats, you can specify the option when you call `pg_restore`.
- no-unlogged-table-data
Do not dump the contents of unlogged tables. This option has no effect on whether or not the table definitions (schema) are dumped; it only suppresses dumping the table data. Data in unlogged tables is always excluded when dumping from a standby server.
- quote-all-identifiers
Force quoting of all identifiers. This option is recommended when dumping a database from a server whose Greenplum Database major version is different from `pg_dump`'s, or when the output is intended to be loaded into a server of a different major version. By default, `pg_dump` quotes only identifiers that are reserved words in its own major version. This sometimes results in compatibility issues when dealing with servers of other versions that may have slightly different sets of reserved words. Using `--quote-all-identifiers` prevents such issues, at the price of a harder-to-read dump script.
- section=sectionname
Only dump the named section. The section name can be `pre-data`, `data`, or `post-data`. This option can be specified more than once to select multiple sections. The default is to dump all sections.

The `data` section contains actual table data and sequence values. `post-data` items include definitions of indexes, triggers, rules, and constraints other than validated check constraints. `pre-data` items include all other data definition items.
- serializable-deferrable
Use a serializable transaction for the dump, to ensure that the snapshot used is consistent with later database states; but do this by waiting for a point in the transaction stream at which no anomalies can be present, so that there isn't a risk of the dump failing or causing other transactions to roll back with a `serialization_failure`.

This option is not beneficial for a dump which is intended only for disaster recovery. It could be useful for a dump used to load a copy of the database for reporting or other read-only load sharing while the original database continues to be updated. Without it the dump may reflect a state which is not consistent with any serial execution of the transactions eventually committed. For example, if batch processing techniques are used, a batch may show as closed in the dump without all of the items which are in the batch appearing.

This option will make no difference if there are no read-write transactions active when `pg_dump` is started. If read-write transactions are active, the start of the dump may be delayed for an indeterminate length of time. Once running, performance with or without the switch is the same.

Note: Because Greenplum Database does not support serializable transactions, the `--serializable-deferrable` option has no effect in Greenplum Database.
- use-set-session-authorization
Output SQL-standard `SET SESSION AUTHORIZATION` commands instead of `ALTER OWNER` commands to determine object ownership. This makes the dump more standards-compatible,

but depending on the history of the objects in the dump, may not restore properly. A dump using `SET SESSION AUTHORIZATION` will require superuser privileges to restore correctly, whereas `ALTER OWNER` requires lesser privileges.

`-gp-syntax | -no-gp-syntax`

Use `--gp-syntax` to dump Greenplum Database syntax in the `CREATE TABLE` statements. This allows the distribution policy (`DISTRIBUTED BY` or `DISTRIBUTED RANDOMLY` clauses) of a Greenplum Database table to be dumped, which is useful for restoring into other Greenplum Database systems. The default is to include Greenplum Database syntax when connected to a Greenplum Database system, and to exclude it when connected to a regular PostgreSQL system.

`-function-oids oids`

Dump the function(s) specified in the oids list of object identifiers.

Note: This option is provided solely for use by other administration utilities; its use for any other purpose is not recommended or supported. The behavior of the option may change in future releases without notice.

`-relation-oids oids`

Dump the relation(s) specified in the oids list of object identifiers.

Note: This option is provided solely for use by other administration utilities; its use for any other purpose is not recommended or supported. The behavior of the option may change in future releases without notice.

`-? | -help`

Show help about `pg_dump` command line arguments, and exit.

Connection Options

`-d dbname | -dbname=dbname`

Specifies the name of the database to connect to. This is equivalent to specifying `dbname` as the first non-option argument on the command line.

If this parameter contains an `=` sign or starts with a valid URI prefix (`postgresql://` or `postgres://`), it is treated as a conninfo string. See [Connection Strings](#) in the PostgreSQL documentation for more information.

`-h host | -host=host`

The host name of the machine on which the Greenplum Database master database server is running. If not specified, reads from the environment variable `PGHOST` or defaults to `localhost`.

`-p port | -port=port`

The TCP port on which the Greenplum Database master database server is listening for connections. If not specified, reads from the environment variable `PGPORT` or defaults to 5432.

`-U username | -username=username`

The database role name to connect as. If not specified, reads from the environment variable `PGUSER` or defaults to the current system role name.

`-W | -password`

Force a password prompt.

`-w | -no-password`

Never issue a password prompt. If the server requires password authentication and a password is not available by other means such as a `.pgpass` file the connection attempt will fail. This option can be useful in batch jobs and scripts where no user is present to enter a password.

`-role=rolename`

Specifies a role name to be used to create the dump. This option causes `pg_dump` to issue a `SET ROLE rolename` command after connecting to the database. It is useful when the

authenticated user (specified by `-U`) lacks privileges needed by `pg_dump`, but can switch to a role with the required rights. Some installations have a policy against logging in directly as a superuser, and use of this option allows dumps to be made without violating the policy.

Notes

When a data-only dump is chosen and the option `--disable-triggers` is used, `pg_dump` emits commands to disable triggers on user tables before inserting the data and commands to re-enable them after the data has been inserted. If the restore is stopped in the middle, the system catalogs may be left in the wrong state.

The dump file produced by `pg_dump` does not contain the statistics used by the optimizer to make query planning decisions. Therefore, it is wise to run `ANALYZE` after restoring from a dump file to ensure optimal performance.

The database activity of `pg_dump` is normally collected by the statistics collector. If this is undesirable, you can set parameter `track_counts` to false via `PGOPTIONS` or the `ALTER USER` command.

Because `pg_dump` may be used to transfer data to newer versions of Greenplum Database, the output of `pg_dump` can be expected to load into Greenplum Database versions newer than `pg_dump`'s version. `pg_dump` can also dump from Greenplum Database versions older than its own version. However, `pg_dump` cannot dump from Greenplum Database versions newer than its own major version; it will refuse to even try, rather than risk making an invalid dump. Also, it is not guaranteed that `pg_dump`'s output can be loaded into a server of an older major version — not even if the dump was taken from a server of that version. Loading a dump file into an older server may require manual editing of the dump file to remove syntax not understood by the older server. Use of the `--quote-all-identifiers` option is recommended in cross-version cases, as it can prevent problems arising from varying reserved-word lists in different Greenplum Database versions.

Examples

Dump a database called `mydb` into a SQL-script file:

```
pg_dump mydb > db.sql
```

To reload such a script into a (freshly created) database named `newdb`:

```
psql -d newdb -f db.sql
```

Dump a Greenplum Database in tar file format and include distribution policy information:

```
pg_dump -Ft --gp-syntax mydb > db.tar
```

To dump a database into a custom-format archive file:

```
pg_dump -Fc mydb > db.dump
```

To dump a database into a directory-format archive:

```
pg_dump -Fd mydb -f dumpdir
```

To dump a database into a directory-format archive in parallel with 5 worker jobs:

```
pg_dump -Fd mydb -j 5 -f dumpdir
```

To reload an archive file into a (freshly created) database named `newdb`:

```
pg_restore -d newdb db.dump
```

To dump a single table named `mytab`:

```
pg_dump -t mytab mydb > db.sql
```

To specify an upper-case or mixed-case name in `-t` and related switches, you need to double-quote the name; else it will be folded to lower case. But double quotes are special to the shell, so in turn they must be quoted. Thus, to dump a single table with a mixed-case name, you need something like:

```
pg_dump -t '"MixedCaseName"' mydb > mytab.sql
```

See Also

[pg_dumpall](#), [pg_restore](#), [psql](#)

pg_dumpall

Extracts all databases in a Greenplum Database system to a single script file or other archive file.

Synopsis

```
pg_dumpall [<connection-option> ...] [<dump_option> ...]

pg_dumpall -? | --help

pg_dumpall -V | --version
```

Description

`pg_dumpall` is a standard PostgreSQL utility for backing up all databases in a Greenplum Database (or PostgreSQL) instance, and is also supported in Greenplum Database. It creates a single (non-parallel) dump file. For routine backups of Greenplum Database it is better to use the Greenplum Database backup utility, [gpbackup](#), for the best performance.

`pg_dumpall` creates a single script file that contains SQL commands that can be used as input to [psql](#) to restore the databases. It does this by calling `pg_dump` for each database. `pg_dumpall` also dumps global objects that are common to all databases. (`pg_dump` does not save these objects.) This currently includes information about database users and groups, and access permissions that apply to databases as a whole.

Since `pg_dumpall` reads tables from all databases you will most likely have to connect as a database superuser in order to produce a complete dump. Also you will need superuser privileges to run the saved script in order to be allowed to add users and groups, and to create databases.

The SQL script will be written to the standard output. Use the `[-f | --file]` option or shell operators to redirect it into a file.

`pg_dumpall` needs to connect several times to the Greenplum Database master server (once per database). If you use password authentication it is likely to ask for a password each time. It is convenient to have a `~/.pgpass` file in such cases.

Options

Dump Options

- a | -data-only
Dump only the data, not the schema (data definitions). This option is only meaningful for the plain-text format. For the archive formats, you may specify the option when you call `pg_restore`.
- c | -clean
Output commands to clean (drop) database objects prior to (the commands for) creating them. This option is only meaningful for the plain-text format. For the archive formats, you may specify the option when you call `pg_restore`.
- f filename | -file=filename
Send output to the specified file.
- g | -globals-only
Dump only global objects (roles and tablespaces), no databases.
- o | -oids
Dump object identifiers (OIDs) as part of the data for every table. Use of this option is not recommended for files that are intended to be restored into Greenplum Database.
- O | -no-owner
Do not output commands to set ownership of objects to match the original database. By default, `pg_dump` issues `ALTER OWNER` or `SET SESSION AUTHORIZATION` statements to set ownership of created database objects. These statements will fail when the script is run unless it is started by a superuser (or the same user that owns all of the objects in the script). To make a script that can be restored by any user, but will give that user ownership of all the objects, specify `-o`. This option is only meaningful for the plain-text format. For the archive formats, you may specify the option when you call `pg_restore`.
- r | -roles-only
Dump only roles, not databases or tablespaces.
- s | -schema-only
Dump only the object definitions (schema), not data.
- S username | -superuser=username
Specify the superuser user name to use when disabling triggers. This is relevant only if `--disable-triggers` is used. It is better to leave this out, and instead start the resulting script as a superuser.

Note: Greenplum Database does not support user-defined triggers.
- t | -tablespaces-only
Dump only tablespaces, not databases or roles.
- v | -verbose
Specifies verbose mode. This will cause `[pg_]_dump` (`pg_dump.html`) to output detailed object comments and start/stop times to the dump file, and progress messages to standard error.
- V | -version
Print the `pg_dumpall` version and exit.
- x | -no-privileges | -no-acl
Prevent dumping of access privileges (`GRANT/REVOKE` commands).
- binary-upgrade
This option is for use by in-place upgrade utilities. Its use for other purposes is not recommended or supported. The behavior of the option may change in future releases without notice.
- column-inserts | -attribute-inserts
Dump data as `INSERT` commands with explicit column names (`INSERT INTO <table> (<column>, ...) VALUES ...`). This will make restoration very slow; it is mainly useful for

making dumps that can be loaded into non-PostgreSQL-based databases. Also, since this option generates a separate command for each row, an error in reloading a row causes only that row to be lost rather than the entire table contents.

– disable-dollar-quoting

This option disables the use of dollar quoting for function bodies, and forces them to be quoted using SQL standard string syntax.

– disable-triggers

This option is relevant only when creating a data-only dump. It instructs `pg_dumpall` to include commands to temporarily disable triggers on the target tables while the data is reloaded. Use this if you have triggers on the tables that you do not want to invoke during data reload. The commands emitted for `--disable-triggers` must be done as superuser. So, you should also specify a superuser name with `-S`, or preferably be careful to start the resulting script as a superuser.

Note: Greenplum Database does not support user-defined triggers.

– inserts

Dump data as `INSERT` commands (rather than `COPY`). This will make restoration very slow; it is mainly useful for making dumps that can be loaded into non-PostgreSQL-based databases. Also, since this option generates a separate command for each row, an error in reloading a row causes only that row to be lost rather than the entire table contents. Note that the restore may fail altogether if you have rearranged column order. The `--column-inserts` option is safe against column order changes, though even slower.

– lock-wait-timeout=timeout

Do not wait forever to acquire shared table locks at the beginning of the dump. Instead, fail if unable to lock a table within the specified timeout. The timeout may be specified in any of the formats accepted by `SET statement_timeout`. Allowed values vary depending on the server version you are dumping from, but an integer number of milliseconds is accepted by all Greenplum Database versions.

– no-security-labels

Do not dump security labels.

– no-tablespaces

Do not output commands to select tablespaces. With this option, all objects will be created in whichever tablespace is the default during restore.

– no-unlogged-table-data

Do not dump the contents of unlogged tables. This option has no effect on whether or not the table definitions (schema) are dumped; it only suppresses dumping the table data.

– quote-all-identifiers

Force quoting of all identifiers. This option is recommended when dumping a database from a server whose Greenplum Database major version is different from `pg_dumpall`'s, or when the output is intended to be loaded into a server of a different major version. By default, `pg_dumpall` quotes only identifiers that are reserved words in its own major version. This sometimes results in compatibility issues when dealing with servers of other versions that may have slightly different sets of reserved words. Using `--quote-all-identifiers` prevents such issues, at the price of a harder-to-read dump script.

– resource-queues

Dump resource queue definitions.

– resource-groups

Dump resource group definitions.

– use-set-session-authorization

Output SQL-standard `SET SESSION AUTHORIZATION` commands instead of `ALTER OWNER` commands to determine object ownership. This makes the dump more standards compatible, but depending on the history of the objects in the dump, may not restore properly. A dump

using `SET SESSION AUTHORIZATION` will require superuser privileges to restore correctly, whereas `ALTER OWNER` requires lesser privileges.

– gp-syntax

Output Greenplum Database syntax in the `CREATE TABLE` statements. This allows the distribution policy (`DISTRIBUTED BY` or `DISTRIBUTED RANDOMLY` clauses) of a Greenplum Database table to be dumped, which is useful for restoring into other Greenplum Database systems.

– no-gp-syntax

Do not output the table distribution clauses in the `CREATE TABLE` statements.

–? | – help

Show help about `pg_dumpall` command line arguments, and exit.

Connection Options

–d connstr | – dbname=connstr

Specifies parameters used to connect to the server, as a connection string. See [Connection Strings](#) in the PostgreSQL documentation for more information.

The option is called `--dbname` for consistency with other client applications, but because `pg_dumpall` needs to connect to many databases, the database name in the connection string will be ignored. Use the `-l` option to specify the name of the database used to dump global objects and to discover what other databases should be dumped.

–h host | – host=host

The host name of the machine on which the Greenplum master database server is running. If not specified, reads from the environment variable `PGHOST` or defaults to `localhost`.

–l dbname | – database=dbname

Specifies the name of the database in which to connect to dump global objects. If not specified, the `postgres` database is used. If the `postgres` database does not exist, the `template1` database is used.

–p port | – port=port

The TCP port on which the Greenplum master database server is listening for connections. If not specified, reads from the environment variable `PGPORT` or defaults to 5432.

–U username | – username= username

The database role name to connect as. If not specified, reads from the environment variable `PGUSER` or defaults to the current system role name.

–w | – no-password

Never issue a password prompt. If the server requires password authentication and a password is not available by other means such as a `.pgpass` file the connection attempt will fail. This option can be useful in batch jobs and scripts where no user is present to enter a password.

–W | – password

Force a password prompt.

– role=rolename

Specifies a role name to be used to create the dump. This option causes `pg_dumpall` to issue a `SET ROLE <rolename>` command after connecting to the database. It is useful when the authenticated user (specified by `-u`) lacks privileges needed by `pg_dumpall`, but can switch to a role with the required rights. Some installations have a policy against logging in directly as a superuser, and use of this option allows dumps to be made without violating the policy.

Notes

Since `pg_dumpall` calls `pg_dump` internally, some diagnostic messages will refer to `pg_dump`.

Once restored, it is wise to run `ANALYZE` on each database so the query planner has useful statistics. You can also run `vacuumdb -a -z` to vacuum and analyze all databases.

`pg_dumpall` requires all needed tablespace directories to exist before the restore; otherwise, database creation will fail for databases in non-default locations.

Examples

To dump all databases:

```
pg_dumpall > db.out
```

To reload database(s) from this file, you can use:

```
psql template1 -f db.out
```

To dump only global objects (including resource queues):

```
pg_dumpall -g --resource-queues
```

psql

Interactive command-line interface for Greenplum Database

Synopsis

```
psql [<option> ...] [<dbname> [<username>]]
```

Description

`psql` is a terminal-based front-end to Greenplum Database. It enables you to type in queries interactively, issue them to Greenplum Database, and see the query results. Alternatively, input can be from a file. In addition, it provides a number of meta-commands and various shell-like features to facilitate writing scripts and automating a wide variety of tasks.

Options

`-a` | `-echo-all`

Print all nonempty input lines to standard output as they are read. (This does not apply to lines read interactively.) This is equivalent to setting the variable `ECHO` to `all`.

`-A` | `-no-align`

Switches to unaligned output mode. (The default output mode is aligned.)

`-c 'command'` | `-command= 'command'`

Specifies that `psql` is to run the specified command string, and then exit. This is useful in shell scripts. `command` must be either a command string that is completely parseable by the server, or a single backslash command. Thus you cannot mix SQL and `psql` meta-commands with this option. To achieve that, you could pipe the string into `psql`, like this:

```
echo '\x \ SELECT * FROM foo;' | psql
```

(\\ is the separator meta-command.)

If the command string contains multiple SQL commands, they are processed in a single transaction, unless there are explicit `BEGIN/COMMIT` commands included in the string to divide it into multiple transactions. This is different from the behavior when the same string is fed to `psql`'s standard input. Also, only the result of the last SQL command is returned.

`-d dbname | -dbname=dbname`

Specifies the name of the database to connect to. This is equivalent to specifying `dbname` as the first non-option argument on the command line.

If this parameter contains an `=` sign or starts with a valid URI prefix (`postgresql://` or `postgres://`), it is treated as a `conninfo` string. See [Connection Strings](#) in the PostgreSQL documentation for more information.

`-e | -echo-queries`

Copy all SQL commands sent to the server to standard output as well.

`-E | -echo-hidden`

Echo the actual queries generated by `\d` and other backslash commands. You can use this to study `psql`'s internal operations. This is equivalent to setting the variable `ECHO_HIDDEN` to `on`.

`-f filename | -file=filename`

Use the file `filename` as the source of commands instead of reading commands interactively. After the file is processed, `psql` terminates. This is in many ways equivalent to the meta-command `\i`.

If `filename` is `-` (hyphen), then standard input is read until an EOF indication or `\q` meta-command. Note however that Readline is not used in this case (much as if `-n` had been specified).

Using this option is subtly different from writing `psql < <filename>`. In general, both will do what you expect, but using `-f` enables some nice features such as error messages with line numbers. There is also a slight chance that using this option will reduce the start-up overhead. On the other hand, the variant using the shell's input redirection is (in theory) guaranteed to yield exactly the same output you would have received had you entered everything by hand.

`-F separator | -field-separator=separator`

Use the specified separator as the field separator for unaligned output.

`-H | -html`

Turn on HTML tabular output.

`-l | -list`

List all available databases, then exit. Other non-connection options are ignored.

`-L filename | -log-file=filename`

Write all query output into the specified log file, in addition to the normal output destination.

`-n | -no-readline`

Do not use Readline for line editing and do not use the command history. This can be useful to turn off tab expansion when cutting and pasting.

`-o filename | -output=filename`

Put all query output into the specified file.

`-P assignment | -pset=assignment`

Allows you to specify printing options in the style of `\pset` on the command line. Note that here you have to separate name and value with an equal sign instead of a space. Thus to set the output format to `LaTeX`, you could write `-P format=latex`.

`-q | -quiet`

Specifies that `psql` should do its work quietly. By default, it prints welcome messages and

various informational output. If this option is used, none of this happens. This is useful with the `-c` option. This is equivalent to setting the variable `QUIET` to `on`.

`-R separator | -record-separator=separator`

Use separator as the record separator for unaligned output.

`-s | -single-step`

Run in single-step mode. That means the user is prompted before each command is sent to the server, with the option to cancel execution as well. Use this to debug scripts.

`-S | -single-line`

Runs in single-line mode where a new line terminates an SQL command, as a semicolon does.

`-t | -tuples-only`

Turn off printing of column names and result row count footers, etc. This command is equivalent to `\pset tuples_only` and is provided for convenience.

`-T table_options | -table-attr= table_options`

Allows you to specify options to be placed within the HTML table tag. See `\pset` for details.

`-v assignment | -set=assignment | -variable= assignment`

Perform a variable assignment, like the `\set` meta command. Note that you must separate name and value, if any, by an equal sign on the command line. To unset a variable, leave off the equal sign. To set a variable with an empty value, use the equal sign but leave off the value. These assignments are done during a very early stage of start-up, so variables reserved for internal purposes might get overwritten later.

`-V | -version`

Print the `psql` version and exit.

`-x | -expanded`

Turn on the expanded table formatting mode.

`-X | -no-psqlrc`

Do not read the start-up file (neither the system-wide `psqlrc` file nor the user's `~/.psqlrc` file).

`-z | -field-separator-zero`

Set the field separator for unaligned output to a zero byte.

`-O | -record-separator-zero`

Set the record separator for unaligned output to a zero byte. This is useful for interfacing, for example, with `xargs -0`.

`-1 | -single-transaction`

When `psql` runs a script, adding this option wraps `BEGIN/COMMIT` around the script to run it as a single transaction. This ensures that either all the commands complete successfully, or no changes are applied.

If the script itself uses `BEGIN`, `COMMIT`, or `ROLLBACK`, this option will not have the desired effects. Also, if the script contains any command that cannot be run inside a transaction block, specifying this option will cause that command (and hence the whole transaction) to fail.

`-? | -help`

Show help about `psql` command line arguments, and exit.

Connection Options

`-h host | -host=host`

The host name of the machine on which the Greenplum master database server is running. If not specified, reads from the environment variable `PGHOST` or defaults to `localhost`.

When starting `psql` on the master host, if the host value begins with a slash, it is used as the directory for the UNIX-domain socket.

`-p port | -port=port`

The TCP port on which the Greenplum master database server is listening for connections. If not specified, reads from the environment variable `PGPORT` or defaults to 5432.

`-U username` | `-username=username`

The database role name to connect as. If not specified, reads from the environment variable `PGUSER` or defaults to the current system role name.

`-W` | `-password`

Force a password prompt. `psql` should automatically prompt for a password whenever the server requests password authentication. However, currently password request detection is not totally reliable, hence this option to force a prompt. If no password prompt is issued and the server requires password authentication, the connection attempt will fail.

`-w` `-no-password`

Never issue a password prompt. If the server requires password authentication and a password is not available by other means such as a `.pgpass` file, the connection attempt will fail. This option can be useful in batch jobs and scripts where no user is present to enter a password.

Note: This option remains set for the entire session, and so it affects uses of the meta-command `\connect` as well as the initial connection attempt.

Exit Status

`psql` returns 0 to the shell if it finished normally, 1 if a fatal error of its own (out of memory, file not found) occurs, 2 if the connection to the server went bad and the session was not interactive, and 3 if an error occurred in a script and the variable `ON_ERROR_STOP` was set.

Usage

Connecting to a Database

`psql` is a client application for Greenplum Database. In order to connect to a database you need to know the name of your target database, the host name and port number of the Greenplum master server and what database user name you want to connect as. `psql` can be told about those parameters via command line options, namely `-d`, `-h`, `-p`, and `-U` respectively. If an argument is found that does not belong to any option it will be interpreted as the database name (or the user name, if the database name is already given). Not all of these options are required; there are useful defaults. If you omit the host name, `psql` will connect via a UNIX-domain socket to a master server on the local host, or via TCP/IP to `localhost` on machines that do not have UNIX-domain sockets. The default master port number is 5432. If you use a different port for the master, you must specify the port. The default database user name is your operating-system user name, as is the default database name. Note that you cannot just connect to any database under any user name. Your database administrator should have informed you about your access rights.

When the defaults are not right, you can save yourself some typing by setting any or all of the environment variables `PGAPPNAME`, `PGDATABASE`, `PGHOST`, `PGPORT`, and `PGUSER` to appropriate values.

It is also convenient to have a `~/.pgpass` file to avoid regularly having to type in passwords. This file should reside in your home directory and contain lines of the following format:

```
<hostname>:<port>:<database>:<username>:<password>
```

The permissions on `.pgpass` must disallow any access to world or group (for example: `chmod 0600 ~/.pgpass`). If the permissions are less strict than this, the file will be ignored. (The file permissions are not currently checked on Microsoft Windows clients, however.)

An alternative way to specify connection parameters is in a `conninfo` string or a URI, which is used

instead of a database name. This mechanism gives you very wide control over the connection. For example:

```
$ psql "service=myservice sslmode=require"
$ psql postgresql://gpmaster:5433/mydb?sslmode=require
```

This way you can also use LDAP for connection parameter lookup as described in [LDAP Lookup of Connection Parameters](#) in the PostgreSQL documentation. See [Parameter Keywords](#) in the PostgreSQL documentation for more information on all the available connection options.

If the connection could not be made for any reason (insufficient privileges, server is not running, etc.), `psql` will return an error and terminate.

If at least one of standard input or standard output are a terminal, then `psql` sets the client encoding to `auto`, which will detect the appropriate client encoding from the locale settings (`LC_CTYPE` environment variable on Unix systems). If this doesn't work out as expected, the client encoding can be overridden using the environment variable `PGCLIENTENCODING`.

Entering SQL Commands

In normal operation, `psql` provides a prompt with the name of the database to which `psql` is currently connected, followed by the string `=>` for a regular user or `=#` for a superuser. For example:

```
testdb=>
testdb=#
```

At the prompt, the user may type in SQL commands. Ordinarily, input lines are sent to the server when a command-terminating semicolon is reached. An end of line does not terminate a command. Thus commands can be spread over several lines for clarity. If the command was sent and run without error, the results of the command are displayed on the screen.

If untrusted users have access to a database that has not adopted a [secure schema usage pattern](#), begin your session by removing publicly-writable schemas from `search_path`. You can add `options=-csearch_path=` to the connection string or issue `SELECT pg_catalog.set_config('search_path', '', false)` before other SQL commands. This consideration is not specific to `psql`; it applies to every interface for running arbitrary SQL commands.

Meta-Commands

Anything you enter in `psql` that begins with an unquoted backslash is a `psql` meta-command that is processed by `psql` itself. These commands help make `psql` more useful for administration or scripting. Meta-commands are more commonly called slash or backslash commands.

The format of a `psql` command is the backslash, followed immediately by a command verb, then any arguments. The arguments are separated from the command verb and each other by any number of whitespace characters.

To include whitespace into an argument you may quote it with single quotes. To include a single quote into such an argument, write two single quotes within single-quoted text. Anything contained in single quotes is furthermore subject to C-like substitutions for `\n` (new line), `\t` (tab), `\b` (backspace), `\r` (carriage return), `\f` (form feed), `\digits` (octal), and `\xdigits` (hexadecimal). A backslash preceding any other character within single-quoted text quotes that single character, whatever it is.

Within an argument, text that is enclosed in backquotes (``) is taken as a command line that is passed to the shell. The output of the command (with any trailing newline removed) replaces the backquoted text.

If an unquoted colon (:) followed by a `psql` variable name appears within an argument, it is replaced by the variable's value, as described in [SQL Interpolation](#).

Some commands take an SQL identifier (such as a table name) as argument. These arguments follow the syntax rules of SQL: Unquoted letters are forced to lowercase, while double quotes (") protect letters from case conversion and allow incorporation of whitespace into the identifier. Within double quotes, paired double quotes reduce to a single double quote in the resulting name. For example, `FOO"BAR"BAZ` is interpreted as `fooBARbaz`, and `"A weird" name"` becomes `A weird name`.

Parsing for arguments stops when another unquoted backslash occurs. This is taken as the beginning of a new meta-command. The special sequence `\\` (two backslashes) marks the end of arguments and continues parsing SQL commands, if any. That way SQL and `psql` commands can be freely mixed on a line. But in any case, the arguments of a meta-command cannot continue beyond the end of the line.

The following meta-commands are defined:

`\a`

If the current table output format is unaligned, it is switched to aligned. If it is not unaligned, it is set to unaligned. This command is kept for backwards compatibility. See `\pset` for a more general solution.

`\c | \connect [dbname [username] [host] [port]] | conninfo`

Establishes a new Greenplum Database connection. The connection parameters to use can be specified either using a positional syntax, or using `conninfo` connection strings as detailed in [libpq Connection Strings](#).

Where the command omits database name, user, host, or port, the new connection can reuse values from the previous connection. By default, values from the previous connection are reused except when processing a `conninfo` string. Passing a first argument of `-reuse-previous=on` or `-reuse-previous=off` overrides that default. When the command neither specifies nor reuses a particular parameter, the `libpq` default is used. Specifying any of `dbname`, `username`, `host` or `port` as `-` is equivalent to omitting that parameter.

If the new connection is successfully made, the previous connection is closed. If the connection attempt failed, the previous connection will only be kept if `psql` is in interactive mode. When running a non-interactive script, processing will immediately stop with an error. This distinction was chosen as a user convenience against typos, and a safety mechanism that scripts are not accidentally acting on the wrong database.

Examples:

```
=> \c mydb myuser host.dom 6432
=> \c service=foo
=> \c "host=localhost port=5432 dbname=mydb connect_timeout=10 sslmode=disable"
=> \c postgresql://tom@localhost/mydb?application_name=myapp
```

`\C [title]`

Sets the title of any tables being printed as the result of a query or unset any such title. This command is equivalent to `\pset title`.

`\cd [directory]`

Changes the current working directory. Without argument, changes to the current user's home directory. To print your current working directory, use `\!pwd`.

`\conninfo`

Displays information about the current connection including the database name, the user name, the type of connection (UNIX domain socket, `TCP/IP`, etc.), the host, and the port.

`\copy {table [(column_list)] | (query)} {from | to} { 'filename' | program 'command' | stdin |`

`stdout | pstdin | pstdout` [with] (option [, ...])]

Performs a frontend (client) copy. This is an operation that runs an SQL `[COPY]` ([../ref_guide/sql_commands/COPY.html](#)) command, but instead of the server reading or writing the specified file, `psql` reads or writes the file and routes the data between the server and the local file system. This means that file accessibility and privileges are those of the local user, not the server, and no SQL superuser privileges are required.

When `program` is specified, command is run by `psql` and the data from or to command is routed between the server and the client. This means that the execution privileges are those of the local user, not the server, and no SQL superuser privileges are required.

`\copy ... from stdin | to stdout` reads/writes based on the command input and output respectively. All rows are read from the same source that issued the command, continuing until `\.` is read or the stream reaches EOF. Output is sent to the same place as command output. To read/write from `psql`'s standard input or output, use `pstdin` or `pstdout`. This option is useful for populating tables in-line within a SQL script file.

The syntax of the command is similar to that of the SQL `COPY` command, and option must indicate one of the options of the SQL `COPY` command. Note that, because of this, special parsing rules apply to the `\copy` command. In particular, the variable substitution rules and backslash escapes do not apply.

This operation is not as efficient as the SQL `COPY` command because all data must pass through the client/server connection.

`\copyright`

Shows the copyright and distribution terms of PostgreSQL on which Greenplum Database is based.

`\d [relation_pattern] | \d+ [relation_pattern] | \dS [relation_pattern]`

For each relation (table, external table, view, materialized view, index, sequence, or foreign table) or composite type matching the relation pattern, show all columns, their types, the tablespace (if not the default) and any special attributes such as `NOT NULL` or defaults. Associated indexes, constraints, rules, and triggers are also shown. For foreign tables, the associated foreign server is shown as well.

- For some types of relation, `\d` shows additional information for each column: column values for sequences, indexed expressions for indexes, and foreign data wrapper options for foreign tables.
- The command form `\d+` is identical, except that more information is displayed: any comments associated with the columns of the table are shown, as is the presence of OIDs in the table, the view definition if the relation is a view.

For partitioned tables, the command `\d` or `\d+` specified with the root partition table or child partition table displays information about the table including partition keys on the current level of the partition table. The command `\d+` also displays the immediate child partitions of the table and whether the child partition is an external table or regular table.

For append-optimized tables and column-oriented tables, `\d+` displays the storage options for a table. For append-optimized tables, the options are displayed for the table. For column-oriented tables, storage options are displayed for each column.

- By default, only user-created objects are shown; supply a pattern or the `s` modifier to include system objects.

Note: If `\d` is used without a pattern argument, it is equivalent to `\dtvmsE` which will

show a list of all visible tables, views, materialized views, sequences, and foreign tables.

`\da[S] [aggregate_pattern]`

Lists aggregate functions, together with the data types they operate on. If a pattern is specified, only aggregates whose names match the pattern are shown. By default, only user-created objects are shown; supply a pattern or the `s` modifier to include system objects.

`\db[+] [tablespace_pattern]`

Lists all available tablespaces and their corresponding paths. If pattern is specified, only tablespaces whose names match the pattern are shown. If `+` is appended to the command name, each object is listed with its associated permissions.

`\dc[S+] [conversion_pattern]`

Lists conversions between character-set encodings. If a pattern is specified, only conversions whose names match the pattern are listed. By default, only user-created objects are shown; supply a pattern or the `s` modifier to include system objects. If `+` is appended to the command name, each object is listed with its associated description.

`\dC[+] [pattern]`

Lists type casts. If a pattern is specified, only casts whose source or target types match the pattern are listed. If `+` is appended to the command name, each object is listed with its associated description.

`\dd[S] [pattern]`

Shows the descriptions of objects of type `constraint`, `operator class`, `operator family`, `rule`, and `trigger`. All other comments may be viewed by the respective backslash commands for those object types.

`\dd` displays descriptions for objects matching the pattern, or of visible objects of the appropriate type if no argument is given. But in either case, only objects that have a description are listed. By default, only user-created objects are shown; supply a pattern or the `s` modifier to include system objects.

Descriptions for objects can be created with the `COMMENT` SQL command.

`\ddp [pattern]`

Lists default access privilege settings. An entry is shown for each role (and schema, if applicable) for which the default privilege settings have been changed from the built-in defaults. If pattern is specified, only entries whose role name or schema name matches the pattern are listed.

The `ALTER DEFAULT PRIVILEGES` command is used to set default access privileges. The meaning of the privilege display is explained under `GRANT`.

`\dD[S+] [domain_pattern]`

Lists domains. If a pattern is specified, only domains whose names match the pattern are shown. By default, only user-created objects are shown; supply a pattern or the `s` modifier to include system objects. If `+` is appended to the command name, each object is listed with its associated permissions and description.

`\dEimstPv[S+] [external_table | index | materialized_view | sequence | table | parent table | view]`

This is not the actual command name: the letters `E`, `i`, `m`, `s`, `t`, `P`, and `v` stand for external table, index, materialized view, sequence, table, parent table, and view, respectively. You can specify any or all of these letters, in any order, to obtain a listing of objects of these types. For example, `\dit` lists indexes and tables. If `+` is appended to the command name, each object is listed with its physical size on disk and its associated description, if any. If a pattern is specified, only objects whose names match the pattern are listed. By default, only user-created objects are shown; supply a pattern or the `s` modifier to include system objects.

`\des[+] [foreign_server_pattern]`

Lists foreign servers. If a pattern is specified, only those servers whose name matches the pattern are listed. If the form `\des+` is used, a full description of each server is shown, including the server's ACL, type, version, options, and description.

`\det[+] [foreign_table_pattern]`

Lists all foreign tables. If a pattern is specified, only entries whose table name or schema name matches the pattern are listed. If the form `\det+` is used, generic options and the foreign table description are also displayed.

`\deu[+] [user_mapping_pattern]`

Lists user mappings. If a pattern is specified, only those mappings whose user names match the pattern are listed. If the form `\deu+` is used, additional information about each mapping is shown.

Warning: `\deu+` might also display the user name and password of the remote user, so care should be taken not to disclose them.

`\dew[+] [foreign_data_wrapper_pattern]`

Lists foreign-data wrappers. If a pattern is specified, only those foreign-data wrappers whose name matches the pattern are listed. If the form `\dew+` is used, the ACL, options, and description of the foreign-data wrapper are also shown.

`\df[antwS+] [function_pattern]`

Lists functions, together with their arguments, return types, and function types, which are classified as “agg” (aggregate), “normal”, “trigger”, or “window”. To display only functions of a specific type(s), add the corresponding letters `a`, `n`, `t`, or `w`, to the command. If a pattern is specified, only functions whose names match the pattern are shown. If the form `\df+` is used, additional information about each function, including security, volatility, language, source code, and description, is shown. By default, only user-created objects are shown; supply a pattern or the `s` modifier to include system objects.

`\dF[+] [pattern]`

Lists text search configurations. If a pattern is specified, only configurations whose names match the pattern are shown. If the form `\dF+` is used, a full description of each configuration is shown, including the underlying text search parser and the dictionary list for each parser token type.

`\dFd[+] [pattern]`

Lists text search dictionaries. If a pattern is specified, only dictionaries whose names match the pattern are shown. If the form `\dFd+` is used, additional information is shown about each selected dictionary, including the underlying text search template and the option values.

`\dFp[+] [pattern]`

Lists text search parsers. If a pattern is specified, only parsers whose names match the pattern are shown. If the form `\dFp+` is used, a full description of each parser is shown, including the underlying functions and the list of recognized token types.

`\dFt[+] [pattern]`

Lists text search templates. If a pattern is specified, only templates whose names match the pattern are shown. If the form `\dFt+` is used, additional information is shown about each template, including the underlying function names.

`\dg[+] [role_pattern]`

Lists database roles. (Since the concepts of “users” and “groups” have been unified into “roles”, this command is now equivalent to `\du`.) If a pattern is specified, only those roles whose names match the pattern are listed. If the form `\dg+` is used, additional information is shown about each role; currently this adds the comment for each role.

`\dl`

This is an alias for `\lo_list`, which shows a list of large objects.

Note: Greenplum Database does not support the PostgreSQL [large object facility](#) for

streaming user data that is stored in large-object structures.

\dL[S+] [pattern]

Lists procedural languages. If a pattern is specified, only languages whose names match the pattern are listed. By default, only user-created languages are shown; supply the **s** modifier to include system objects. If **+** is appended to the command name, each language is listed with its call handler, validator, access privileges, and whether it is a system object.

\dn[S+] [schema_pattern]

Lists all available schemas (namespaces). If a pattern is specified, only schemas whose names match the pattern are listed. By default, only user- create objects are show; supply a pattern or the **s** modifier to include system objects. If **+** is appended to the command name, each object is listed with its associated permissions and description, if any.

\do[S] [operator_pattern]

Lists available operators with their operand and return types. If a pattern is specified, only operators whose names match the pattern are listed. By default, only user-created objects are shown; supply a pattern or the **s** modifier to include system objects.

\dO[S+] [pattern]

Lists collations. If a pattern is specified, only collations whose names match the pattern are listed. By default, only user-created objects are shown; supply a pattern or the **s** modifier to include system objects. If **+** is appended to the command name, each collation is listed with its associated description, if any. Note that only collations usable with the current database' s encoding are shown, so the results may vary in different databases of the same installation.

\dp [relation_pattern_to_show_privileges]

Lists tables, views, and sequences with their associated access privileges. If a pattern is specified, only tables, views, and sequences whose names match the pattern are listed. The **GRANT** and **REVOKE** commands are used to set access privileges. The meaning of the privilege display is explained under **GRANT**.

\drds [role-pattern [database-pattern]]

Lists defined configuration settings. These settings can be role-specific, database-specific, or both. role-pattern and database-pattern are used to select specific roles and database to list, respectively. If omitted, or if ***** is specified, all settings are listed, including those not role-specific or database-specific, respectively.

The **ALTER ROLE** and **ALTER DATABASE** commands are used to define per-role and per-database role configuration settings.

\dT[S+] [datatype_pattern]

Lists data types. If a pattern is specified, only types whose names match the pattern are listed. If **+** is appended to the command name, each type is listed with its internal name and size, its allowed values if it is an **enum** type, and its associated permissions. By default, only user-created objects are shown; supply a pattern or the **s** modifier to include system objects.

\du[+] [role_pattern]

Lists database roles. (Since the concepts of “users” and “groups” have been unified into “roles” , this command is now equivalent to **\dg**.) If a pattern is specified, only those roles whose names match the pattern are listed. If the form **\du+** is used, additional information is shown about each role; currently this adds the comment for each role.

\dx[+] [extension_pattern]

Lists installed extensions. If a pattern is specified, only those extensions whose names match the pattern are listed. If the form **\dx+** is used, all of the objects belonging to each matching extension are listed.

\dy[+] [pattern]

Lists event triggers. If a pattern is specified, only those triggers whose names match the pattern are listed. If **+** is appended to the command name, each object is listed with its associated description.

\dy[+] [pattern]

Lists event triggers. If a pattern is specified, only those triggers whose names match the pattern are listed. If `+` is appended to the command name, each object is listed with its associated description.

Note: Greenplum Database does not support user-defined triggers.

\e | \edit [filename] [line_number]

If filename is specified, the file is edited; after the editor exits, its content is copied back to the query buffer. If no filename is given, the current query buffer is copied to a temporary file which is then edited in the same fashion.

The new query buffer is then re-parsed according to the normal rules of `psql`, where the whole buffer is treated as a single line. (Thus you cannot make scripts this way. Use `\i` for that.) This means also that if the query ends with (or rather contains) a semicolon, it is immediately run. In other cases it will merely wait in the query buffer; type semicolon or `\g` to send it, or `\r` to cancel.

If a line number is specified, `psql` will position the cursor on the specified line of the file or query buffer. Note that if a single all-digits argument is given, `psql` assumes it is a line number, not a file name.

See [Environment](#) for information about configuring and customizing your editor.

\echo text [...]

Prints the arguments to the standard output, separated by one space and followed by a newline. This can be useful to intersperse information in the output of scripts. If the first argument is an unquoted `-n`, the trailing newline is not written.

Note: If you use the `\o` command to redirect your query output you might wish to use `\qecho` instead of this command.

\ef [function_description [line_number]]

This command fetches and edits the definition of the named function, in the form of a `CREATE OR REPLACE FUNCTION` command. Editing is done in the same way as for `\edit`. After the editor exits, the updated command waits in the query buffer; type semicolon or `\g` to send it, or `\r` to cancel.

The target function can be specified by name alone, or by name and arguments, for example `foo(integer, text)`. The argument types must be given if there is more than one function with the same name.

If no function is specified, a blank `CREATE FUNCTION` template is presented for editing.

If a line number is specified, `psql` will position the cursor on the specified line of the function body. (Note that the function body typically does not begin on the first line of the file.)

See [Environment](#) for information about configuring and customizing your editor.

\encoding [encoding]

Sets the client character set encoding. Without an argument, this command shows the current encoding.

\f [field_separator_string]

Sets the field separator for unaligned query output. The default is the vertical bar (`|`). See also `\pset` for a generic way of setting output options.

\g [filename]**\g [| command]**

Sends the current query input buffer to the server, and optionally stores the query's output in filename or pipes the output to the shell command command. The file or command is

written to only if the query successfully returns zero or more tuples, not if the query fails or is a non-data-returning SQL command.

A bare `\g` is essentially equivalent to a semi-colon. A `\g` with argument is a one-shot alternative to the `\o` command.

`\gset` [prefix]

Sends the current query input buffer to the server and stores the query's output into `psql` variables. The query to be run must return exactly one row. Each column of the row is stored into a separate variable, named the same as the column. For example:

```
=> SELECT 'hello' AS var1, 10 AS var2;
-> \gset
=> \echo :var1 :var2
hello 10
```

If you specify a prefix, that string is prepended to the query's column names to create the variable names to use:

```
=> SELECT 'hello' AS var1, 10 AS var2;
-> \gset result_
=> \echo :result_var1 :result_var2
hello 10
```

If a column result is NULL, the corresponding variable is unset rather than being set.

If the query fails or does not return one row, no variables are changed.

`\h` | `\help` [sql_command]

Gives syntax help on the specified SQL command. If a command is not specified, then `psql` will list all the commands for which syntax help is available. If command is an asterisk (*) then syntax help on all SQL commands is shown. To simplify typing, commands that consist of several words do not have to be quoted.

`\H` | `\html`

Turns on HTML query output format. If the HTML format is already on, it is switched back to the default aligned text format. This command is for compatibility and convenience, but see `\pset` about setting other output options.

`\i` | `\include` filename

Reads input from the file filename and runs it as though it had been typed on the keyboard.

If filename is - (hyphen), then standard input is read until an EOF indication or `\q` meta-command. This can be used to intersperse interactive input with input from files. Note that Readline behavior will be used only if it is active at the outermost level.

If you want to see the lines on the screen as they are read you must set the variable `ECHO` to `all`.

`\ir` | `\include_relative` filename

The `\ir` command is similar to `\i`, but resolves relative file names differently. When running in interactive mode, the two commands behave identically. However, when invoked from a script, `\ir` interprets file names relative to the directory in which the script is located, rather than the current working directory.

`\l` | `\list` [pattern]

List the databases in the server and show their names, owners, character set encodings, and access privileges. If a pattern is specified, only databases whose names match the pattern are listed. If + is appended to the command name, database sizes, default tablespaces, and descriptions are also displayed. (Size information is only available for databases that the current

user can connect to.)

`\lo_export oid filename`

Reads the large object with OID `oid` from the database and writes it to `filename`. Note that this is subtly different from the server function `lo_export`, which acts with the permissions of the user that the database server runs as and on the server's file system. Use `\lo_list` to find out the large object's OID.

Note: Greenplum Database does not support the PostgreSQL [large object facility](#) for streaming user data that is stored in large-object structures.

`\lo_import large_object_filename [comment]`

Stores the file into a large object. Optionally, it associates the given comment with the object.

Example:

```
mydb=> \lo_import '/home/gpadmin/pictures/photo.xcf' 'a
picture of me'
lo_import 152801
```

The response indicates that the large object received object ID 152801 which one ought to remember if one wants to access the object ever again. For that reason it is recommended to always associate a human-readable comment with every object. Those can then be seen with the `\lo_list` command. Note that this command is subtly different from the server-side `lo_import` because it acts as the local user on the local file system, rather than the server's user and file system.

Note: Greenplum Database does not support the PostgreSQL [large object facility](#) for streaming user data that is stored in large-object structures.

`\lo_list`

Shows a list of all large objects currently stored in the database, along with any comments provided for them.

Note: Greenplum Database does not support the PostgreSQL [large object facility](#) for streaming user data that is stored in large-object structures.

`\lo_unlink largeobject_oid`

Deletes the large object of the specified OID from the database. Use `\lo_list` to find out the large object's OID.

Note: Greenplum Database does not support the PostgreSQL [large object facility](#) for streaming user data that is stored in large-object structures.

`\o | \out [filename]`

`\o | \out [| command]`

Saves future query results to the file `filename` or pipes future results to the shell command `command`. If no argument is specified, the query output is reset to the standard output. Query results include all tables, command responses, and notices obtained from the database server, as well as output of various backslash commands that query the database (such as `\d`), but not error messages. To intersperse text output in between query results, use `\qecho`.

`\p`

Print the current query buffer to the standard output.

`\password [username]`

Changes the password of the specified user (by default, the current user). This command prompts for the new password, encrypts it, and sends it to the server as an `ALTER ROLE` command. This makes sure that the new password does not appear in cleartext in the command history, the server log, or elsewhere.

`\prompt [text] name`

Prompts the user to supply text, which is assigned to the variable `name`. An optional prompt

string, text, can be specified. (For multiword prompts, surround the text with single quotes.)

By default, `\prompt` uses the terminal for input and output. However, if the `-f` command line switch was used, `\prompt` uses standard input and standard output.

`\pset [print_option [value]]`

This command sets options affecting the output of query result tables. `print_option` describes which option is to be set. The semantics of `value` vary depending on the selected option. For some options, omitting `value` causes the option to be toggled or unset, as described under the particular option. If no such behavior is mentioned, then omitting `value` just results in the current setting being displayed.

`\pset` without any arguments displays the current status of all printing options.

Adjustable printing options are:

- `border` – The value must be a number. In general, the higher the number the more borders and lines the tables will have, but this depends on the particular format. In HTML format, this will translate directly into the `border=...` attribute; in the other formats only values 0 (no border), 1 (internal dividing lines), and 2 (table frame) make sense. `latex` and `latex-longtable` also support a `border` value of 3 which adds a dividing line between each row.
- `columns` – Sets the target width for the `wrapped` format, and also the width limit for determining whether output is wide enough to require the pager or switch to the vertical display in expanded auto mode. The default is zero. Zero causes the target width to be controlled by the environment variable `COLUMNS`, or the detected screen width if `COLUMNS` is not set. In addition, if `columns` is zero then the wrapped format affects screen output only. If `columns` is nonzero then file and pipe output is wrapped to that width as well.

After setting the target width, use the command `\pset format wrapped` to enable the wrapped format.

- `expanded | x` – If value is specified it must be either `on` or `off`, which will enable or disable expanded mode, or `auto`. If value is omitted the command toggles between the `on` and `off` settings. When expanded mode is enabled, query results are displayed in two columns, with the column name on the left and the data on the right. This mode is useful if the data wouldn't fit on the screen in the normal "horizontal" mode. In the `auto` setting, the expanded mode is used whenever the query output is wider than the screen, otherwise the regular mode is used. The `auto` setting is only effective in the aligned and wrapped formats. In other formats, it always behaves as if the expanded mode is `off`.
- `fieldsep` – Specifies the field separator to be used in unaligned output mode. That way one can create, for example, tab- or comma-separated output, which other programs might prefer. To set a tab as field separator, type `\pset fieldsep '\t'`. The default field separator is `'|'` (a vertical bar).
- `fieldsep_zero` – Sets the field separator to use in unaligned output format to a zero byte.
- `footer` – If value is specified it must be either `on` or `off` which will enable or disable display of the table footer (the (n rows) count). If value is omitted the command toggles footer display on or off.
- `format` – Sets the output format to one of `unaligned`, `aligned`, `html`, `latex` (uses `tabular`), `latex-longtable`, `troff-ms`, or `wrapped`. Unique abbreviations are allowed.

`unaligned` format writes all columns of a row on one line, separated by the currently active field separator. This is useful for creating output that might be intended to be read in by other programs (for example, tab-separated or comma-separated format).

`aligned` format is the standard, human-readable, nicely formatted text output; this is the default.

The `html`, `latex`, `latex-longtable`, and `troff-ms` formats put out tables that are intended to be included in documents using the respective mark-up language. They are not complete documents! (This might not be so dramatic in HTML, but in LaTeX you must have a complete document wrapper. `latex-longtable` also requires the LaTeX `longtable` and `booktabs` packages.)

The `wrapped` format is like `aligned`, but wraps wide data values across lines to make the output fit in the target column width. The target width is determined as described under the `columns` option. Note that `psql` does not attempt to wrap column header titles; the `wrapped` format behaves the same as `aligned` if the total width needed for column headers exceeds the target.

- `linestyle [unicode | ascii | old-ascii]` – Sets the border line drawing style to one of unicode, ascii, or old-ascii. Unique abbreviations, including one letter, are allowed for the three styles. The default setting is `ascii`. This option only affects the `aligned` and `wrapped` output formats.

`ascii` – uses plain ASCII characters. Newlines in data are shown using a `+` symbol in the right-hand margin. When the wrapped format wraps data from one line to the next without a newline character, a dot (`.`) is shown in the right-hand margin of the first line, and again in the left-hand margin of the following line.

`old-ascii` – style uses plain ASCII characters, using the formatting style used in PostgreSQL 8.4 and earlier. Newlines in data are shown using a `:` symbol in place of the left-hand column separator. When the data is wrapped from one line to the next without a newline character, a `;` symbol is used in place of the left-hand column separator.

`unicode` – style uses Unicode box-drawing characters. Newlines in data are shown using a carriage return symbol in the right-hand margin. When the data is wrapped from one line to the next without a newline character, an ellipsis symbol is shown in the right-hand margin of the first line, and again in the left-hand margin of the following line.

When the `border` setting is greater than zero, this option also determines the characters with which the border lines are drawn. Plain ASCII characters work everywhere, but Unicode characters look nicer on displays that recognize them.

- `null 'string'` – The second argument is a string to print whenever a column is null. The default is to print nothing, which can easily be mistaken for an empty string. For example, one might prefer `\pset null '(null)'`.
- `numericlocale` – If value is specified it must be either `on` or `off` which will enable or disable display of a locale-specific character to separate groups of digits to the left of the decimal marker. If value is omitted the command toggles between regular and locale-specific numeric output.

- `pager` – Controls the use of a pager for query and `psql` help output. If the environment variable `PAGER` is set, the output is piped to the specified program. Otherwise a platform-dependent default (such as `more`) is used. When `off`, the pager program is not used. When `on`, the pager is used only when appropriate, i.e. when the output is to a terminal and will not fit on the screen. Pager can also be set to `always`, which causes the pager to be used for all terminal output regardless of whether it fits on the screen. `\pset pager` without a value toggles pager use on and off.
- `recordsep` – Specifies the record (line) separator to use in unaligned output mode. The default is a newline character.
- `recordsep_zero` – Sets the record separator to use in unaligned output format to a zero byte.
- `tableattr` | `T` [text] – In HTML format, this specifies attributes to be placed inside the HTML `table` tag. This could for example be `cellpadding` or `bgcolor`. Note that you probably don't want to specify `border` here, as that is already taken care of by `\pset border`. If no value is given, the table attributes are unset.

In `latex-longtable` format, this controls the proportional width of each column containing a left-aligned data type. It is specified as a whitespace-separated list of values, e.g. `'0.2 0.2 0.6'`. Unspecified output columns use the last specified value.

- `title` [text] – Sets the table title for any subsequently printed tables. This can be used to give your output descriptive tags. If no value is given, the title is unset.
- `tuples_only` | `t` [novalue | on | off] – If value is specified, it must be either `on` or `off` which will enable or disable tuples-only mode. If value is omitted the command toggles between regular and tuples-only output. Regular output includes extra information such as column headers, titles, and various footers. In tuples-only mode, only actual table data is shown. The `\t` command is equivalent to `\pset` tuples_only` and is provided for convenience.

Tip:

There are various shortcut commands for `\pset`. See `\a`, `\C`, `\f`, `\H`, `\t`, `\T`, and `\x`.

`\q` | `\quit`

Quits the `psql` program. In a script file, only execution of that script is terminated.

`\qecho` text [...]

This command is identical to `\echo` except that the output will be written to the query output channel, as set by `\o`.

`\r` | `\reset`

Resets (clears) the query buffer.

`\s` [filename]

Print `psql`'s command line history to `filename`. If `filename` is omitted, the history is written to the standard output (using the pager if appropriate). This command is not available if `psql` was built without `Readline` support.

`\set` [name [value [...]]]

Sets the `psql` variable name to value, or if more than one value is given, to the concatenation of all of them. If only one argument is given, the variable is just set with an empty value. To unset a variable, use the `\unset` command.

`\set` without any arguments displays the names and values of all currently-set `psql` variables.

Valid variable names can contain characters, digits, and underscores. See “Variables” in [Advanced Features](#). Variable names are case-sensitive.

Although you are welcome to set any variable to anything you want, `psql` treats several variables as special. They are documented in the topic about variables.

This command is unrelated to the SQL command `SET`.

`\setenv name [value]`

Sets the environment variable `name` to `value`, or if the value is not supplied, unsets the environment variable. Example:

```
testdb=> \setenv PAGER less
testdb=> \setenv LESS -imx4F
```

`\sf[+] function_description`

This command fetches and shows the definition of the named function, in the form of a `CREATE OR REPLACE FUNCTION` command. The definition is printed to the current query output channel, as set by `\o`.

The target function can be specified by name alone, or by name and arguments, for example `foo(integer, text)`. The argument types must be given if there is more than one function of the same name.

If `+` is appended to the command name, then the output lines are numbered, with the first line of the function body being line 1.

`\t [novalue | on | off]`

The `\t` command by itself toggles a display of output column name headings and row count footer. The values `on` and `off` set the tuples display, regardless of the current setting. This command is equivalent to `\pset tuples_only` and is provided for convenience.

`\T table_options`

Specifies attributes to be placed within the `table` tag in HTML output format. This command is equivalent to `\pset tableattr table_options`

`\timing [novalue | on | off]`

Without a parameter, toggles a display of how long each SQL statement takes, in milliseconds. The values `on` and `off` set the time display, regardless of the current setting.

`\unset name`

Unsets (deletes) the `psql` variable name.

`\w | \write filename`

`\w | \write | command`

Outputs the current query buffer to the file `filename` or pipes it to the shell command `command`.

`\watch [seconds]`

Repeatedly runs the current query buffer (like `\g`) until interrupted or the query fails. Wait the specified number of seconds (default 2) between executions.

`\x [on | off | auto]`

Sets or toggles expanded table formatting mode. As such it is equivalent to `\pset expanded`.

`\z [pattern]`

Lists tables, views, and sequences with their associated access privileges. If a pattern is specified, only tables, views and sequences whose names match the pattern are listed. This is an alias for `\dp`.

`\! [command]`

Escapes to a separate shell or runs the shell command `command`. The arguments are not further interpreted; the shell will see them as-is. In particular, the variable substitution rules and backslash escapes do not apply.

`\?`

Shows help information about the `psql` backslash commands.

Patterns

The various `\d` commands accept a pattern parameter to specify the object name(s) to be displayed. In the simplest case, a pattern is just the exact name of the object. The characters within a pattern are normally folded to lower case, just as in SQL names; for example, `\dt FOO` will display the table named `foo`. As in SQL names, placing double quotes around a pattern stops folding to lower case. Should you need to include an actual double quote character in a pattern, write it as a pair of double quotes within a double-quote sequence; again this is in accord with the rules for SQL quoted identifiers. For example, `\dt "FOO""BAR"` will display the table named `FOO"BAR` (not `foo"bar`). Unlike the normal rules for SQL names, you can put double quotes around just part of a pattern, for instance `\dt FOO"FOO"BAR` will display the table named `fooFOObar`.

Within a pattern, `*` matches any sequence of characters (including no characters) and `?` matches any single character. (This notation is comparable to UNIX shell file name patterns.) For example, `\dt int*` displays all tables whose names begin with `int`. But within double quotes, `*` and `?` lose these special meanings and are just matched literally.

A pattern that contains a dot (`.`) is interpreted as a schema name pattern followed by an object name pattern. For example, `\dt foo*.bar*` displays all tables whose table name starts with `bar` that are in schemas whose schema name starts with `foo`. When no dot appears, then the pattern matches only objects that are visible in the current schema search path. Again, a dot within double quotes loses its special meaning and is matched literally.

Advanced users can use regular-expression notations. All regular expression special characters work as specified in the [PostgreSQL documentation on regular expressions](#), except for `.` which is taken as a separator as mentioned above, `*` which is translated to the regular-expression notation `.*`, and `?` which is translated to `.`. You can emulate these pattern characters at need by writing `?` for `.`, ``(R+|)`` for `R*`, or `(R|)`` for `R?`. Remember that the pattern must match the whole name, unlike the usual interpretation of regular expressions; write `*` at the beginning and/or end if you don't wish the pattern to be anchored. Note that within double quotes, all regular expression special characters lose their special meanings and are matched literally. Also, the regular expression special characters are matched literally in operator name patterns (such as the argument of `\do`).

Whenever the pattern parameter is omitted completely, the `\d` commands display all objects that are visible in the current schema search path – this is equivalent to using the pattern `*`. To see all objects in the database, use the pattern `*.*`.

Advanced Features

Variables

`psql` provides variable substitution features similar to common UNIX command shells. Variables are simply name/value pairs, where the value can be any string of any length. The name must consist of letters (including non-Latin letters), digits, and underscores.

To set a variable, use the `psql` meta-command `\set`. For example,

```
testdb=> \set foo bar
```

sets the variable `foo` to the value `bar`. To retrieve the content of the variable, precede the name with a colon, for example:

```
testdb=> \echo :foo
bar
```

This works in both regular SQL commands and meta-commands; there is more detail in [SQL Interpolation](#).

If you call `\set` without a second argument, the variable is set, with an empty string as value. To unset (i.e., delete) a variable, use the command `\unset`. To show the values of all variables, call `\set` without any argument.

Note: The arguments of `\set` are subject to the same substitution rules as with other commands. Thus you can construct interesting references such as `\set :foo 'something'` and get ‘soft links’ or ‘variable variables’ of Perl or PHP fame, respectively. Unfortunately, there is no way to do anything useful with these constructs. On the other hand, `\set bar :foo` is a perfectly valid way to copy a variable.

A number of these variables are treated specially by `psql`. They represent certain option settings that can be changed at run time by altering the value of the variable, or in some cases represent changeable state of `psql`. Although you can use these variables for other purposes, this is not recommended, as the program behavior might grow really strange really quickly. By convention, all specially treated variables’ names consist of all upper-case ASCII letters (and possibly digits and underscores). To ensure maximum compatibility in the future, avoid using such variable names for your own purposes. A list of all specially treated variables follows.

AUTOCOMMIT

When on (the default), each SQL command is automatically committed upon successful completion. To postpone commit in this mode, you must enter a `BEGIN` or `START TRANSACTION` SQL command. When off or unset, SQL commands are not committed until you explicitly issue `COMMIT` or `END`. The autocommit-on mode works by issuing an implicit `BEGIN` for you, just before any command that is not already in a transaction block and is not itself a `BEGIN` or other transaction-control command, nor a command that cannot be run inside a transaction block (such as `VACUUM`).

In autocommit-off mode, you must explicitly abandon any failed transaction by entering `ABORT` or `ROLLBACK`. Also keep in mind that if you exit the session without committing, your work will be lost.

The autocommit-on mode is PostgreSQL’s traditional behavior, but autocommit-off is closer to the SQL spec. If you prefer autocommit-off, you may wish to set it in your `~/.psqlrc` file.

COMP_KEYWORD_CASE

Determines which letter case to use when completing an SQL key word. If set to `lower` or `upper`, the completed word will be in lower or upper case, respectively. If set to `preserve-lower` or `preserve-upper` (the default), the completed word will be in the case of the word already entered, but words being completed without anything entered will be in lower or upper case, respectively.

DBNAME

The name of the database you are currently connected to. This is set every time you connect to a database (including program start-up), but can be unset.

ECHO

If set to `all`, all nonempty input lines are printed to standard output as they are read. (This does not apply to lines read interactively.) To select this behavior on program start-up, use the switch `-a`. If set to queries, `psql` prints each query to standard output as it is sent to the server. The switch for this is `-e`.

ECHO_HIDDEN

When this variable is set to `on` and a backslash command queries the database, the query is first shown. This feature helps you to study Greenplum Database internals and provide similar functionality in your own programs. (To select this behavior on program start-up, use the

switch `-E`.) If you set the variable to the value `noexec`, the queries are just shown but are not actually sent to the server and run.

ENCODING

The current client character set encoding.

FETCH_COUNT

If this variable is set to an integer value > 0 , the results of `SELECT` queries are fetched and displayed in groups of that many rows, rather than the default behavior of collecting the entire result set before display. Therefore only a limited amount of memory is used, regardless of the size of the result set. Settings of 100 to 1000 are commonly used when enabling this feature. Keep in mind that when using this feature, a query may fail after having already displayed some rows.

Although you can use any output format with this feature, the default aligned format tends to look bad because each group of `FETCH_COUNT` rows will be formatted separately, leading to varying column widths across the row groups. The other output formats work better.

HISTCONTROL

If this variable is set to `ignoreSPACE`, lines which begin with a space are not entered into the history list. If set to a value of `ignoreDUPS`, lines matching the previous history line are not entered. A value of `ignoreBOTH` combines the two options. If unset, or if set to any other value than those above, all lines read in interactive mode are saved on the history list.

HISTFILE

The file name that will be used to store the history list. The default value is `~/.psql_history`. For example, putting

```
\set HISTFILE ~/.psql_history- :DBNAME
```

in `~/.psqlrc` will cause `psql` to maintain a separate history for each database.

HISTSIZE

The number of commands to store in the command history. The default value is 500.

HOST

The database server host you are currently connected to. This is set every time you connect to a database (including program start-up), but can be unset.

IGNOREEOF

If unset, sending an `EOF` character (usually `CTRL+D`) to an interactive session of `psql` will terminate the application. If set to a numeric value, that many `EOF` characters are ignored before the application terminates. If the variable is set but has no numeric value, the default is 10.

LASTOID

The value of the last affected OID, as returned from an `INSERT` or `lo_import` command. This variable is only guaranteed to be valid until after the result of the next SQL command has been displayed.

ON_ERROR_ROLLBACK

When set to `on`, if a statement in a transaction block generates an error, the error is ignored and the transaction continues. When set to `interactive`, such errors are only ignored in interactive sessions, and not when reading script files. When unset or set to `off`, a statement in a transaction block that generates an error cancels the entire transaction. The error rollback mode works by issuing an implicit `SAVEPOINT` for you, just before each command that is in a transaction block, and rolls back to the savepoint on error.

ON_ERROR_STOP

By default, command processing continues after an error. When this variable is set to `on`, processing will instead stop immediately. In interactive mode, `psql` will return to the command prompt; otherwise, `psql` will exit, returning error code 3 to distinguish this case from fatal error

conditions, which are reported using error code 1. In either case, any currently running scripts (the top-level script, if any, and any other scripts which it may have invoked) will be terminated immediately. If the top-level command string contained multiple SQL commands, processing will stop with the current command.

PORT

The database server port to which you are currently connected. This is set every time you connect to a database (including program start-up), but can be unset.

PROMPT1

PROMPT2

PROMPT3

These specify what the prompts `psql` issues should look like. See “Prompting” .

QUIET

Setting this variable to `on` is equivalent to the command line option `-q`. It is not very useful in interactive mode.

SINGLELINE

This variable is equivalent to the command line option `-s`.

SINGLESTEP

Setting this variable to `on` is equivalent to the command line option `-s`.

USER

The database user you are currently connected as. This is set every time you connect to a database (including program start-up), but can be unset.

VERBOSITY

This variable can be set to the values `default`, `verbose`, or `terse` to control the verbosity of error reports.

SQL Interpolation

A key feature of `psql` variables is that you can substitute (“interpolate”) them into regular SQL statements, as well as the arguments of meta-commands. Furthermore, `psql` provides facilities for ensuring that variable values used as SQL literals and identifiers are properly quoted. The syntax for interpolating a value without any quoting is to prepend the variable name with a colon (`:`). For example,

```
testdb=> \set foo 'my_table'
testdb=> SELECT * FROM :foo;
```

would query the table `my_table`. Note that this may be unsafe: the value of the variable is copied literally, so it can contain unbalanced quotes, or even backslash commands. You must make sure that it makes sense where you put it.

When a value is to be used as an SQL literal or identifier, it is safest to arrange for it to be quoted. To quote the value of a variable as an SQL literal, write a colon followed by the variable name in single quotes. To quote the value as an SQL identifier, write a colon followed by the variable name in double quotes. These constructs deal correctly with quotes and other special characters embedded within the variable value. The previous example would be more safely written this way:

```
testdb=> \set foo 'my_table'
testdb=> SELECT * FROM :'foo';
```

Variable interpolation will not be performed within quoted SQL literals and identifiers. Therefore, a construction such as `':foo'` doesn't work to produce a quoted literal from a variable's value (and it would be unsafe if it did work, since it wouldn't correctly handle quotes embedded in the value).

One example use of this mechanism is to copy the contents of a file into a table column. First load the file into a variable and then interpolate the variable's value as a quoted string:

```
testdb=> \set content `cat my_file.txt`
testdb=> INSERT INTO my_table VALUES (: 'content');
```

(Note that this still won't work if `my_file.txt` contains `NUL` bytes. `psql` does not support embedded `NUL` bytes in variable values.)

Since colons can legally appear in SQL commands, an apparent attempt at interpolation (that is, `:name`, `:'name'`, or `:"name"`) is not replaced unless the named variable is currently set. In any case, you can escape a colon with a backslash to protect it from substitution.

The colon syntax for variables is standard SQL for embedded query languages, such as ECPG. The colon syntaxes for array slices and type casts are Greenplum Database extensions, which can sometimes conflict with the standard usage. The colon-quote syntax for escaping a variable's value as an SQL literal or identifier is a `psql` extension.

Prompting

The prompts `psql` issues can be customized to your preference. The three variables `PROMPT1`, `PROMPT2`, and `PROMPT3` contain strings and special escape sequences that describe the appearance of the prompt. Prompt 1 is the normal prompt that is issued when `psql` requests a new command. Prompt 2 is issued when more input is expected during command entry, for example because the command was not terminated with a semicolon or a quote was not closed. Prompt 3 is issued when you are running an SQL `COPY FROM STDIN` command and you need to type in a row value on the terminal.

The value of the selected prompt variable is printed literally, except where a percent sign (`%`) is encountered. Depending on the next character, certain other text is substituted instead. Defined substitutions are:

`%M`

The full host name (with domain name) of the database server, or `[local]` if the connection is over a UNIX domain socket, or `[local:/dir/name]`, if the UNIX domain socket is not at the compiled in default location.

`%m`

The host name of the database server, truncated at the first dot, or `[local]` if the connection is over a UNIX domain socket.

`%>`

The port number at which the database server is listening.

`%n`

The database session user name. (The expansion of this value might change during a database session as the result of the command `SET SESSION AUTHORIZATION`.)

`%/`

The name of the current database.

`%~`

Like `%/`, but the output is `~` (tilde) if the database is your default database.

`%#`

If the session user is a database superuser, then a `#`, otherwise a `>`. (The expansion of this value might change during a database session as the result of the command `SET SESSION AUTHORIZATION`.)

`%R`

In prompt 1 normally `=`, but `^` if in single-line mode, or `!` if the session is disconnected from the database (which can happen if `\connect` fails). In prompt 2 `%R` is replaced by a character that depends on why `psql` expects more input: `-` if the command simply wasn't terminated yet, but `*` if there is an unfinished `/* ... */` comment, a single quote if there is an unfinished quoted string, a double quote if there is an unfinished quoted identifier, a dollar sign if there is

an unfinished dollar-quoted string, or (if there is an unmatched left parenthesis. In prompt 3 `%R` doesn't produce anything.

`%x`

Transaction status: an empty string when not in a transaction block, or * when in a transaction block, or ! when in a failed transaction block, or ? when the transaction state is indeterminate (for example, because there is no connection).

`%digits`

The character with the indicated octal code is substituted.

`%:name:`

The value of the `psql` variable name. See “Variables” in [Advanced Features](#) for details.

`%`command``

The output of command, similar to ordinary back-tick substitution.

`%[... %]`

Prompts may contain terminal control characters which, for example, change the color, background, or style of the prompt text, or change the title of the terminal window. In order for line editing to work properly, these non-printing control characters must be designated as invisible by surrounding them with `%[` and `%;]`. Multiple pairs of these may occur within the prompt. For example,

```
testdb=> \set PROMPT1 '%[%033[1;33;40m%;n@%/%R%[%033[0m%;%#'
```

results in a boldfaced (1;) yellow-on-black (33;40) prompt on VT100-compatible, color-capable terminals. To insert a percent sign into your prompt, write `%%`. The default prompts are `'%/%R%# '` for prompts 1 and 2, and `'>> '` for prompt 3.

Command-Line Editing

`psql` uses the `readline` library for convenient line editing and retrieval. The command history is automatically saved when `psql` exits and is reloaded when `psql` starts up. Tab-completion is also supported, although the completion logic makes no claim to be an SQL parser. The queries generated by tab-completion can also interfere with other SQL commands, e.g. `SET TRANSACTION ISOLATION LEVEL`. If for some reason you do not like the tab completion, you can turn it off by putting this in a file named `.inputrc` in your home directory:

```
$if psql
set disable-completion on
$endif
```

Environment

COLUMNS

If `\pset columns` is zero, controls the width for the wrapped format and width for determining if wide output requires the pager or should be switched to the vertical format in expanded auto mode.

PAGER

If the query results do not fit on the screen, they are piped through this command. Typical values are `more` or `less`. The default is platform-dependent. The use of the pager can be disabled by setting `PAGER` to empty, or by using pager-related options of the `\pset` command.

PGDATABASE

PGHOST

PGPORT

PGUSER

Default connection parameters.

PSQL_EDITOR

EDITOR

VISUAL

Editor used by the `\e` and `\ef` commands. The variables are examined in the order listed; the first that is set is used.

The built-in default editors are `vi` on Unix systems and `notepad.exe` on Windows systems.

PSQL_EDITOR_LINENUMBER_ARG

When `\e` or `\ef` is used with a line number argument, this variable specifies the command-line argument used to pass the starting line number to the user's editor. For editors such as Emacs or `vi`, this is a plus sign. Include a trailing space in the value of the variable if there needs to be space between the option name and the line number. Examples:

```
PSQL_EDITOR_LINENUMBER_ARG='+'
PSQL_EDITOR_LINENUMBER_ARG='--line '
```

The default is `+` on Unix systems (corresponding to the default editor `vi`, and useful for many other common editors); but there is no default on Windows systems.

PSQL_HISTORY

Alternative location for the command history file. Tilde (`~`) expansion is performed.

PSQLRC

Alternative location of the user's `.psqlrc` file. Tilde (`~`) expansion is performed.

SHELL

Command run by the `\!` command.

TMPDIR

Directory for storing temporary files. The default is `/tmp`.

Files

`psqlrc` and `~/.psqlrc`

Unless it is passed an `-X` or `-c` option, `psql` attempts to read and run commands from the system-wide startup file (`psqlrc`) and then the user's personal startup file (`~/.psqlrc`), after connecting to the database but before accepting normal commands. These files can be used to set up the client and/or the server to taste, typically with `\set` and `SET` commands.

The system-wide startup file is named `psqlrc` and is sought in the installation's "system configuration" directory, which is most reliably identified by running `pg_config --sysconfdir`. By default this directory will be `./etc/` relative to the directory containing the Greenplum Database executables. The name of this directory can be set explicitly via the `PGSYSCONFDIR` environment variable.

The user's personal startup file is named `.psqlrc` and is sought in the invoking user's home directory. On Windows, which lacks such a concept, the personal startup file is named `%APPDATA%\postgresql\psqlrc.conf`. The location of the user's startup file can be set explicitly via the `PSQLRC` environment variable.

Both the system-wide startup file and the user's personal startup file can be made `psql`-version-specific by appending a dash and the underlying PostgreSQL major or minor release number to the file name, for example `~/.psqlrc-9.4`. The most specific version-matching file will be read in preference to a non-version-specific file.

`.psql_history`

The command-line history is stored in the file `~/.psql_history`,

or `%APPDATA%\postgresql\psql_history` on Windows.

The location of the history file can be set explicitly via the `PSQL_HISTORY` environment variable.

Notes

`psql` works best with servers of the same or an older major version. Backslash commands are particularly likely to fail if the server is of a newer version than `psql` itself. However, backslash commands of the `\d` family should work with older server versions, though not necessarily with servers newer than `psql` itself. The general functionality of running SQL commands and displaying query results should also work with servers of a newer major version, but this cannot be guaranteed in all cases.

If you want to use `psql` to connect to several servers of different major versions, it is recommended that you use the newest version of `psql`. Alternatively, you can keep a copy of `psql` from each major version around and be sure to use the version that matches the respective server. But in practice, this additional complication should not be necessary.

Notes for Windows Users

`psql` is built as a console application. Since the Windows console windows use a different encoding than the rest of the system, you must take special care when using 8-bit characters within `psql`. If `psql` detects a problematic console code page, it will warn you at startup. To change the console code page, two things are necessary:

Set the code page by entering:

```
cmd.exe /c chcp 1252
```

1252 is a character encoding of the Latin alphabet, used by Microsoft Windows for English and some other Western languages. If you are using Cygwin, you can put this command in `/etc/profile`.

Set the console font to Lucida Console, because the raster font does not work with the ANSI code page.

Examples

Start `psql` in interactive mode:

```
psql -p 54321 -U sally mydatabase
```

In `psql` interactive mode, spread a command over several lines of input. Notice the changing prompt:

```
testdb=> CREATE TABLE my_table (
testdb(> first integer not null default 0,
testdb(> second text)
testdb-> ;
CREATE TABLE
```

Look at the table definition:

```
testdb=> \d my_table
               Table "public.my_table"
  Column      |  Type   | Modifiers
-----+-----+-----
 first       | integer | not null default 0
```

```
second      | text      |
Distributed by: (first)
```

Run `psql` in non-interactive mode by passing in a file containing SQL commands:

```
psql -f /home/gpadmin/test/myscript.sql
```

Loading Data Using an External Table

Use SQL commands such as `INSERT` and `SELECT` to query a readable external table, the same way that you query a regular database table. For example, to load travel expense data from an external table, `ext_expenses`, into a database table, `expenses_travel`:

```
=# INSERT INTO expenses_travel
   SELECT * from ext_expenses where category='travel';
```

To load all data into a new database table:

```
=# CREATE TABLE expenses AS SELECT * from ext_expenses;
```

Parent topic: [Loading and Unloading Data](#)

Loading and Writing Non-HDFS Custom Data

Greenplum Database supports `TEXT` and `CSV` formats for importing and exporting data through external tables. You can load and save data in other formats by defining a custom format or custom protocol or by setting up a transformation with the `gpfdist` parallel file server.

- [Using a Custom Format](#)
- [Using a Custom Protocol](#)

Parent topic: [Loading and Unloading Data](#)

Using a Custom Format

You specify a custom data format in the `FORMAT` clause of `CREATE EXTERNAL TABLE`.

```
FORMAT 'CUSTOM' (formatter=format_function, key1=val1,...keyn=valn)
```

Where the `'CUSTOM'` keyword indicates that the data has a custom format and `formatter` specifies the function to use to format the data, followed by comma-separated parameters to the formatter function.

Greenplum Database provides functions for formatting fixed-width data, but you must author the formatter functions for variable-width data. The steps are as follows.

1. Author and compile input and output functions as a shared library.
2. Specify the shared library function with `CREATE FUNCTION` in Greenplum Database.
3. Use the `formatter` parameter of `CREATE EXTERNAL TABLE`'s `FORMAT` clause to call the function.
4. [Importing and Exporting Fixed Width Data](#)
5. [Examples: Read Fixed-Width Data](#)

Parent topic: [Loading and Writing Non-HDFS Custom Data](#)

Importing and Exporting Fixed Width Data

Specify custom formats for fixed-width data with the Greenplum Database functions `fixedwidth_in` and `fixedwidth_out`. These functions already exist in the file `$GPHOME/share/postgresql/cdb_external_extensions.sql`. The following example declares a custom format, then calls the `fixedwidth_in` function to format the data.

```
CREATE READABLE EXTERNAL TABLE students (
name varchar(20), address varchar(30), age int)
LOCATION ('file://<host>/file/path/')
FORMAT 'CUSTOM' (formatter=fixedwidth_in,
               name='20', address='30', age='4');
```

The following options specify how to import fixed width data.

- Read all the data.

To load all the fields on a line of fixed width data, you must load them in their physical order. You must specify the field length, but cannot specify a starting and ending position. The fields names in the fixed width arguments must match the order in the field list at the beginning of the `CREATE TABLE` command.

- Set options for blank and null characters.

Trailing blanks are trimmed by default. To keep trailing blanks, use the `preserve_blanks=on` option. You can reset the trailing blanks option to the default with the `preserve_blanks=off` option.

Use the `null='null_string_value'` option to specify a value for null characters.

- If you specify `preserve_blanks=on`, you must also define a value for null characters.
- If you specify `preserve_blanks=off`, null is not defined, and the field contains only blanks, Greenplum writes a null to the table. If null is defined, Greenplum writes an empty string to the table.

Use the `line_delim='line_ending'` parameter to specify the line ending character. The following examples cover most cases. The `\E` specifies an escape string constant.

```
line_delim=E'\n'
line_delim=E'\r'
line_delim=E'\r\n'
line_delim='abc'
```

Parent topic: [Using a Custom Format](#)

Examples of Reading Fixed-Width Data

The following examples show how to read fixed-width data.

Example 1 – Loading a table with all fields defined

```
CREATE READABLE EXTERNAL TABLE students (
name varchar(20), address varchar(30), age int)
LOCATION ('file://<host>/file/path/')
FORMAT 'CUSTOM' (formatter=fixedwidth_in,
```

```
name=20, address=30, age=4);
```

Example 2 – Loading a table with PRESERVED_BLANKS on

```
CREATE READABLE EXTERNAL TABLE students (
name varchar(20), address varchar(30), age int)
LOCATION ('gpfdist://<host>:<portNum>/file/path/')
FORMAT 'CUSTOM' (formatter=fixedwidth_in,
name=20, address=30, age=4,
preserve_blanks='on', null='NULL');
```

Example 3 – Loading data with no line delimiter

```
CREATE READABLE EXTERNAL TABLE students (
name varchar(20), address varchar(30), age int)
LOCATION ('file://<host>/file/path/')
FORMAT 'CUSTOM' (formatter=fixedwidth_in,
name='20', address='30', age='4', line_delim='?@')
```

Example 4 – Create a writable external table with a \r\n line delimiter

```
CREATE WRITABLE EXTERNAL TABLE students_out (
name varchar(20), address varchar(30), age int)
LOCATION ('gpfdist://<host>:<portNum>/file/path/students_out.txt')
FORMAT 'CUSTOM' (formatter=fixedwidth_out,
name=20, address=30, age=4, line_delim='E'\r\n');
```

Parent topic: [Using a Custom Format](#)

Using a Custom Protocol

Greenplum Database provides protocols such as gpfdist, [http](#), and [file](#) for accessing data over a network, or you can author a custom protocol. You can use the standard data formats, [TEXT](#) and [CSV](#), or a custom data format with custom protocols.

You can create a custom protocol whenever the available built-in protocols do not suffice for a particular need. For example, you could connect Greenplum Database in parallel to another system directly, and stream data from one to the other without the need to materialize the data on disk or use an intermediate process such as gpfdist. You must be a superuser to create and register a custom protocol.

1. Author the send, receive, and (optionally) validator functions in C, with a predefined API. These functions are compiled and registered with the Greenplum Database. For an example custom protocol, see [Example Custom Data Access Protocol](#).
2. After writing and compiling the read and write functions into a shared object (.so), declare a database function that points to the .so file and function names.

The following examples use the compiled import and export code.

```
CREATE FUNCTION myread() RETURNS integer
```

```
as '$libdir/gpextprotocol.so', 'myprot_import'
LANGUAGE C STABLE;
CREATE FUNCTION mywrite() RETURNS integer
as '$libdir/gpextprotocol.so', 'myprot_export'
LANGUAGE C STABLE;
```

The format of the optional validator function is:

```
CREATE OR REPLACE FUNCTION myvalidate() RETURNS void
AS '$libdir/gpextprotocol.so', 'myprot_validate'
LANGUAGE C STABLE;
```

3. Create a protocol that accesses these functions. `Validatorfunc` is optional.

```
CREATE TRUSTED PROTOCOL myprot(
writefunc='mywrite',
readfunc='myread',
validatorfunc='myvalidate');
```

4. Grant access to any other users, as necessary.

```
GRANT ALL ON PROTOCOL myprot TO otheruser;
```

5. Use the protocol in readable or writable external tables.

```
CREATE WRITABLE EXTERNAL TABLE ext_sales(LIKE sales)
LOCATION ('myprot://<meta>/<meta>/...')
FORMAT 'TEXT';
CREATE READABLE EXTERNAL TABLE ext_sales(LIKE sales)
LOCATION('myprot://<meta>/<meta>/...')
FORMAT 'TEXT';
```

Declare custom protocols with the SQL command `CREATE TRUSTED PROTOCOL`, then use the `GRANT` command to grant access to your users. For example:

- Allow a user to create a readable external table with a trusted protocol

```
GRANT SELECT ON PROTOCOL <protocol name> TO <user name>;
```

- Allow a user to create a writable external table with a trusted protocol

```
GRANT INSERT ON PROTOCOL <protocol name> TO <user name>;
```

- Allow a user to create readable and writable external tables with a trusted protocol

```
GRANT ALL ON PROTOCOL <protocol name> TO <user name>;
```

Parent topic: [Loading and Writing Non-HDFS Custom Data](#)

Handling Load Errors

Readable external tables are most commonly used to select data to load into regular database tables. You use the `CREATE TABLE AS SELECT` or `INSERT INTO` commands to query the external table data. By default, if the data contains an error, the entire command fails and the data is not loaded into the target database table.

The `SEGMENT REJECT LIMIT` clause allows you to isolate format errors in external table data and to continue loading correctly formatted rows. Use `SEGMENT REJECT LIMIT` to set an error threshold, specifying the reject limit `count` as number of `ROWS` (the default) or as a `PERCENT` of total rows (1-100).

The entire external table operation is cancelled, and no rows are processed, if the number of error rows reaches the `SEGMENT REJECT LIMIT`. The limit of error rows is per-segment, not per entire operation. The operation processes all good rows, and it discards and optionally logs formatting errors for erroneous rows, if the number of error rows does not reach the `SEGMENT REJECT LIMIT`.

The `LOG ERRORS` clause allows you to keep error rows for further examination. For information about the `LOG ERRORS` clause, see the `CREATE EXTERNAL TABLE` command in the *Greenplum Database Reference Guide*.

When you set `SEGMENT REJECT LIMIT`, Greenplum scans the external data in single row error isolation mode. Single row error isolation mode applies to external data rows with format errors such as extra or missing attributes, attributes of a wrong data type, or invalid client encoding sequences. Greenplum does not check constraint errors, but you can filter constraint errors by limiting the `SELECT` from an external table at runtime. For example, to eliminate duplicate key errors:

```
=# INSERT INTO table_with_pkeys
  SELECT DISTINCT * FROM external_table;
```

Note: When loading data with the `COPY` command or an external table, the value of the server configuration parameter `gp_initial_bad_row_limit` limits the initial number of rows that are processed that are not formatted properly. The default is to stop processing if the first 1000 rows contain formatting errors. See the *Greenplum Database Reference Guide* for information about the parameter.

- [Define an External Table with Single Row Error Isolation](#)
- [Capture Row Formatting Errors and Declare a Reject Limit](#)
- [Viewing Bad Rows in the Error Log](#)
- [Moving Data between Tables](#)

Parent topic: [Loading and Unloading Data](#)

Define an External Table with Single Row Error Isolation

The following example logs errors internally in Greenplum Database and sets an error threshold of 10 errors.

```
=# CREATE EXTERNAL TABLE ext_expenses ( name text,
  date date, amount float4, category text, desc1 text )
  LOCATION ('gpfdist://etlhost-1:8081/*',
            'gpfdist://etlhost-2:8082/*')
  FORMAT 'TEXT' (DELIMITER '|')
  LOG ERRORS SEGMENT REJECT LIMIT 10
  ROWS;
```

Use the built-in SQL function `gp_read_error_log('external_table')` to read the error log data. This example command displays the log errors for `ext_expenses`:

```
SELECT gp_read_error_log('ext_expenses');
```

For information about the format of the error log, see [Viewing Bad Rows in the Error Log](#).

The built-in SQL function `gp_truncate_error_log('external_table')` deletes the error data. This

example deletes the error log data created from the previous external table example :

```
SELECT gp_truncate_error_log('ext_expenses');
```

Parent topic: [Handling Load Errors](#)

Capture Row Formatting Errors and Declare a Reject Limit

The following SQL fragment captures formatting errors internally in Greenplum Database and declares a reject limit of 10 rows.

```
LOG ERRORS SEGMENT REJECT LIMIT 10 ROWS
```

Use the built-in SQL function `gp_read_error_log()` to read the error log data. For information about viewing log errors, see [Viewing Bad Rows in the Error Log](#).

Parent topic: [Handling Load Errors](#)

Viewing Bad Rows in the Error Log

If you use single row error isolation (see [Define an External Table with Single Row Error Isolation](#) or [Running COPY in Single Row Error Isolation Mode](#)), any rows with formatting errors are logged internally by Greenplum Database.

Greenplum Database captures the following error information in a table format:

column	type	description
cmdtime	timestampz	Timestamp when the error occurred.
relname	text	The name of the external table or the target table of a <code>COPY</code> command.
filename	text	The name of the load file that contains the error.
linenum	int	If <code>COPY</code> was used, the line number in the load file where the error occurred. For external tables using <code>file://</code> protocol or <code>gpfdist://</code> protocol and CSV format, the file name and line number is logged.
bytenum	int	For external tables with the <code>gpfdist://</code> protocol and data in TEXT format: the byte offset in the load file where the error occurred. <code>gpfdist</code> parses TEXT files in blocks, so logging a line number is not possible. CSV files are parsed a line at a time so line number tracking is possible for CSV files.
errmsg	text	The error message text.
rawdata	text	The raw data of the rejected row.
rawbytes	bytea	In cases where there is a database encoding error (the client encoding used cannot be converted to a server-side encoding), it is not possible to log the encoding error as <code>rawdata</code> . Instead the raw bytes are stored and you will see the octal code for any non seven bit ASCII characters.

You can use the Greenplum Database built-in SQL function `gp_read_error_log()` to display formatting errors that are logged internally. For example, this command displays the error log information for the table `ext_expenses`:

```
SELECT gp_read_error_log('ext_expenses');
```

For information about managing formatting errors that are logged internally, see the command `COPY` or `CREATE EXTERNAL TABLE` in the *Greenplum Database Reference Guide*.

Parent topic: [Handling Load Errors](#)

Moving Data between Tables

You can use `CREATE TABLE AS` or `INSERT...SELECT` to load external and external web table data into another (non-external) database table, and the data will be loaded in parallel according to the external or external web table definition.

If an external table file or external web table data source has an error, one of the following will happen, depending on the isolation mode used:

- **Tables without error isolation mode:** any operation that reads from that table fails. Loading from external and external web tables without error isolation mode is an all or nothing operation.
- **Tables with error isolation mode:** the entire file will be loaded, except for the problematic rows (subject to the configured `REJECT_LIMIT`)

Parent topic: [Handling Load Errors](#)

Loading Data with gpload

The Greenplum `gpload` utility loads data using readable external tables and the Greenplum parallel file server (`gpfdist` or `gpfdists`). It handles parallel file-based external table setup and allows users to configure their data format, external table definition, and `gpfdist` or `gpfdists` setup in a single configuration file.

Note: `gpfdist` and `gpload` are compatible only with the Greenplum Database major version in which they are shipped. For example, a `gpfdist` utility that is installed with Greenplum Database 4.x cannot be used with Greenplum Database 5.x or 6.x.

Note: `MERGE` and `UPDATE` operations are not supported if the target table column name is a reserved keyword, has capital letters, or includes any character that requires quotes (" ") to identify the column.

To use gpload

1. Ensure that your environment is set up to run `gpload`. Some dependent files from your Greenplum Database installation are required, such as `gpfdist` and Python, as well as network access to the Greenplum segment hosts.

See the *Greenplum Database Reference Guide* for details.

2. Create your load control file. This is a YAML-formatted file that specifies the Greenplum Database connection information, `gpfdist` configuration information, external table options, and data format.

See the *Greenplum Database Reference Guide* for details.

For example:

```
---
VERSION: 1.0.0.1
DATABASE: ops
USER: gpadmin
HOST: mdw-1
PORT: 5432
GPLOAD:
  INPUT:
    - SOURCE:
        LOCAL_HOSTNAME:
```

```

- etl1-1
- etl1-2
- etl1-3
- etl1-4
PORT: 8081
FILE:
- /var/load/data/*
- COLUMNS:
- name: text
- amount: float4
- category: text
- descr: text
- date: date
- FORMAT: text
- DELIMITER: '|'
- ERROR_LIMIT: 25
- LOG_ERRORS: true
OUTPUT:
- TABLE: payables.expenses
- MODE: INSERT
PRELOAD:
- REUSE_TABLES: true
SQL:
- BEFORE: "INSERT INTO audit VALUES('start', current_timestamp)"
- AFTER: "INSERT INTO audit VALUES('end', current_timestamp)"

```

3. Run `gpload`, passing in the load control file. For example:

```
gpload -f my_load.yml
```

Parent topic: [Loading and Unloading Data](#)

Accessing External Data with PXF

Data managed by your organization may already reside in external sources such as Hadoop, object stores, and other SQL databases. The Greenplum Platform Extension Framework (PXF) provides access to this external data via built-in connectors that map an external data source to a Greenplum Database table definition.

PXF is installed with Hadoop and Object Storage connectors. These connectors enable you to read external data stored in text, Avro, JSON, RCFile, Parquet, SequenceFile, and ORC formats. You can use the JDBC connector to access an external SQL database.

Note: In previous versions of Greenplum Database, you may have used the `gphdfs` external table protocol to access data stored in Hadoop. Greenplum Database version 6.0.0 removes the `gphdfs` protocol. Use PXF and the `pxf` external table protocol to access Hadoop in Greenplum Database version 6.x.

The Greenplum Platform Extension Framework includes a C-language extension and a Java service. After you configure and initialize PXF, you start a single PXF JVM process on each Greenplum Database segment host. This long-running process concurrently serves multiple query requests.

For detailed information about the architecture of and using PXF, refer to the [Greenplum Platform Extension Framework \(PXF\)](#) documentation.

Parent topic: [Working with External Data](#)

Parent topic: [Loading and Unloading Data](#)

Transforming External Data with gpfdist and gpload

The `gpfdist` parallel file server allows you to set up transformations that enable Greenplum Database external tables to read and write files in formats that are not supported with the `CREATE EXTERNAL TABLE` command's `FORMAT` clause. An *input* transformation reads a file in the foreign data format and outputs rows to `gpfdist` in the CSV or other text format specified in the external table's `FORMAT` clause. An *output* transformation receives rows from `gpfdist` in text format and converts them to the foreign data format.

Note: `gpfdist` and `gpload` are compatible only with the Greenplum Database major version in which they are shipped. For example, a `gpfdist` utility that is installed with Greenplum Database 4.x cannot be used with Greenplum Database 5.x or 6.x.

This topic describes the tasks to set up data transformations that work with `gpfdist` to read or write external data files with formats that Greenplum Database does not support.

- [About gpfdist Transformations](#)
- [Determine the Transformation Schema](#)
- [Write a Transformation](#)
- [Write the gpfdist Configuration File](#)
- [Transfer the Data](#)
- [Configuration File Format](#)
- [XML Transformation Examples](#)

Parent topic: [Loading and Unloading Data](#)

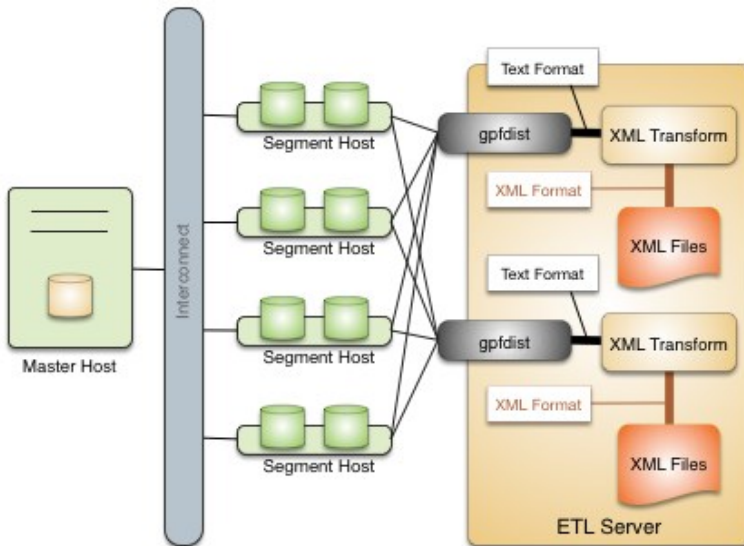

About gpfdist Transformations

To set up a transformation for a data format, you provide an executable command that `gpfdist` can call with the name of the file containing data. For example, you could write a shell script that runs an XSLT transformation on an XML file to output rows with columns delimited with a vertical bar (|) character and rows delimited with linefeeds.

Transformations are configured in a YAML-formatted configuration file passed to `gpfdist` on the command line.

If you want to load the external data into a table in the Greenplum database, you can use the `gpload` utility to automate the tasks to create an external table, run `gpfdist`, and load the transformed data into the database table.

Accessing data in external XML files from within the database is a common example requiring transformation. The following diagram shows `gpfdist` performing a transformation on XML files on an ETL server.

Following are the high-level steps to set up a `gpfdist` transformation for external data files. The process is illustrated with an XML example.

1. [Determine the transformation schema.](#)
2. [Write a transformation.](#)
3. [Write the gpfdist configuration file.](#)
4. [Transfer the data.](#)

Determine the Transformation Schema

To prepare for the transformation project:

1. Determine the goal of the project, such as indexing data, analyzing data, combining data, and so on.
2. Examine the source files and note the file structure and element names.
3. Choose the elements to import and decide if any other limits are appropriate.

For example, the following XML file, *prices.xml*, is a simple XML file that contains price records. Each price record contains two fields: an item number and a price.

```
<?xml version="1.0" encoding="ISO-8859-1" ?>
<prices>
  <pricerecord>
    <itemnumber>708421</itemnumber>
    <price>19.99</price>
  </pricerecord>
  <pricerecord>
    <itemnumber>708466</itemnumber>
    <price>59.25</price>
  </pricerecord>
  <pricerecord>
    <itemnumber>711121</itemnumber>
    <price>24.99</price>
  </pricerecord>
</prices>
```

The goal of this transformation is to import all the data into a Greenplum Database readable external table with an integer `itemnumber` column and a decimal `price` column.

Write a Transformation

The transformation specifies what to extract from the data. You can use any authoring environment and language appropriate for your project. For XML transformations choose from technologies such as XSLT, Joost (STX), Java, Python, or Perl, based on the goals and scope of the project.

In the price example, the next step is to transform the XML data into a two-column delimited text format.

```
708421|19.99
708466|59.25
711121|24.99
```

The following STX transform, called *input_transform.stx*, performs the data transformation.

```
<?xml version="1.0"?>
<stx:transform version="1.0"
  xmlns:stx="http://stx.sourceforge.net/2002/ns"
  pass-through="none">
  <!-- declare variables -->
  <stx:variable name="itemnumber"/>
  <stx:variable name="price"/>
  <!-- match and output prices as columns delimited by | -->
  <stx:template match="/prices/pricerecord">
    <stx:process-children/>
    <stx:value-of select="$itemnumber"/>
  <stx:text>|</stx:text>
    <stx:value-of select="$price"/>      <stx:text>
  </stx:template>
  </stx:template>
  <stx:template match="itemnumber">
    <stx:assign name="itemnumber" select="."/>
  </stx:template>
  <stx:template match="price">
    <stx:assign name="price" select="."/>
  </stx:template>
</stx:transform>
```

This STX transform declares two temporary variables, *itemnumber* and *price*, and the following rules.

1. When an element that satisfies the XPath expression `/prices/pricerecord` is found, examine the child elements and generate output that contains the value of the *itemnumber* variable, a `|` character, the value of the price variable, and a newline.
2. When an `<itemnumber>` element is found, store the content of that element in the variable *itemnumber*.
3. When a `<price>` element is found, store the content of that element in the variable *price*.

Write the gpfdist Configuration File

The gpfdist configuration is specified as a YAML 1.1 document. It contains rules that gpfdist uses to select a transformation to apply when loading or extracting data.

This example gpfdist configuration contains the following items that are required for the *prices.xml* transformation scenario:

- the `config.yaml` file defining `TRANSFORMATIONS`
- the `input_transform.sh` wrapper script, referenced in the `config.yaml` file

- the `input_transform.stx` joost transformation, called from `input_transform.sh`

Aside from the ordinary YAML rules, such as starting the document with three dashes (`---`), a `gpfdist` configuration must conform to the following restrictions:

1. A `VERSION` setting must be present with the value `1.0.0.1`.
2. A `TRANSFORMATIONS` setting must be present and contain one or more mappings.
3. Each mapping in the `TRANSFORMATION` must contain:
 - a `TYPE` with the value `'input'` or `'output'`
 - a `COMMAND` indicating how the transformation is run.
4. Each mapping in the `TRANSFORMATION` can contain optional `CONTENT`, `SAFE`, and `STDERR` settings.

The following `gpfdist` configuration, called `config.yaml`, applies to the prices example. The initial indentation on each line is significant and reflects the hierarchical nature of the specification. The transformation name `prices_input` in the following example will be referenced later when creating the table in SQL.

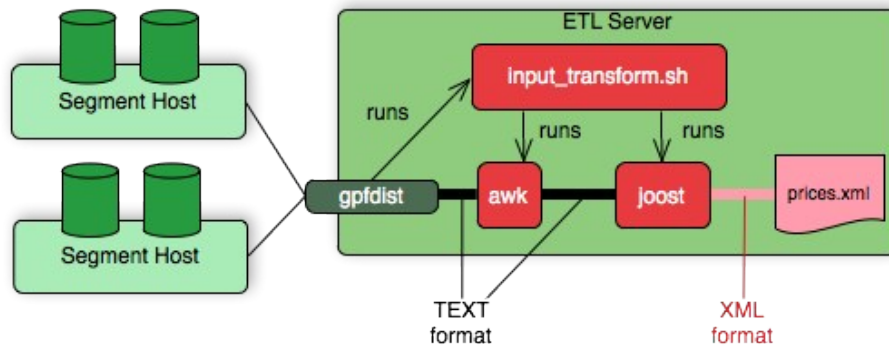

```
---
VERSION: 1.0.0.1
TRANSFORMATIONS:
  prices_input:
    TYPE:      input
    COMMAND:   /bin/bash input_transform.sh %filename%
```

The `COMMAND` setting uses a wrapper script called `input_transform.sh` with a `%filename%` placeholder. When `gpfdist` runs the `prices_input` transform, it invokes `input_transform.sh` with `/bin/bash` and replaces the `%filename%` placeholder with the path to the input file to transform. The wrapper script called `input_transform.sh` contains the logic to invoke the STX transformation and return the output.

If Joost is used, the Joost STX engine must be installed.

```
#!/bin/bash
# input_transform.sh - sample input transformation,
# demonstrating use of Java and Joost STX to convert XML into
# text to load into Greenplum Database.
# java arguments:
#   -jar joost.jar           joost STX engine
#   -nodecl                 don't generate a <?xml?> declaration
#   $1                      filename to process
#   input_transform.stx     the STX transformation
#
# the AWK step eliminates a blank line joost emits at the end
java \
  -jar joost.jar \
  -nodecl \
  $1 \
  input_transform.stx \
  | awk 'NF>0'
```

The `input_transform.sh` file uses the Joost STX engine with the AWK interpreter. The following diagram shows the process flow as `gpfdist` runs the transformation.

Transfer the Data

Create the target database tables with SQL statements based on the appropriate schema.

There are no special requirements for Greenplum Database tables that hold loaded data. In the prices example, the following command creates the `prices` table, where the data is to be loaded.

```
CREATE TABLE prices (
    itemnumber integer,
    price decimal
)
DISTRIBUTED BY (itemnumber);
```

Next, use one of the following approaches to transform the data with `gpfdist`.

- `gpload` supports only input transformations, but in many cases is easier to implement.
- `gpfdist` with `INSERT INTO SELECT FROM` supports both input and output transformations, but exposes details that `gpload` automates for you.

Transforming with `gpload`

The Greenplum Database `gpload` utility orchestrates a data load operation using the `gpfdist` parallel file server and a YAML-formatted configuration file. `gpload` automates these tasks:

- Creates a readable external table in the database.
- Starts `gpfdist` instances with the configuration file that contains the transformation.
- Runs `INSERT INTO table_name SELECT FROM external_table` to load the data.
- Removes the external table definition.

Transforming data with `gpload` requires that the settings `TRANSFORM` and `TRANSFORM_CONFIG` appear in the `INPUT` section of the `gpload` control file.

For more information about the syntax and placement of these settings in the `gpload` control file, see the *Greenplum Database Reference Guide*.

- `TRANSFORM_CONFIG` specifies the name of the `gpfdist` configuration file.
- The `TRANSFORM` setting indicates the name of the transformation that is described in the file named in `TRANSFORM_CONFIG`.

```
---
VERSION: 1.0.0.1
DATABASE: ops
USER: gpadmin
```

```

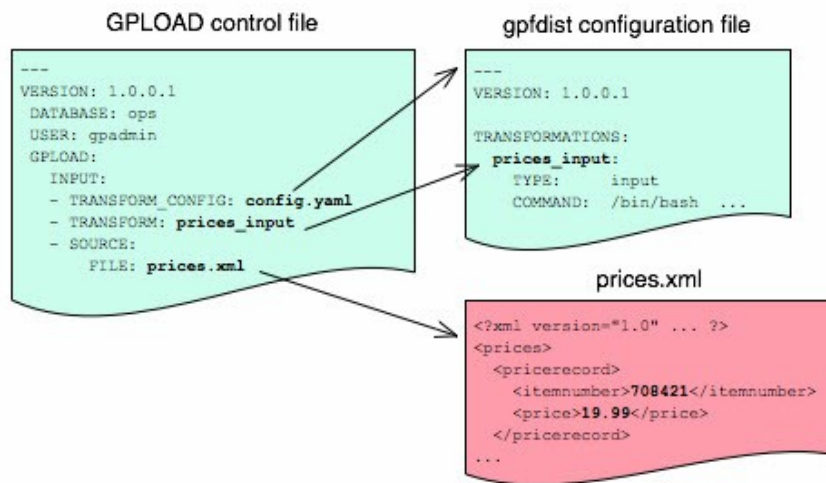

Gpload:
  INPUT:
    - TRANSFORM_CONFIG: config.yaml
    - TRANSFORM: prices_input
    - SOURCE:
      FILE: prices.xml

```

The transformation name must appear in two places: in the `TRANSFORM` setting of the `gpfdist` configuration file and in the `TRANSFORMATIONS` section of the file named in the `TRANSFORM_CONFIG` section.

In the `gpload` control file, the optional parameter `MAX_LINE_LENGTH` specifies the maximum length of a line in the XML transformation data that is passed to `gpload`.

The following diagram shows the relationships between the `gpload` control file, the `gpfdist` configuration file, and the XML data file.

Transforming with gpfdist and INSERT INTO SELECT FROM

With this load method, you perform each of the tasks that `gpload` automates. You start `gpfdist`, create an external table, load the data, and clean up by dropping the table and stopping `gpfdist`.

Specify the transformation in the `CREATE EXTERNAL TABLE` definition's `LOCATION` clause. For example, the transform is shown in bold in the following command. (Run `gpfdist` first, using the command `gpfdist -c config.yaml`).

```

CREATE READABLE EXTERNAL TABLE prices_readable (LIKE prices)
  LOCATION ('gpfdist://hostname:8080/prices.xml#transform=prices_input')
  FORMAT 'TEXT' (DELIMITER '|')
  LOG ERRORS SEGMENT REJECT LIMIT 10;

```

In the command above, change `hostname` to your hostname. `prices_input` comes from the `gpfdist` configuration file.

The following query then loads the data into the `prices` table.

```

INSERT INTO prices SELECT * FROM prices_readable;

```

Configuration File Format

The `gpfdist` configuration file uses the YAML 1.1 document format and implements a schema for

defining the transformation parameters. The configuration file must be a valid YAML document.

The gpfdist program processes the document in order and uses indentation (spaces) to determine the document hierarchy and relationships of the sections to one another. The use of white space is significant. Do not use white space for formatting and do not use tabs.

The following is the basic structure of a configuration file.

```
---
VERSION: 1.0.0.1
TRANSFORMATIONS:
  transformation_name1:
    TYPE: input | output
    COMMAND: command
    CONTENT: data | paths
    SAFE: posix-regex
    STDERR: server | console
  transformation_name2:
    TYPE: input | output
    COMMAND: command
...
```

VERSION

Required. The version of the gpfdist configuration file schema. The current version is 1.0.0.1.

TRANSFORMATIONS

Required. Begins the transformation specification section. A configuration file must have at least one transformation. When gpfdist receives a transformation request, it looks in this section for an entry with the matching transformation name.

TYPE

Required. Specifies the direction of transformation. Values are `input` or `output`.

- `input`: gpfdist treats the standard output of the transformation process as a stream of records to load into Greenplum Database.
- `output`: gpfdist treats the standard input of the transformation process as a stream of records from Greenplum Database to transform and write to the appropriate output.

COMMAND

Required. Specifies the command gpfdist will run to perform the transformation.

For input transformations, gpfdist invokes the command specified in the `CONTENT` setting. The command is expected to open the underlying file(s) as appropriate and produce one line of `TEXT` for each row to load into Greenplum Database. The input transform determines whether the entire content should be converted to one row or to multiple rows.

For output transformations, gpfdist invokes this command as specified in the `CONTENT` setting. The output command is expected to open and write to the underlying file(s) as appropriate. The output transformation determines the final placement of the converted output.

CONTENT

Optional. The values are `data` and `paths`. The default value is `data`.

- When `CONTENT` specifies `data`, the text `%filename%` in the `COMMAND` section is replaced by the path to the file to read or write.
- When `CONTENT` specifies `paths`, the text `%filename%` in the `COMMAND` section is replaced by the path to the temporary file that contains the list of files to read or write.

The following is an example of a `COMMAND` section showing the text `%filename%` that is replaced.

```
COMMAND: /bin/bash input_transform.sh %filename%
```

SAFE

Optional. A [POSIX](#) regular expression that the paths must match to be passed to the transformation. Specify [SAFE](#) when there is a concern about injection or improper interpretation of paths passed to the command. The default is no restriction on paths.

STDERR

Optional. The values are [server](#) and [console](#).

This setting specifies how to handle standard error output from the transformation. The default, [server](#), specifies that gpfdist will capture the standard error output from the transformation in a temporary file and send the first 8k of that file to Greenplum Database as an error message. The error message will appear as an SQL error. [Console](#) specifies that gpfdist does not redirect or transmit the standard error output from the transformation.

XML Transformation Examples

The following examples demonstrate the complete process for different types of XML data and STX transformations. Files and detailed instructions associated with these examples are in the GitHub repo [github.com://greenplum-db/gpdb](https://github.com/greenplum-db/gpdb) in the [gpMgmt/demo/gpfdist_transform](#) directory. Read the README file in the *Before You Begin* section before you run the examples. The README file explains how to download the example data file used in the examples.

Command-based External Web Tables

The output of a shell command or script defines command-based web table data. Specify the command in the [EXECUTE](#) clause of [CREATE EXTERNAL WEB TABLE](#). The data is current as of the time the command runs. The [EXECUTE](#) clause runs the shell command or script on the specified master, and/or segment host or hosts. The command or script must reside on the hosts corresponding to the host(s) defined in the [EXECUTE](#) clause.

By default, the command is run on segment hosts when active segments have output rows to process. For example, if each segment host runs four primary segment instances that have output rows to process, the command runs four times per segment host. You can optionally limit the number of segment instances that run the web table command. All segments included in the web table definition in the [ON](#) clause run the command in parallel.

The command that you specify in the external table definition runs from the database and cannot access environment variables from [.bashrc](#) or [.profile](#). Set environment variables in the [EXECUTE](#) clause. For example:

```
=# CREATE EXTERNAL WEB TABLE output (output text)
  EXECUTE 'PATH=/home/gpadmin/programs; export PATH; myprogram.sh'
  FORMAT 'TEXT';
```

Scripts must be executable by the [gpadmin](#) user and reside in the same location on the master or segment hosts.

The following command defines a web table that runs a script. The script runs on each segment host where a segment has output rows to process.

```
=# CREATE EXTERNAL WEB TABLE log_output
  (linenum int, message text)
  EXECUTE '/var/load_scripts/get_log_data.sh' ON HOST
  FORMAT 'TEXT' (DELIMITER '|');
```

IRS MeF XML Files (In demo Directory)

This example demonstrates loading a sample IRS Modernized eFile tax return using a Joost STX transformation. The data is in the form of a complex XML file.

The U.S. Internal Revenue Service (IRS) made a significant commitment to XML and specifies its use in its Modernized e-File (MeF) system. In MeF, each tax return is an XML document with a deep hierarchical structure that closely reflects the particular form of the underlying tax code.

XML, XML Schema and stylesheets play a role in their data representation and business workflow. The actual XML data is extracted from a ZIP file attached to a MIME “transmission file” message. For more information about MeF, see [Modernized e-File \(Overview\)](#) on the IRS web site.

The sample XML document, *RET990EZ_2006.xml*, is about 350KB in size with two elements:

- ReturnHeader
- ReturnData

The <ReturnHeader> element contains general details about the tax return such as the taxpayer’s name, the tax year of the return, and the preparer. The <ReturnData> element contains multiple sections with specific details about the tax return and associated schedules.

The following is an abridged sample of the XML file.

```
<?xml version="1.0" encoding="UTF-8"?>
<Return returnVersion="2006v2.0"
  xmlns="https://www.irs.gov/efile"
  xmlns:efile="https://www.irs.gov/efile"
  xsi:schemaLocation="https://www.irs.gov/efile"
  xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance">
  <ReturnHeader binaryAttachmentCount="1">
    <ReturnId>AAAAAAAAAAAAAAAAAAAA</ReturnId>
    <Timestamp>1999-05-30T12:01:01+05:01</Timestamp>
    <ReturnType>990EZ</ReturnId>
    <TaxPeriodBeginDate>2005-01-01</TaxPeriodBeginDate>
    <TaxPeriodEndDate>2005-12-31</TaxPeriodEndDate>
    <Filer>
      <EIN>011248772</EIN>
      ... more data ...
    </Filer>
    <Preparer>
      <Name>Percy Polar</Name>
      ... more data ...
    </Preparer>
    <TaxYear>2005</TaxYear>
  </ReturnHeader>
  ... more data ..
```

The goal is to import all the data into a Greenplum database. First, convert the XML document into text with newlines “escaped” , with two columns: *ReturnId* and a single column on the end for the entire MeF tax return. For example:

```
AAAAAAAAAAAAAAAAAAAA|<Return returnVersion="2006v2.0"...
```

Load the data into Greenplum Database.

WITSML™ Files (In demo Directory)

This example demonstrates loading sample data describing an oil rig using a Joost STX transformation. The data is in the form of a complex XML file downloaded from energistics.org.

The Wellsite Information Transfer Standard Markup Language (WITSML™) is an oil industry initiative to provide open, non-proprietary, standard interfaces for technology and software to share information among oil companies, service companies, drilling contractors, application vendors, and regulatory agencies. For more information about WITSML™, see <http://www.energistics.org/>.

The oil rig information consists of a top level `<rigs>` element with multiple child elements such as `<documentInfo>`, `<rig>`, and so on. The following excerpt from the file shows the type of information in the `<rig>` tag.

```
<?xml version="1.0" encoding="UTF-8"?>
<?xml-stylesheet href="../../stylesheets/rig.xsl" type="text/xsl" media="screen"?>
<rigs
  xmlns="http://www.energistics.org/schemas/131"
  xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
  xsi:schemaLocation="http://www.energistics.org/schemas/131 ../obj_rig.xsd"
  version="1.3.1.1">
  <documentInfo>
  ... misc data ...
  </documentInfo>
  <rig uidWell="W-12" uidWellbore="B-01" uid="xr31">
    <nameWell>6507/7-A-42</nameWell>
    <nameWellbore>A-42</nameWellbore>
    <name>Deep Drill #5</name>
    <owner>Deep Drilling Co.</owner>
    <typeRig>floater</typeRig>
    <manufacturer>Fitsui Engineering</manufacturer>
    <yearEntService>1980</yearEntService>
    <classRig>ABS Class A1 M CSDU AMS ACCU</classRig>
    <approvals>DNV</approvals>
  ... more data ...
```

The goal is to import the information for this rig into Greenplum Database.

The sample document, *rig.xml*, is about 11KB in size. The input does not contain tabs so the relevant information can be converted into records delimited with a pipe (|).

```
W-12|6507/7-A-42|xr31|Deep Drill #5|Deep Drilling Co.|John Doe|John.Doe@example.com|
```

With the columns:

- `well_uid` text, – e.g. W-12
- `well_name` text, – e.g. 6507/7-A-42
- `rig_uid` text, – e.g. xr31
- `rig_name` text, – e.g. Deep Drill #5
- `rig_owner` text, – e.g. Deep Drilling Co.
- `rig_contact` text, – e.g. John Doe
- `rig_email` text, – e.g. John.Doe@example.com
- `doc xml`

Then, load the data into Greenplum Database.

Loading Data with COPY

`COPY FROM` copies data from a file or standard input into a table and appends the data to the table contents. `COPY` is non-parallel: data is loaded in a single process using the Greenplum master

instance. Using `COPY` is only recommended for very small data files.

The `COPY` source file must be accessible to the `postgres` process on the master host. Specify the `COPY` source file name relative to the data directory on the master host, or specify an absolute path.

Greenplum copies data from `STDIN` or `STDOUT` using the connection between the client and the master server.

Parent topic: [Loading and Unloading Data](#)

Loading From a File

The `COPY` command asks the `postgres` backend to open the specified file, read it and append it to the table. In order to be able to read the file, the backend needs to have read permissions on the file, and the file name must be specified using an absolute path on the master host, or a relative path to the master data directory.

```
COPY <table_name> FROM </path/to/filename>;
```

Loading From STDIN

To avoid the problem of copying the data file to the master host before loading the data, `COPY FROM STDIN` uses the Standard Input channel and feeds data directly into the `postgres` backend. After the `COPY FROM STDIN` command started, the backend will accept lines of data until a single line only contains a backslash-period (`\.`).

```
COPY <table_name> FROM <STDIN>;
```

Loading Data Using `\copy` in psql

Do not confuse the psql `\copy` command with the `COPY` SQL command. The `\copy` invokes a regular `COPY FROM STDIN` and sends the data from the psql client to the backend. Therefore any file must reside on the host where the psql client runs, and must be accessible to the user which runs the client.

To avoid the problem of copying the data file to the master host before loading the data, `COPY FROM STDIN` uses the Standard Input channel and feeds data directly into the `postgres` backend. After the `COPY FROM STDIN` command started, the backend will accept lines of data until a single line only contains a backslash-period (`\.`). psql is wrapping all of this into the handy `\copy` command.

```
\copy <table_name> FROM <filename>;
```

Input Format

`COPY FROM` accepts a `FORMAT` parameter, which specifies the format of the input data. The possible values are `TEXT`, `CSV` (Comma Separated Values), and `BINARY`.

```
COPY <table_name> FROM </path/to/filename> WITH (FORMAT csv);
```

The `FORMAT csv` will read comma-separated values. The `FORMAT text` by default uses tabulators to separate the values, the `DELIMITER` option specifies a different character as value delimiter.

```
COPY <table_name> FROM </path/to/filename> WITH (FORMAT text, DELIMITER '|');
```

By default, the default client encoding is used, this can be changed with the `ENCODING` option. This is useful if data is coming from another operating system.

```
COPY <table_name> FROM </path/to/filename> WITH (ENCODING 'latin1');
```

Running COPY in Single Row Error Isolation Mode

By default, `COPY` stops an operation at the first error: if the data contains an error, the operation fails and no data loads. If you run `COPY FROM` in *single row error isolation mode*, Greenplum skips rows that contain format errors and loads properly formatted rows. Single row error isolation mode applies only to rows in the input file that contain format errors. If the data contains a constraint error such as violation of a `NOT NULL`, `CHECK`, or `UNIQUE` constraint, the operation fails and no data loads.

Specifying `SEGMENT REJECT LIMIT` runs the `COPY` operation in single row error isolation mode. Specify the acceptable number of error rows on each segment, after which the entire `COPY FROM` operation fails and no rows load. The error row count is for each Greenplum Database segment, not for the entire load operation.

If the `COPY` operation does not reach the error limit, Greenplum loads all correctly-formatted rows and discards the error rows. Use the `LOG ERRORS` clause to capture data formatting errors internally in Greenplum Database. For example:

```
=> COPY country FROM '/data/gpdb/country_data'
    WITH DELIMITER '|' LOG ERRORS
    SEGMENT REJECT LIMIT 10 ROWS;
```

See [Viewing Bad Rows in the Error Log](#) for information about investigating error rows.

Parent topic: [Loading and Unloading Data](#)

Optimizing Data Load and Query Performance

Use the following tips to help optimize your data load and subsequent query performance.

- Drop indexes before loading data into existing tables.
Creating an index on pre-existing data is faster than updating it incrementally as each row is loaded. You can temporarily increase the `maintenance_work_mem` server configuration parameter to help speed up `CREATE INDEX` commands, though load performance is affected. Drop and recreate indexes only when there are no active users on the system.
- Create indexes last when loading data into new tables. Create the table, load the data, and create any required indexes.
- Run `ANALYZE` after loading data. If you significantly altered the data in a table, run `ANALYZE` or `VACUUM ANALYZE` to update table statistics for the query optimizer. Current statistics ensure that the optimizer makes the best decisions during query planning and avoids poor performance due to inaccurate or nonexistent statistics.
- Run `VACUUM` after load errors. If the load operation does not run in single row error isolation mode, the operation stops at the first error. The target table contains the rows loaded before the error occurred. You cannot access these rows, but they occupy disk space. Use the `VACUUM` command to recover the wasted space.

Parent topic: [Loading and Unloading Data](#)

Unloading Data from Greenplum Database

A writable external table allows you to select rows from other database tables and output the rows to files, named pipes, to applications, or as output targets for Greenplum parallel MapReduce calculations. You can define file-based and web-based writable external tables.

This topic describes how to unload data from Greenplum Database using parallel unload (writable external tables) and non-parallel unload ([COPY](#)).

- [Defining a File-Based Writable External Table](#)
- [Defining a Command-Based Writable External Web Table](#)
- [Unloading Data Using a Writable External Table](#)
- [Unloading Data Using COPY](#)

Parent topic: [Loading and Unloading Data](#)

Defining a File-Based Writable External Table

Writable external tables that output data to files can use the Greenplum parallel file server program, gpfdist, or the Greenplum Platform Extension Framework (PXF), Greenplum's interface to Hadoop.

Use the `CREATE WRITABLE EXTERNAL TABLE` command to define the external table and specify the location and format of the output files. See [Using the Greenplum Parallel File Server \(gpfdist\)](#) for instructions on setting up gpfdist for use with an external table and [Accessing External Data with PXF](#) for instructions on setting up PXF for use with an external table

- With a writable external table using the gpfdist protocol, the Greenplum segments send their data to gpfdist, which writes the data to the named file. gpfdist must run on a host that the Greenplum segments can access over the network. gpfdist points to a file location on the output host and writes data received from the Greenplum segments to the file. To divide the output data among multiple files, list multiple gpfdist URIs in your writable external table definition.
- A writable external web table sends data to an application as a stream of data. For example, unload data from Greenplum Database and send it to an application that connects to another database or ETL tool to load the data elsewhere. Writable external web tables use the `EXECUTE` clause to specify a shell command, script, or application to run on the segment hosts and accept an input stream of data. See [Defining a Command-Based Writable External Web Table](#) for more information about using `EXECUTE` commands in a writable external table definition.

You can optionally declare a distribution policy for your writable external tables. By default, writable external tables use a random distribution policy. If the source table you are exporting data from has a hash distribution policy, defining the same distribution key column(s) for the writable external table improves unload performance by eliminating the requirement to move rows over the interconnect. If you unload data from a particular table, you can use the `LIKE` clause to copy the column definitions and distribution policy from the source table.

- [Example 1—Greenplum file server \(gpfdist\)](#)
- [Example 2—Hadoop file server \(pxf\)](#)

Parent topic: [Unloading Data from Greenplum Database](#)

Example 1—Greenplum file server (gpfdist)

```
=# CREATE WRITABLE EXTERNAL TABLE unload_expenses
( LIKE expenses )
LOCATION ('gpfdist://etlhost-1:8081/expenses1.out',
```

```
'gpfdist://etlhost-2:8081/expenses2.out')
FORMAT 'TEXT' (DELIMITER ',')
DISTRIBUTED BY (exp_id);
```

Parent topic: [Defining a File-Based Writable External Table](#)

Example 2—Hadoop file server (pxf)

```
=# CREATE WRITABLE EXTERNAL TABLE unload_expenses
  ( LIKE expenses )
  LOCATION ('pxf://dir/path?PROFILE=hdfs:text')
  FORMAT 'TEXT' (DELIMITER ',')
  DISTRIBUTED BY (exp_id);
```

You specify an HDFS directory for a writable external table that you create with the `pxf` protocol.

Parent topic: [Defining a File-Based Writable External Table](#)

Defining a Command-Based Writable External Web Table

You can define writable external web tables to send output rows to an application or script. The application must accept an input stream, reside in the same location on all of the Greenplum segment hosts, and be executable by the `gpadmin` user. All segments in the Greenplum system run the application or script, whether or not a segment has output rows to process.

Use `CREATE WRITABLE EXTERNAL WEB TABLE` to define the external table and specify the application or script to run on the segment hosts. Commands run from within the database and cannot access environment variables (such as `$PATH`). Set environment variables in the `EXECUTE` clause of your writable external table definition. For example:

```
=# CREATE WRITABLE EXTERNAL WEB TABLE output (output text)
  EXECUTE 'export PATH=$PATH:/home/`gpadmin`
          /programs;
          myprogram.sh'
  FORMAT 'TEXT'
  DISTRIBUTED RANDOMLY;
```

The following Greenplum Database variables are available for use in OS commands run by a web or writable external table. Set these variables as environment variables in the shell that runs the command(s). They can be used to identify a set of requests made by an external table statement across the Greenplum Database array of hosts and segment instances.

Variable	Description
<code>\$GP_CID</code>	Command count of the transaction running the external table statement.
<code>\$GP_DATABASE</code>	The database in which the external table definition resides.
<code>\$GP_DATE</code>	The date on which the external table command ran.
<code>\$GP_MASTER_HOST</code>	The host name of the Greenplum master host from which the external table statement was dispatched.
<code>\$GP_MASTER_PORT</code>	The port number of the Greenplum master instance from which the external table statement was dispatched.
<code>\$GP_QUERY_STRING</code>	The SQL command (DML or SQL query) run by Greenplum Database.

Variable	Description
\$GP_SEG_DATADIR	The location of the data directory of the segment instance running the external table command.
\$GP_SEG_PG_CONF	The location of the <code>postgresql.conf</code> file of the segment instance running the external table command.
\$GP_SEG_PORT	The port number of the segment instance running the external table command.
\$GP_SEGMENT_COUNT	The total number of primary segment instances in the Greenplum Database system.
\$GP_SEGMENT_ID	The ID number of the segment instance running the external table command (same as <code>content</code> in <code>gp_segment_configuration</code>).
\$GP_SESSION_ID	The database session identifier number associated with the external table statement.
\$GP_SN	Serial number of the external table scan node in the query plan of the external table statement.
\$GP_TIME	The time the external table command was run.
\$GP_USER	The database user running the external table statement.
\$GP_XID	The transaction ID of the external table statement.

- [Disabling EXECUTE for Web or Writable External Tables](#)

Parent topic: [Unloading Data from Greenplum Database](#)

Disabling EXECUTE for Web or Writable External Tables

There is a security risk associated with allowing external tables to run OS commands or scripts. To disable the use of `EXECUTE` in web and writable external table definitions, set the `gp_external_enable_exec` server configuration parameter to off in your master `postgresql.conf` file:

```
gp_external_enable_exec = off
```

Note: You must restart the database in order for changes to the `gp_external_enable_exec` server configuration parameter to take effect.

Parent topic: [Defining a Command-Based Writable External Web Table](#)

Unloading Data Using a Writable External Table

Writable external tables allow only `INSERT` operations. You must grant `INSERT` permission on a table to enable access to users who are not the table owner or a superuser. For example:

```
GRANT INSERT ON writable_ext_table TO admin;
```

To unload data using a writable external table, select the data from the source table(s) and insert it into the writable external table. The resulting rows are output to the writable external table. For example:

```
INSERT INTO writable_ext_table SELECT * FROM regular_table;
```

Parent topic: [Unloading Data from Greenplum Database](#)

Unloading Data Using COPY

`COPY TO` copies data from a table to a file (or standard input) on the Greenplum master host using a single process on the Greenplum master instance. Use `COPY` to output a table's entire contents, or filter the output using a `SELECT` statement. For example:

```
COPY (SELECT * FROM country WHERE country_name LIKE 'A%')
TO '/home/gpadmin/a_list_countries.out';
```

Parent topic: [Unloading Data from Greenplum Database](#)

Formatting Data Files

When you use the Greenplum tools for loading and unloading data, you must specify how your data is formatted. `COPY`, `CREATE EXTERNAL TABLE`, and `gpload` have clauses that allow you to specify how your data is formatted. Data can be delimited text (`TEXT`) or comma separated values (`CSV`) format. External data must be formatted correctly to be read by Greenplum Database. This topic explains the format of data files expected by Greenplum Database.

- [Formatting Rows](#)
- [Formatting Columns](#)
- [Representing NULL Values](#)
- [Escaping](#)
- [Character Encoding](#)

Parent topic: [Loading and Unloading Data](#)

Formatting Rows

Greenplum Database expects rows of data to be separated by the `LF` character (Line feed, `0x0A`), `CR` (Carriage return, `0x0D`), or `CR` followed by `LF` (`CR+LF`, `0x0D 0x0A`). `LF` is the standard newline representation on UNIX or UNIX-like operating systems. Operating systems such as Windows or Mac OS X use `CR` or `CR+LF`. All of these representations of a newline are supported by Greenplum Database as a row delimiter. For more information, see [Importing and Exporting Fixed Width Data](#).

Parent topic: [Formatting Data Files](#)

Formatting Columns

The default column or field delimiter is the horizontal `TAB` character (`0x09`) for text files and the comma character (`0x2C`) for CSV files. You can declare a single character delimiter using the `DELIMITER` clause of `COPY`, `CREATE EXTERNAL TABLE` or `gpload` when you define your data format. The delimiter character must appear between any two data value fields. Do not place a delimiter at the beginning or end of a row. For example, if the pipe character (`|`) is your delimiter:

```
data value 1|data value 2|data value 3
```

The following command shows the use of the pipe character as a column delimiter:

```
=# CREATE EXTERNAL TABLE ext_table (name text, date date)
LOCATION ('gpfdist://<hostname>/filename.txt')
FORMAT 'TEXT' (DELIMITER '|');
```

Parent topic: [Formatting Data Files](#)

Representing NULL Values

`NULL` represents an unknown piece of data in a column or field. Within your data files you can designate a string to represent null values. The default string is `\N` (backslash-N) in `TEXT` mode, or an empty value with no quotations in `CSV` mode. You can also declare a different string using the `NULL` clause of `COPY`, `CREATE EXTERNAL TABLE` or `gpload` when defining your data format. For example, you can use an empty string if you do not want to distinguish nulls from empty strings. When using the Greenplum Database loading tools, any data item that matches the designated null string is considered a null value.

Parent topic: [Formatting Data Files](#)

Escaping

There are two reserved characters that have special meaning to Greenplum Database:

- The designated delimiter character separates columns or fields in the data file.
- The newline character designates a new row in the data file.

If your data contains either of these characters, you must escape the character so that Greenplum treats it as data and not as a field separator or new row. By default, the escape character is a `\` (backslash) for text-formatted files and a double quote (") for csv-formatted files.

- [Escaping in Text Formatted Files](#)
- [Escaping in CSV Formatted Files](#)

Parent topic: [Formatting Data Files](#)

Escaping in Text Formatted Files

By default, the escape character is a `\` (backslash) for text-formatted files. You can declare a different escape character in the `ESCAPE` clause of `COPY`, `CREATE EXTERNAL TABLE` or `gpload`. If your escape character appears in your data, use it to escape itself.

For example, suppose you have a table with three columns and you want to load the following three fields:

- `backslash = \`
- `vertical bar = |`
- `exclamation point = !`

Your designated delimiter character is `|` (pipe character), and your designated escape character is `\` (backslash). The formatted row in your data file looks like this:

```
backslash = \\ | vertical bar = \| | exclamation point = !
```

Notice how the backslash character that is part of the data is escaped with another backslash character, and the pipe character that is part of the data is escaped with a backslash character.

You can use the escape character to escape octal and hexadecimal sequences. The escaped value is converted to the equivalent character when loaded into Greenplum Database. For example, to load the ampersand character (`&`), use the escape character to escape its equivalent hexadecimal

(\0x26) or octal (\046) representation.

You can disable escaping in `TEXT`-formatted files using the `ESCAPE` clause of `COPY`, `CREATE EXTERNAL TABLE` or `gpload` as follows:

```
ESCAPE 'OFF'
```

This is useful for input data that contains many backslash characters, such as web log data.

Parent topic: [Escaping](#)

Escaping in CSV Formatted Files

By default, the escape character is a " (double quote) for CSV-formatted files. If you want to use a different escape character, use the `ESCAPE` clause of `COPY`, `CREATE EXTERNAL TABLE` or `gpload` to declare a different escape character. In cases where your selected escape character is present in your data, you can use it to escape itself.

For example, suppose you have a table with three columns and you want to load the following three fields:

- Free trip to A,B
- 5.89
- Special rate "1.79"

Your designated delimiter character is , (comma), and your designated escape character is " (double quote). The formatted row in your data file looks like this:

```
"Free trip to A,B","5.89","Special rate ""1.79"""
```

The data value with a comma character that is part of the data is enclosed in double quotes. The double quotes that are part of the data are escaped with a double quote even though the field value is enclosed in double quotes.

Embedding the entire field inside a set of double quotes guarantees preservation of leading and trailing whitespace characters:

```
"Free trip to A,B ","5.89 ","Special rate ""1.79"" "
```

Note: In CSV mode, all characters are significant. A quoted value surrounded by white space, or any characters other than `DELIMITER`, includes those characters. This can cause errors if you import data from a system that pads CSV lines with white space to some fixed width. In this case, preprocess the CSV file to remove the trailing white space before importing the data into Greenplum Database.

Parent topic: [Escaping](#)

Character Encoding

Character encoding systems consist of a code that pairs each character from a character set with something else, such as a sequence of numbers or octets, to facilitate data transmission and storage. Greenplum Database supports a variety of character sets, including single-byte character sets such as the ISO 8859 series and multiple-byte character sets such as EUC (Extended UNIX Code), UTF-8, and Mule internal code. The server-side character set is defined during database initialization, UTF-8 is the default and can be changed. Clients can use all supported character sets transparently, but a few are not supported for use within the server as a server-side encoding. When loading or inserting data into Greenplum Database, Greenplum transparently converts the data from the specified client

encoding into the server encoding. When sending data back to the client, Greenplum converts the data from the server character encoding into the specified client encoding.

Data files must be in a character encoding recognized by Greenplum Database. See the *Greenplum Database Reference Guide* for the supported character sets. Data files that contain invalid or unsupported encoding sequences encounter errors when loading into Greenplum Database.

Note: On data files generated on a Microsoft Windows operating system, run the `dos2unix` system command to remove any Windows-only characters before loading into Greenplum Database.

Note: If you *change* the `ENCODING` value in an existing `gpload` control file, you must manually drop any external tables that were creating using the previous `ENCODING` configuration. `gpload` does not drop and recreate external tables to use the new `ENCODING` if `REUSE_TABLES` is set to `true`.

Parent topic: [Formatting Data Files](#)

Changing the Client-Side Character Encoding

The client-side character encoding can be changed for a session by setting the server configuration parameter `client_encoding`

```
SET client_encoding TO 'latin1';
```

Change the client-side character encoding back to the default value:

```
RESET client_encoding;
```

Show the current client-side character encoding setting:

```
SHOW client_encoding;
```

Example Custom Data Access Protocol

The following is the API for the Greenplum Database custom data access protocol. The example protocol implementation [gpextprotocol.c](#) is written in C and shows how the API can be used. For information about accessing a custom data access protocol, see [Using a Custom Protocol](#).

```
/* ---- Read/Write function API ----*/
CALLED_AS_EXTPROTOCOL(fcinfo)
EXTPROTOCOL_GET_URL(fcinfo) (fcinfo)
EXTPROTOCOL_GET_DATABUF(fcinfo)
EXTPROTOCOL_GET_DATALEN(fcinfo)
EXTPROTOCOL_GET_SCANQUALS(fcinfo)
EXTPROTOCOL_GET_USER_CTX(fcinfo)
EXTPROTOCOL_IS_LAST_CALL(fcinfo)
EXTPROTOCOL_SET_LAST_CALL(fcinfo)
EXTPROTOCOL_SET_USER_CTX(fcinfo, p)

/* ----- Validator function API -----*/
CALLED_AS_EXTPROTOCOL_VALIDATOR(fcinfo)
EXTPROTOCOL_VALIDATOR_GET_URL_LIST(fcinfo)
EXTPROTOCOL_VALIDATOR_GET_NUM_URLS(fcinfo)
EXTPROTOCOL_VALIDATOR_GET_NTH_URL(fcinfo, n)
EXTPROTOCOL_VALIDATOR_GET_DIRECTION(fcinfo)
```

Notes

The protocol corresponds to the example described in [Using a Custom Protocol](#). The source code file name and shared object are `gpextprotocol.c` and `gpextprotocol.so`.

The protocol has the following properties:

- The name defined for the protocol is `myprot`.
- The protocol has the following simple form: the protocol name and a path, separated by `://`.
`myprot:// path`
- Three functions are implemented:
 - ◊ `myprot_import()` a read function
 - ◊ `myprot_export()` a write function
 - ◊ `myprot_validate_urls()` a validation function These functions are referenced in the `CREATE PROTOCOL` statement when the protocol is created and declared in the database.

The example implementation `gpextprotocal.c` uses `fopen()` and `fread()` to simulate a simple protocol that reads local files. In practice, however, the protocol would implement functionality such as a remote connection to some process over the network.

- **Installing the External Table Protocol**

Parent topic: [Loading and Unloading Data](#)

Installing the External Table Protocol

To use the example external table protocol, you use the C compiler `cc` to compile and link the source code to create a shared object that can be dynamically loaded by Greenplum Database. The commands to compile and link the source code on a Linux system are similar to this:

```
cc -fpic -c gpextprotocal.c cc -shared -o gpextprotocal.so gpextprotocal.o
```

The option `-fpic` specifies creating position-independent code (PIC) and the `-c` option compiles the source code without linking and creates an object file. The object file needs to be created as position-independent code (PIC) so that it can be loaded at any arbitrary location in memory by Greenplum Database.

The flag `-shared` specifies creating a shared object (shared library) and the `-o` option specifies the shared object file name `gpextprotocal.so`. Refer to the GCC manual for more information on the `cc` options.

The header files that are declared as include files in `gpextprotocal.c` are located in subdirectories of `$GPHOME/include/postgresql/`.

For more information on compiling and linking dynamically-loaded functions and examples of compiling C source code to create a shared library on other operating systems, see the PostgreSQL documentation at <https://www.postgresql.org/docs/9.4/xfunc-c.html#DFUNC>.

The manual pages for the C compiler `cc` and the link editor `ld` for your operating system also contain information on compiling and linking source code on your system.

The compiled code (shared object file) for the custom protocol must be placed in the same location on every host in your Greenplum Database array (master and all segments). This location must also be in the `LD_LIBRARY_PATH` so that the server can locate the files. It is recommended to locate shared libraries either relative to `$libdir` (which is located at `$GPHOME/lib`) or through the dynamic library

path (set by the `dynamic_library_path` server configuration parameter) on all master segment instances in the Greenplum Database array. You can use the Greenplum Database utilities `gpssh` and `gpscp` to update segments.

    if (strlen(uri_str) <= protocol_len)
        ereport(ERROR,
            (errcode(ERRCODE_SYNTAX_ERROR),
             errmsg("invalid myprot URI \'%s\' : missing path",
                    uri_str),
             errOmitLocation(true)));

    /* parse path */
    uri->path = pstrdup(uri_str + protocol_len + strlen("://"));

    return uri;
}
static
void FreeDemoUri(DemoUri *uri)
{
    if (uri->path)
        pfree(uri->path);
    if (uri->protocol)
        pfree(uri->protocol);

    pfree(uri);
}

```

Querying Data

This topic provides information about using SQL in Greenplum databases.

You enter SQL statements called queries to view, change, and analyze data in a database using the `psql` interactive SQL client and other client tools.

- **About Greenplum Query Processing**
This topic provides an overview of how Greenplum Database processes queries. Understanding this process can be useful when writing and tuning queries.
- **About GPORCA**

In Greenplum Database, the default GPORCA optimizer co-exists with the Postgres Planner.

- **Defining Queries**
Greenplum Database is based on the PostgreSQL implementation of the SQL standard.
- **WITH Queries (Common Table Expressions)**
The `WITH` clause provides a way to use subqueries or perform a data modifying operation in a larger `SELECT` query. You can also use the `WITH` clause in an `INSERT`, `UPDATE`, or `DELETE` command.
- **Using Functions and Operators**
Description of user-defined and built-in functions and operators in Greenplum Database.
- **Working with JSON Data**
Greenplum Database supports the `json` and `jsonb` data types that store JSON (JavaScript Object Notation) data.
- **Working with XML Data**
Greenplum Database supports the `xml` data type that stores XML data.
- **Using Full Text Search**
Greenplum Database provides data types, functions, operators, index types, and configurations for querying natural language documents.
- **Using Greenplum MapReduce**
MapReduce is a programming model developed by Google for processing and generating large data sets on an array of commodity servers. Greenplum MapReduce allows programmers who are familiar with the MapReduce model to write map and reduce functions and submit them to the Greenplum Database parallel engine for processing.
- **Query Performance**
Greenplum Database dynamically eliminates irrelevant partitions in a table and optimally allocates memory for different operators in a query.
- **Managing Spill Files Generated by Queries**
Greenplum Database creates spill files, also known as workfiles, on disk if it does not have sufficient memory to run an SQL query in memory.
- **Query Profiling**
Examine the query plans of poorly performing queries to identify possible performance tuning opportunities.

Parent topic: [Greenplum Database Administrator Guide](#)

About Greenplum Query Processing

This topic provides an overview of how Greenplum Database processes queries. Understanding this process can be useful when writing and tuning queries.

Users issue queries to Greenplum Database as they would to any database management system. They connect to the database instance on the Greenplum master host using a client application such as `psql` and submit SQL statements.

Parent topic: [Querying Data](#)

Understanding Query Planning and Dispatch

The master receives, parses, and optimizes the query. The resulting query plan is either parallel or targeted. The master dispatches parallel query plans to all segments, as shown in [Figure 1](#). The master dispatches targeted query plans to a single segment, as shown in [Figure 2](#). Each segment is

responsible for running local database operations on its own set of data.

Most database operations—such as table scans, joins, aggregations, and sorts—run across all segments in parallel. Each operation is performed on a segment database independent of the data stored in the other segment databases.

Certain queries may access only data on a single segment, such as single-row **INSERT**, **UPDATE**, **DELETE**, or **SELECT** operations or queries that filter on the table distribution key column(s). In queries such as these, the query plan is not dispatched to all segments, but is targeted at the segment that contains the affected or relevant row(s).

Understanding Greenplum Query Plans

A query plan is the set of operations Greenplum Database will perform to produce the answer to a query. Each *node* or step in the plan represents a database operation such as a table scan, join, aggregation, or sort. Plans are read and run from bottom to top.

In addition to common database operations such as table scans, joins, and so on, Greenplum Database has an additional operation type called *motion*. A motion operation involves moving tuples between the segments during query processing. Note that not every query requires a motion. For example, a targeted query plan does not require data to move across the interconnect.

To achieve maximum parallelism during query runtime, Greenplum divides the work of the query plan into *slices*. A slice is a portion of the plan that segments can work on independently. A query plan is sliced wherever a *motion* operation occurs in the plan, with one slice on each side of the motion.

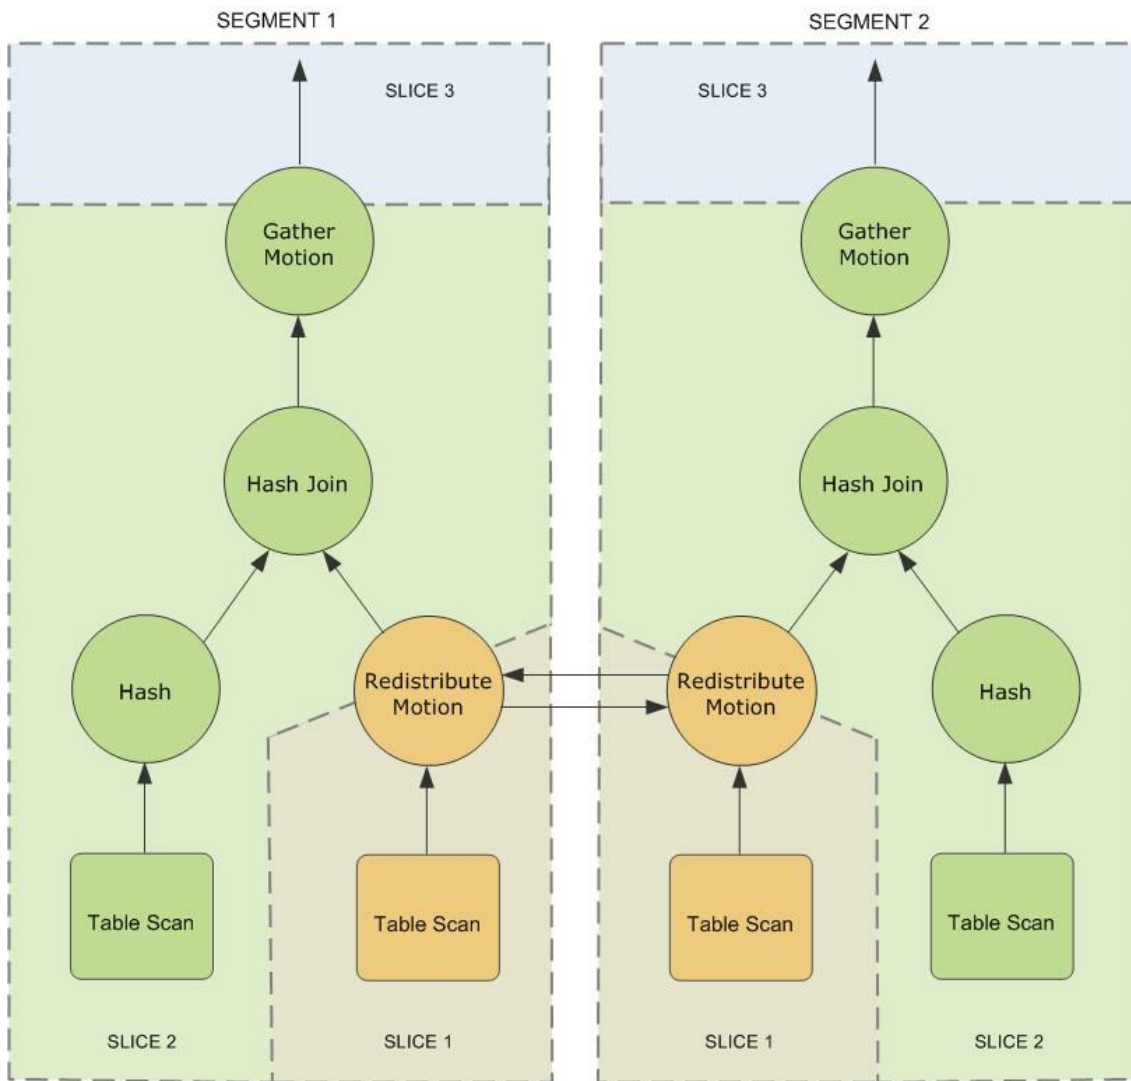

For example, consider the following simple query involving a join between two tables:

```
SELECT customer, amount
FROM sales JOIN customer USING (cust_id)
WHERE dateCol = '04-30-2016';
```

Figure 3 shows the query plan. Each segment receives a copy of the query plan and works on it in parallel.

The query plan for this example has a *redistribute motion* that moves tuples between the segments to complete the join. The redistribute motion is necessary because the customer table is distributed across the segments by *cust_id*, but the sales table is distributed across the segments by *sale_id*. To perform the join, the *sales* tuples must be redistributed by *cust_id*. The plan is sliced on either side of the redistribute motion, creating *slice 1* and *slice 2*.

This query plan has another type of motion operation called a *gather motion*. A gather motion is when the segments send results back up to the master for presentation to the client. Because a query plan is always sliced wherever a motion occurs, this plan also has an implicit slice at the very top of the plan (*slice 3*). Not all query plans involve a gather motion. For example, a `CREATE TABLE x AS SELECT...` statement would not have a gather motion because tuples are sent to the newly created table, not to the master.

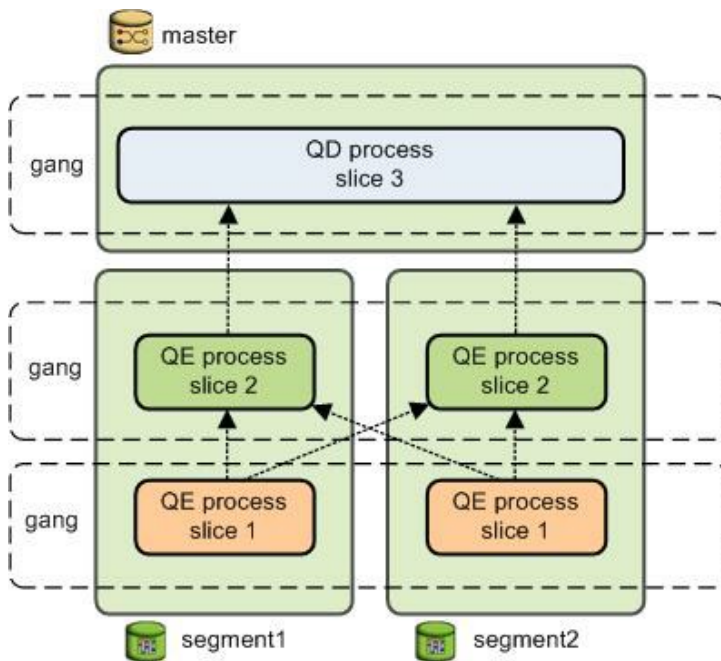

Understanding Parallel Query Execution

Greenplum creates a number of database processes to handle the work of a query. On the master, the query worker process is called the *query dispatcher* (QD). The QD is responsible for creating and dispatching the query plan. It also accumulates and presents the final results. On the segments, a query worker process is called a *query executor* (QE). A QE is responsible for completing its portion of work and communicating its intermediate results to the other worker processes.

There is at least one worker process assigned to each *slice* of the query plan. A worker process works on its assigned portion of the query plan independently. During query runtime, each segment will have a number of processes working on the query in parallel.

Related processes that are working on the same slice of the query plan but on different segments are called *gangs*. As a portion of work is completed, tuples flow up the query plan from one gang of processes to the next. This inter-process communication between the segments is referred to as the *interconnect* component of Greenplum Database.

Figure 4 shows the query worker processes on the master and two segment instances for the query plan illustrated in Figure 3.

About GPORCA

In Greenplum Database, the default GPORCA optimizer co-exists with the Postgres Planner.

- **Overview of GPORCA**
GPORCA extends the planning and optimization capabilities of the Postgres Planner.
- **Enabling and Disabling GPORCA**
By default, Greenplum Database uses GPORCA instead of the Postgres Planner. Server configuration parameters enable or disable GPORCA.
- **Collecting Root Partition Statistics**
For a partitioned table, GPORCA uses statistics of the table root partition to generate query plans. These statistics are used for determining the join order, for splitting and joining aggregate nodes, and for costing the query steps. In contrast, the Postgres Planner uses the statistics of each leaf partition.
- **Considerations when Using GPORCA**
To run queries optimally with GPORCA, consider the query criteria closely.
- **GPORCA Features and Enhancements**
GPORCA, the Greenplum next generation query optimizer, includes enhancements for specific types of queries and operations:
- **Changed Behavior with GPORCA**
There are changes to Greenplum Database behavior with the GPORCA optimizer enabled (the default) as compared to the Postgres Planner.
- **GPORCA Limitations**
There are limitations in Greenplum Database when using the default GPORCA optimizer. GPORCA and the Postgres Planner currently coexist in Greenplum Database because GPORCA does not support all Greenplum Database features.
- **Determining the Query Optimizer that is Used**
When GPORCA is enabled (the default), you can determine if Greenplum Database is using GPORCA or is falling back to the Postgres Planner.
- **About Uniform Multi-level Partitioned Tables**

Parent topic: [Querying Data](#)

Overview of GPORCA

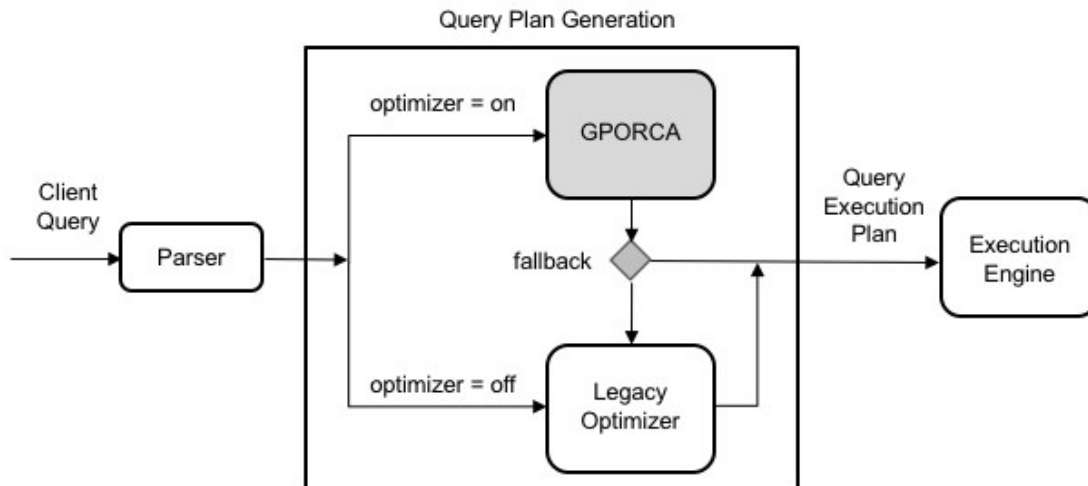

GPORCA extends the planning and optimization capabilities of the Postgres Planner. GPORCA is extensible and achieves better optimization in multi-core architecture environments. Greenplum Database uses GPORCA by default to generate an execution plan for a query when possible.

GPORCA also enhances Greenplum Database query performance tuning in the following areas:

- Queries against partitioned tables
- Queries that contain a common table expression (CTE)
- Queries that contain subqueries

In Greenplum Database, GPORCA co-exists with the Postgres Planner. By default, Greenplum Database uses GPORCA. If GPORCA cannot be used, then the Postgres Planner is used.

The following figure shows how GPORCA fits into the query planning architecture.

Note: All Postgres Planner server configuration parameters are ignored by GPORCA. However, if Greenplum Database falls back to the Postgres Planner, the planner server configuration parameters will impact the query plan generation. For a list of Postgres Planner server configuration parameters, see [Query Tuning Parameters](#).

Parent topic: [About GPORCA](#)

Enabling and Disabling GPORCA

By default, Greenplum Database uses GPORCA instead of the Postgres Planner. Server configuration parameters enable or disable GPORCA.

Although GPORCA is on by default, you can configure GPORCA usage at the system, database, session, or query level using the optimizer parameter. Refer to one of the following sections if you want to change the default behavior:

- [Enabling GPORCA for a System](#)
- [Enabling GPORCA for a Database](#)
- [Enabling GPORCA for a Session or a Query](#)

Note: You can disable the ability to enable or disable GPORCA with the server configuration parameter `optimizer_control`. For information about the server configuration parameters, see the

Greenplum Database Reference Guide.

Parent topic: [About GPORCA](#)

Enabling GPORCA for a System

Set the server configuration parameter optimizer for the Greenplum Database system.

1. Log into the Greenplum Database master host as `gpadmin`, the Greenplum Database administrator.
2. Set the values of the server configuration parameters. These Greenplum Database `gpconfig` utility commands sets the value of the parameters to `on`:

```
$ gpconfig -c optimizer -v on --masteronly
```

3. Restart Greenplum Database. This Greenplum Database `gpstop` utility command reloads the `postgresql.conf` files of the master and segments without shutting down Greenplum Database.

```
gpstop -u
```

Enabling GPORCA for a Database

Set the server configuration parameter optimizer for individual Greenplum databases with the `ALTER DATABASE` command. For example, this command enables GPORCA for the database `test_db`.

```
> ALTER DATABASE test_db SET OPTIMIZER = ON ;
```

Enabling GPORCA for a Session or a Query

You can use the `SET` command to set optimizer server configuration parameter for a session. For example, after you use the `psql` utility to connect to Greenplum Database, this `SET` command enables GPORCA:

```
> set optimizer = on ;
```

To set the parameter for a specific query, include the `SET` command prior to running the query.

Collecting Root Partition Statistics

For a partitioned table, GPORCA uses statistics of the table root partition to generate query plans. These statistics are used for determining the join order, for splitting and joining aggregate nodes, and for costing the query steps. In contrast, the Postgres Planner uses the statistics of each leaf partition.

If you run queries on partitioned tables, you should collect statistics on the root partition and periodically update those statistics to ensure that GPORCA can generate optimal query plans. If the root partition statistics are not up-to-date or do not exist, GPORCA still performs dynamic partition elimination for queries against the table. However, the query plan might not be optimal.

Parent topic: [About GPORCA](#)

Running ANALYZE

By default, running the `ANALYZE` command on the root partition of a partitioned table samples the leaf

partition data in the table, and stores the statistics for the root partition. `ANALYZE` collects statistics on the root and leaf partitions, including HyperLogLog (HLL) statistics on the leaf partitions. `ANALYZE ROOTPARTITION` collects statistics only on the root partition. The server configuration parameter `optimizer_analyze_root_partition` controls whether the `ROOTPARTITION` keyword is required to collect root statistics for the root partition of a partitioned table. See the `ANALYZE` command for information about collecting statistics on partitioned tables.

Keep in mind that `ANALYZE` always scans the entire table before updating the root partition statistics. If your table is very large, this operation can take a significant amount of time. `ANALYZE ROOTPARTITION` also uses an `ACCESS SHARE` lock that prevents certain operations, such as `TRUNCATE` and `VACUUM` operations, during runtime. For these reasons, you should schedule `ANALYZE` operations periodically, or when there are significant changes to leaf partition data.

Follow these best practices for running `ANALYZE` or `ANALYZE ROOTPARTITION` on partitioned tables in your system:

- Run `ANALYZE <root_partition_table_name>` on a new partitioned table after adding initial data. Run `ANALYZE <leaf_partition_table_name>` on a new leaf partition or a leaf partition where data has changed. By default, running the command on a leaf partition updates the root partition statistics if the other leaf partitions have statistics.
- Update root partition statistics when you observe query performance regression in `EXPLAIN` plans against the table, or after significant changes to leaf partition data. For example, if you add a new leaf partition at some point after generating root partition statistics, consider running `ANALYZE` or `ANALYZE ROOTPARTITION` to update root partition statistics with the new tuples inserted from the new leaf partition.
- For very large tables, run `ANALYZE` or `ANALYZE ROOTPARTITION` only weekly, or at some interval longer than daily.
- Avoid running `ANALYZE` with no arguments, because doing so runs the command on all database tables including partitioned tables. With large databases, these global `ANALYZE` operations are difficult to monitor, and it can be difficult to predict the time needed for completion.
- Consider running multiple `ANALYZE <table_name>` or `ANALYZE ROOTPARTITION <table_name>` operations in parallel to speed the operation of statistics collection, if your I/O throughput can support the load.
- You can also use the Greenplum Database utility `analyzedb` to update table statistics. Using `analyzedb` ensures that tables that were previously analyzed are not re-analyzed if no modifications were made to the leaf partition.

GPORCA and Leaf Partition Statistics

Although creating and maintaining root partition statistics is crucial for GPORCA query performance with partitioned tables, maintaining leaf partition statistics is also important. If GPORCA cannot generate a plan for a query against a partitioned table, then the Postgres Planner is used and leaf partition statistics are needed to produce the optimal plan for that query.

GPORCA itself also uses leaf partition statistics for any queries that access leaf partitions directly, instead of using the root partition with predicates to eliminate partitions. For example, if you know which partitions hold necessary tuples for a query, you can directly query the leaf partition table itself; in this case GPORCA uses the leaf partition statistics.

Disabling Automatic Root Partition Statistics Collection

If you do not intend to run queries on partitioned tables with GPORCA (setting the server configuration parameter `optimizer` to `off`), then you can disable the automatic collection of statistics on the root partition of the partitioned table. The server configuration parameter `optimizer_analyze_root_partition` controls whether the `ROOTPARTITION` keyword is required to collect root statistics for the root partition of a partitioned table. The default setting for the parameter is `on`, the `ANALYZE` command can collect root partition statistics without the `ROOTPARTITION` keyword. You can disable automatic collection of root partition statistics by setting the parameter to `off`. When the value is `off`, you must run `ANALYZE ROOTPARTITION` to collect root partition statistics.

1. Log into the Greenplum Database master host as `gpadmin`, the Greenplum Database administrator.
2. Set the values of the server configuration parameters. These Greenplum Database `gpconfig` utility commands sets the value of the parameters to `off`:

```
$ gpconfig -c optimizer_analyze_root_partition -v off --masteronly
```

3. Restart Greenplum Database. This Greenplum Database `gpstop` utility command reloads the `postgresql.conf` files of the master and segments without shutting down Greenplum Database.

```
gpstop -u
```

Considerations when Using GPORCA

To run queries optimally with GPORCA, consider the query criteria closely.

Ensure the following criteria are met:

- The table does not contain multi-column partition keys.
- The multi-level partitioned table is a uniform multi-level partitioned table. See [About Uniform Multi-level Partitioned Tables](#).
- The server configuration parameter `optimizer_enable_master_only_queries` is set to `on` when running against master only tables such as the system table `pg_attribute`. For information about the parameter, see the *Greenplum Database Reference Guide*.
Note: Enabling this parameter decreases performance of short running catalog queries. To avoid this issue, set this parameter only for a session or a query.
- Statistics have been collected on the root partition of a partitioned table.

If the partitioned table contains more than 20,000 partitions, consider a redesign of the table schema.

These server configuration parameters affect GPORCA query processing.

- `optimizer_cte_inlining_bound` controls the amount of inlining performed for common table expression (CTE) queries (queries that contain a `WHERE` clause).
- `optimizer_force_comprehensive_join_implementation` affects GPORCA's consideration of nested loop join and hash join alternatives. When the value is `false` (the default), GPORCA does not consider nested loop join alternatives when a hash join is available.
- `optimizer_force_multistage_agg` forces GPORCA to choose a multi-stage aggregate plan for a scalar distinct qualified aggregate. When the value is `off` (the default), GPORCA chooses between a one-stage and two-stage aggregate plan based on cost.
- `optimizer_force_three_stage_scalar_dqa` forces GPORCA to choose a plan with multistage

aggregates when such a plan alternative is generated.

- `optimizer_join_order` sets the query optimization level for join ordering by specifying which types of join ordering alternatives to evaluate.
- `optimizer_join_order_threshold` specifies the maximum number of join children for which GPORCA uses the dynamic programming-based join ordering algorithm.
- `optimizer_nestloop_factor` controls nested loop join cost factor to apply to during query optimization.
- `optimizer_parallel_union` controls the amount of parallelization that occurs for queries that contain a `UNION` or `UNION ALL` clause. When the value is `on`, GPORCA can generate a query plan of the child operations of a `UNION` or `UNION ALL` operation run in parallel on segment instances.
- `optimizer_sort_factor` controls the cost factor that GPORCA applies to sorting operations during query optimization. The cost factor can be adjusted for queries when data skew is present.
- `gp_enable_relsizes_collection` controls how GPORCA (and the Postgres Planner) handle a table without statistics. By default, GPORCA uses a default value to estimate the number of rows if statistics are not available. When this value is `on`, GPORCA uses the estimated size of a table if there are no statistics for the table.

This parameter is ignored for a root partition of a partitioned table. If the root partition does not have statistics, GPORCA always uses the default value. You can use `ANALYZE ROOTPARTITION` to collect statistics on the root partition. See [ANALYZE](#).

These server configuration parameters control the display and logging of information.

- `optimizer_print_missing_stats` controls the display of column information about columns with missing statistics for a query (default is `true`)
- `optimizer_print_optimization_stats` controls the logging of GPORCA query optimization metrics for a query (default is `off`)

For information about the parameters, see the *Greenplum Database Reference Guide*.

GPORCA generates minidumps to describe the optimization context for a given query. The minidump files are used by VMware support to analyze Greenplum Database issues. The information in the file is not in a format that can be easily used for debugging or troubleshooting. The minidump file is located under the master data directory and uses the following naming format:

```
Minidump_date_time.mdp
```

For information about the minidump file, see the server configuration parameter `optimizer_minidump` in the *Greenplum Database Reference Guide*.

When the `EXPLAIN ANALYZE` command uses GPORCA, the `EXPLAIN` plan shows only the number of partitions that are being eliminated. The scanned partitions are not shown. To show the name of the scanned partitions in the segment logs set the server configuration parameter `gp_log_dynamic_partition_pruning` to `on`. This example `SET` command enables the parameter.

```
SET gp_log_dynamic_partition_pruning = on;
```

Parent topic: [About GPORCA](#)

GPORCA Features and Enhancements

GPORCA, the Greenplum next generation query optimizer, includes enhancements for specific

types of queries and operations:

- [Queries Against Partitioned Tables](#)
- [Queries that Contain Subqueries](#)
- [Queries that Contain Common Table Expressions](#)
- [DML Operation Enhancements with GPORCA](#)

GPORCA also includes these optimization enhancements:

- Improved join ordering
- Join-Aggregate reordering
- Sort order optimization
- Data skew estimates included in query optimization

Parent topic: [About GPORCA](#)

Queries Against Partitioned Tables

GPORCA includes these enhancements for queries against partitioned tables:

- Partition elimination is improved.
- Uniform multi-level partitioned tables are supported. For information about uniform multi-level partitioned tables, see [About Uniform Multi-level Partitioned Tables](#)
- Query plan can contain the Partition selector operator.
- Partitions are not enumerated in EXPLAIN plans.

For queries that involve static partition selection where the partitioning key is compared to a constant, GPORCA lists the number of partitions to be scanned in the [EXPLAIN](#) output under the Partition Selector operator. This example Partition Selector operator shows the filter and number of partitions selected:

```
Partition Selector for Part_Table (dynamic scan id: 1)
  Filter: a > 10
  Partitions selected:  1 (out of 3)
```

For queries that involve dynamic partition selection where the partitioning key is compared to a variable, the number of partitions that are scanned will be known only during query execution. The partitions selected are not shown in the [EXPLAIN](#) output.

- Plan size is independent of number of partitions.
- Out of memory errors caused by number of partitions are reduced.

This example CREATE TABLE command creates a range partitioned table.

```
CREATE TABLE sales(order_id int, item_id int, amount numeric(15,2),
  date date, yr_qtr int)
  PARTITION BY RANGE (yr_qtr) (start (201501) INCLUSIVE end (201504) INCLUSIVE,
  start (201601) INCLUSIVE end (201604) INCLUSIVE,
  start (201701) INCLUSIVE end (201704) INCLUSIVE,
  start (201801) INCLUSIVE end (201804) INCLUSIVE,
  start (201901) INCLUSIVE end (201904) INCLUSIVE,
  start (202001) INCLUSIVE end (202004) INCLUSIVE);
```

GPORCA improves on these types of queries against partitioned tables:

- Full table scan. Partitions are not enumerated in plans.

```
SELECT * FROM sales;
```

- Query with a constant filter predicate. Partition elimination is performed.

```
SELECT * FROM sales WHERE yr_qtr = 201501;
```

- Range selection. Partition elimination is performed.

```
SELECT * FROM sales WHERE yr_qtr BETWEEN 201601 AND 201704 ;
```

- Joins involving partitioned tables. In this example, the partitioned dimension table *date_dim* is joined with fact table *catalog_sales*:

```
SELECT * FROM catalog_sales
WHERE date_id IN (SELECT id FROM date_dim WHERE month=12);
```

Queries that Contain Subqueries

GPORCA handles subqueries more efficiently. A subquery is query that is nested inside an outer query block. In the following query, the SELECT in the WHERE clause is a subquery.

```
SELECT * FROM part
WHERE price > (SELECT avg(price) FROM part);
```

GPORCA also handles queries that contain a correlated subquery (CSQ) more efficiently. A correlated subquery is a subquery that uses values from the outer query. In the following query, the *price* column is used in both the outer query and the subquery.

```
SELECT * FROM part p1 WHERE price > (SELECT avg(price) FROM part p2 WHERE p2.brand = p1.brand);
```

GPORCA generates more efficient plans for the following types of subqueries:

- CSQ in the SELECT list.

```
SELECT *,
(SELECT min(price) FROM part p2 WHERE p1.brand = p2.brand)
AS foo
FROM part p1;
```

- CSQ in disjunctive (OR) filters.

```
SELECT FROM part p1 WHERE p_size > 40 OR
p_retailprice >
(SELECT avg(p_retailprice)
FROM part p2
WHERE p2.p_brand = p1.p_brand)
```

- Nested CSQ with skip level correlations

```
SELECT * FROM part p1 WHERE p1.p_partkey
IN (SELECT p_partkey FROM part p2 WHERE p2.p_retailprice =
(SELECT min(p_retailprice)
FROM part p3
WHERE p3.p_brand = p1.p_brand)
);
```

Note: Nested CSQ with skip level correlations are not supported by the Postgres Planner.

- CSQ with aggregate and inequality. This example contains a CSQ with an inequality.

```
SELECT * FROM part p1 WHERE p1.p_retailprice =
(SELECT min(p_retailprice) FROM part p2 WHERE p2.p_brand <> p1.p_brand);
```

- CSQ that must return one row.

```
SELECT p_partkey,
       (SELECT p_retailprice FROM part p2 WHERE p2.p_brand = p1.p_brand )
FROM part p1;
```

Queries that Contain Common Table Expressions

GPORCA handles queries that contain the WITH clause. The WITH clause, also known as a common table expression (CTE), generates temporary tables that exist only for the query. This example query contains a CTE.

```
WITH v AS (SELECT a, sum(b) as s FROM T where c < 10 GROUP BY a)
SELECT *FROM v AS v1 , v AS v2
WHERE v1.a <> v2.a AND v1.s < v2.s;
```

As part of query optimization, GPORCA can push down predicates into a CTE. For example query, GPORCA pushes the equality predicates to the CTE.

```
WITH v AS (SELECT a, sum(b) as s FROM T GROUP BY a)
SELECT *
FROM v as v1, v as v2, v as v3
WHERE v1.a < v2.a
      AND v1.s < v3.s
      AND v1.a = 10
      AND v2.a = 20
      AND v3.a = 30;
```

GPORCA can handle these types of CTEs:

- CTE that defines one or multiple tables. In this query, the CTE defines two tables.

```
WITH cte1 AS (SELECT a, sum(b) as s FROM T
              where c < 10 GROUP BY a),
      cte2 AS (SELECT a, s FROM cte1 where s > 1000)
SELECT *
FROM cte1 as v1, cte2 as v2, cte2 as v3
WHERE v1.a < v2.a AND v1.s < v3.s;
```

- Nested CTEs.

```
WITH v AS (WITH w AS (SELECT a, b FROM foo
                     WHERE b < 5)
           SELECT w1.a, w2.b
           FROM w AS w1, w AS w2
           WHERE w1.a = w2.a AND w1.a > 2)
SELECT v1.a, v2.a, v2.b
FROM v as v1, v as v2
WHERE v1.a < v2.a;
```

DML Operation Enhancements with GPORCA

GPORCA contains enhancements for DML operations such as INSERT, UPDATE, and DELETE.

- A DML node in a query plan is a query plan operator.

- Can appear anywhere in the plan, as a regular node (top slice only for now)
- Can have consumers
- UPDATE operations use the query plan operator Split and supports these operations:
 - UPDATE operations on the table distribution key columns.
 - UPDATE operations on the table on the partition key column. This example plan shows the Split operator.

```

QUERY PLAN
-----
Update  (cost=0.00..5.46 rows=1 width=1)
->  Redistribute Motion 2:2  (slice1; segments: 2)
    Hash Key: a
    ->  Result  (cost=0.00..3.23 rows=1 width=48)
        ->  Split  (cost=0.00..2.13 rows=1 width=40)
            ->  Result  (cost=0.00..1.05 rows=1 width=40)
                ->  Seq Scan on dmltest

```

- New query plan operator Assert is used for constraints checking.

This example plan shows the Assert operator.

```

QUERY PLAN
-----
Insert  (cost=0.00..4.61 rows=3 width=8)
->  Assert  (cost=0.00..3.37 rows=3 width=24)
    Assert Cond: (dmlsource.a > 2) IS DISTINCT FROM
false
    ->  Assert  (cost=0.00..2.25 rows=3 width=24)
        Assert Cond: NOT dmlsource.b IS NULL
        ->  Result  (cost=0.00..1.14 rows=3 width=24)
            ->  Seq Scan on dmlsource

```

Changed Behavior with GPORCA

There are changes to Greenplum Database behavior with the GPORCA optimizer enabled (the default) as compared to the Postgres Planner.

- UPDATE operations on distribution keys are allowed.
- UPDATE operations on partitioned keys are allowed.
- Queries against uniform partitioned tables are supported.
- Queries against partitioned tables that are altered to use an external table as a leaf child partition fall back to the Postgres Planner.
- Except for **INSERT**, DML operations directly on partition (child table) of a partitioned table are not supported.

For the **INSERT** command, you can specify a leaf child table of the partitioned table to insert data into a partitioned table. An error is returned if the data is not valid for the specified leaf child table. Specifying a child table that is not a leaf child table is not supported.

- The command CREATE TABLE AS distributes table data randomly if the DISTRIBUTED BY clause is not specified and no primary or unique keys are specified.
- Non-deterministic updates not allowed. The following UPDATE command returns an error.

```
update r set b = r.b + 1 from s where r.a in (select a from s);
```

- Statistics are required on the root table of a partitioned table. The ANALYZE command generates statistics on both root and individual partition tables (leaf child tables). See the ROOTPARTITION clause for ANALYZE command.
- Additional Result nodes in the query plan:
 - Query plan Assert operator.
 - Query plan Partition selector operator.
 - Query plan Split operator.
- When running EXPLAIN, the query plan generated by GPORCA is different than the plan generated by the Postgres Planner.
- Greenplum Database adds the log file message `Planner produced plan` when GPORCA is enabled and Greenplum Database falls back to the Postgres Planner to generate the query plan.
- Greenplum Database issues a warning when statistics are missing from one or more table columns. When running an SQL command with GPORCA, Greenplum Database issues a warning if the command performance could be improved by collecting statistics on a column or set of columns referenced by the command. The warning is issued on the command line and information is added to the Greenplum Database log file. For information about collecting statistics on table columns, see the ANALYZE command in the *Greenplum Database Reference Guide*.

Parent topic: [About GPORCA](#)

GPORCA Limitations

There are limitations in Greenplum Database when using the default GPORCA optimizer. GPORCA and the Postgres Planner currently coexist in Greenplum Database because GPORCA does not support all Greenplum Database features.

This section describes the limitations.

- [Unsupported SQL Query Features](#)
- [Performance Regressions](#)

Parent topic: [About GPORCA](#)

Unsupported SQL Query Features

Certain query features are not supported with the default GPORCA optimizer. When an unsupported query is run, Greenplum logs this notice along with the query text:

Feature not supported by the Greenplum Query Optimizer: UTILITY command

These features are unsupported when GPORCA is enabled (the default):

- Prepared statements that have parameterized values.
- Indexed expressions (an index defined as expression based on one or more columns of the table)
- SP-GiST indexing method. GPORCA supports only B-tree, bitmap, GIN, and GiST indexes. GPORCA ignores indexes created with unsupported methods.
- External parameters
- These types of partitioned tables:

- Non-uniform partitioned tables.
 - Partitioned tables that have been altered to use an external table as a leaf child partition.
- SortMergeJoin (SMJ).
- Ordered aggregates are not supported by default. You can enable GPORCA support for ordered aggregates with the `optimizer_enable_orderedagg` server configuration parameter.
- Grouping sets with ordered aggregates.
- Multi-argument `DISTINCT` qualified aggregates, for example `SELECT corr(DISTINCT a, b) FROM tbl1;`, are not supported by default. You can enable GPORCA support for multi-argument distinct aggregates with the `optimizer_enable_orderedagg` server configuration parameter.
- These analytics extensions:
 - CUBE
 - Multiple grouping sets
- These scalar operators:
 - ROW
 - ROWCOMPARE
 - FIELDSELECT
- Aggregate functions that take set operators as input arguments.
- Multiple Distinct Qualified Aggregates, such as `SELECT count(DISTINCT a), sum(DISTINCT b) FROM foo;`, are not supported by default. They can be enabled with the `optimizer_enable_multiple_distinct_aggs` Configuration Parameter.
- percentile_* window functions (ordered-set aggregate functions).
- Inverse distribution functions.
- Queries that run functions that are defined with the `ON MASTER` or `ON ALL SEGMENTS` attribute.
- Queries that contain UNICODE characters in metadata names, such as table names, and the characters are not compatible with the host system locale.
- `SELECT`, `UPDATE`, and `DELETE` commands where a table name is qualified by the `ONLY` keyword.
- Per-column collation. GPORCA supports collation only when all columns in the query use the same collation. If columns in the query use different collations, then Greenplum uses the Postgres Planner.

Performance Regressions

The following features are known performance regressions that occur with GPORCA enabled:

- Short running queries - For GPORCA, short running queries might encounter additional overhead due to GPORCA enhancements for determining an optimal query execution plan.
- ANALYZE - For GPORCA, the ANALYZE command generates root partition statistics for partitioned tables. For the Postgres Planner, these statistics are not generated.
- DML operations - For GPORCA, DML enhancements including the support of updates on partition and distribution keys might require additional overhead.

Also, enhanced functionality of the features from previous versions could result in additional time required when GPORCA runs SQL statements with the features.

Determining the Query Optimizer that is Used

When GPORCA is enabled (the default), you can determine if Greenplum Database is using GPORCA or is falling back to the Postgres Planner.

You can examine the `EXPLAIN` query plan for the query to determine which query optimizer was used by Greenplum Database to run the query:

- The optimizer is listed at the end of the query plan. For example, when GPORCA generates the query plan, the query plan ends with:

```
Optimizer: Pivotal Optimizer (GPORCA)
```

When Greenplum Database falls back to the Postgres Planner to generate the plan, the query plan ends with:

```
Optimizer: Postgres query optimizer
```

- These plan items appear only in the `EXPLAIN` plan output generated by GPORCA. The items are not supported in a Postgres Planner query plan.
 - Assert operator
 - Sequence operator
 - Dynamic Index Scan
 - Dynamic Seq Scan
- When a query against a partitioned table is generated by GPORCA, the `EXPLAIN` plan displays only the number of partitions that are being eliminated is listed. The scanned partitions are not shown. The `EXPLAIN` plan generated by the Postgres Planner lists the scanned partitions.

The log file contains messages that indicate which query optimizer was used. If Greenplum Database falls back to the Postgres Planner, a message with `NOTICE` information is added to the log file that indicates the unsupported feature. Also, the label `Planner produced plan:` appears before the query in the query execution log message when Greenplum Database falls back to the Postgres optimizer.

Note: You can configure Greenplum Database to display log messages on the psql command line by setting the Greenplum Database server configuration parameter `client_min_messages` to `LOG`. See the *Greenplum Database Reference Guide* for information about the parameter.

Parent topic: [About GPORCA](#)

Examples

This example shows the differences for a query that is run against partitioned tables when GPORCA is enabled.

This `CREATE TABLE` statement creates a table with single level partitions:

```
CREATE TABLE sales (trans_id int, date date,
    amount decimal(9,2), region text)
DISTRIBUTED BY (trans_id)
PARTITION BY RANGE (date)
    (START (date '20160101')
        INCLUSIVE END (date '20170101')
        EXCLUSIVE EVERY (INTERVAL '1 month'),
    DEFAULT PARTITION outlying_dates );
```

This query against the table is supported by GPORCA and does not generate errors in the log file:

```
select * from sales ;
```

The **EXPLAIN** plan output lists only the number of selected partitions.

```
-> Partition Selector for sales (dynamic scan id: 1) (cost=10.00..100.00 rows=50 width=4)
    Partitions selected: 13 (out of 13)
```

If a query against a partitioned table is not supported by GPORCA, Greenplum Database falls back to the Postgres Planner. The **EXPLAIN** plan generated by the Postgres Planner lists the selected partitions. This example shows a part of the explain plan that lists some selected partitions.

```
-> Append (cost=0.00..0.00 rows=26 width=53)
    -> Seq Scan on sales2_1_prt_7_2_prt_usa sales2 (cost=0.00..0.00 rows=1 width=53)
    )
    -> Seq Scan on sales2_1_prt_7_2_prt_asia sales2 (cost=0.00..0.00 rows=1 width=53)
    3)
    ...
```

This example shows the log output when the Greenplum Database falls back to the Postgres Planner from GPORCA.

When this query is run, Greenplum Database falls back to the Postgres Planner.

```
explain select * from pg_class;
```

A message is added to the log file. The message contains this **NOTICE** information that indicates the reason GPORCA did not run the query:

```
NOTICE: ""Feature not supported: Queries on master-only tables"
```

About Uniform Multi-level Partitioned Tables

GPORCA supports queries on a multi-level partitioned (MLP) table if the MLP table is a uniform partitioned table. A multi-level partitioned table is a partitioned table that was created with the **SUBPARTITION** clause. A uniform partitioned table must meet these requirements.

- The partitioned table structure is uniform. Each partition node at the same level must have the same hierarchical structure.
- The partition key constraints must be consistent and uniform. At each subpartition level, the sets of constraints on the child tables created for each branch must match.

You can display information about partitioned tables in several ways, including displaying information from these sources:

- The **pg_partitions** system view contains information on the structure of a partitioned table.
- The **pg_constraint** system catalog table contains information on table constraints.
- The psql meta command `\d+ tablename` displays the table constraints for child leaf tables of a partitioned table.

Parent topic: [About GPORCA](#)

Example

This **CREATE TABLE** command creates a uniform partitioned table.

```
CREATE TABLE mlp (id int, year int, month int, day int,
region text)
DISTRIBUTED BY (id)
PARTITION BY RANGE ( year)
SUBPARTITION BY LIST (region)
SUBPARTITION TEMPLATE (
SUBPARTITION usa VALUES ( 'usa'),
SUBPARTITION europe VALUES ( 'europe'),
SUBPARTITION asia VALUES ( 'asia'))
( START ( 2006) END ( 2016) EVERY ( 5));
```

These are child tables and the partition hierarchy that are created for the table `mlp`. This hierarchy consists of one subpartition level that contains two branches.

```
mlp_1_prt_11
  mlp_1_prt_11_2_prt_usa
  mlp_1_prt_11_2_prt_europe
  mlp_1_prt_11_2_prt_asia

mlp_1_prt_21
  mlp_1_prt_21_2_prt_usa
  mlp_1_prt_21_2_prt_europe
  mlp_1_prt_21_2_prt_asia
```

The hierarchy of the table is uniform, each partition contains a set of three child tables (subpartitions). The constraints for the region subpartitions are uniform, the set of constraints on the child tables for the branch table `mlp_1_prt_11` are the same as the constraints on the child tables for the branch table `mlp_1_prt_21`.

As a quick check, this query displays the constraints for the partitions.

```
WITH tbl AS (SELECT oid, partitionlevel AS level,
partitiontablename AS part
FROM pg_partitions, pg_class
WHERE tablename = 'mlp' AND partitiontablename=relname
AND partitionlevel=1 )
SELECT tbl.part, consrc
FROM tbl, pg_constraint
WHERE tbl.oid = conrelid ORDER BY consrc;
```

Note: You will need modify the query for more complex partitioned tables. For example, the query does not account for table names in different schemas.

The `consrc` column displays constraints on the subpartitions. The set of region constraints for the subpartitions in `mlp_1_prt_1` match the constraints for the subpartitions in `mlp_1_prt_2`. The constraints for year are inherited from the parent branch tables.

part		consrc
mlp_1_prt_2_2_prt_asia		(region = 'asia'::text)
mlp_1_prt_1_2_prt_asia		(region = 'asia'::text)
mlp_1_prt_2_2_prt_europe		(region = 'europe'::text)
mlp_1_prt_1_2_prt_europe		(region = 'europe'::text)
mlp_1_prt_1_2_prt_usa		(region = 'usa'::text)
mlp_1_prt_2_2_prt_usa		(region = 'usa'::text)
mlp_1_prt_1_2_prt_asia		((year >= 2006) AND (year < 2011))
mlp_1_prt_1_2_prt_usa		((year >= 2006) AND (year < 2011))
mlp_1_prt_1_2_prt_europe		((year >= 2006) AND (year < 2011))
mlp_1_prt_2_2_prt_usa		((year >= 2011) AND (year < 2016))
mlp_1_prt_2_2_prt_asia		((year >= 2011) AND (year < 2016))
mlp_1_prt_2_2_prt_europe		((year >= 2011) AND (year < 2016))

(12 rows)

If you add a default partition to the example partitioned table with this command:

```
ALTER TABLE mlp ADD DEFAULT PARTITION def
```

The partitioned table remains a uniform partitioned table. The branch created for default partition contains three child tables and the set of constraints on the child tables match the existing sets of child table constraints.

In the above example, if you drop the subpartition `mlp_1_prt_21_2_prt_asia` and add another subpartition for the region `canada`, the constraints are no longer uniform.

```
ALTER TABLE mlp ALTER PARTITION FOR (RANK(2))
DROP PARTITION asia ;

ALTER TABLE mlp ALTER PARTITION FOR (RANK(2))
ADD PARTITION canada VALUES ('canada');
```

Also, if you add a partition `canada` under `mlp_1_prt_21`, the partitioning hierarchy is not uniform.

However, if you add the subpartition `canada` to both `mlp_1_prt_21` and `mlp_1_prt_11` the of the original partitioned table, it remains a uniform partitioned table.

Note: Only the constraints on the sets of partitions at a partition level must be the same. The names of the partitions can be different.

Defining Queries

Greenplum Database is based on the PostgreSQL implementation of the SQL standard.

This topic describes how to construct SQL queries in Greenplum Database.

- [SQL Lexicon](#)
- [SQL Value Expressions](#)

Parent topic: [Querying Data](#)

SQL Lexicon

SQL is a standard language for accessing databases. The language consists of elements that enable data storage, retrieval, analysis, viewing, manipulation, and so on. You use SQL commands to construct queries and commands that the Greenplum Database engine understands. SQL queries consist of a sequence of commands. Commands consist of a sequence of valid tokens in correct syntax order, terminated by a semicolon (;).

For more information about SQL commands, see [SQL Command Reference](#).

Greenplum Database uses PostgreSQL's structure and syntax, with some exceptions. For more information about SQL rules and concepts in PostgreSQL, see "SQL Syntax" in the PostgreSQL documentation.

SQL Value Expressions

SQL value expressions consist of one or more values, symbols, operators, SQL functions, and data. The expressions compare data or perform calculations and return a value as the result. Calculations include logical, arithmetic, and set operations.

The following are value expressions:

- An aggregate expression

- An array constructor
- A column reference
- A constant or literal value
- A correlated subquery
- A field selection expression
- A function call
- A new column value in an `INSERT` or `UPDATE`
- An operator invocation column reference
- A positional parameter reference, in the body of a function definition or prepared statement
- A row constructor
- A scalar subquery
- A search condition in a `WHERE` clause
- A target list of a `SELECT` command
- A type cast
- A value expression in parentheses, useful to group sub-expressions and override precedence
- A window expression

SQL constructs such as functions and operators are expressions but do not follow any general syntax rules. For more information about these constructs, see [Using Functions and Operators](#).

Column References

A column reference has the form:

```
<correlation>.<columnname>
```

Here, `correlation` is the name of a table (possibly qualified with a schema name) or an alias for a table defined with a `FROM` clause or one of the keywords `NEW` or `OLD`. `NEW` and `OLD` can appear only in rewrite rules, but you can use other correlation names in any SQL statement. If the column name is unique across all tables in the query, you can omit the “`correlation.`” part of the column reference.

Positional Parameters

Positional parameters are arguments to SQL statements or functions that you reference by their positions in a series of arguments. For example, `$1` refers to the first argument, `$2` to the second argument, and so on. The values of positional parameters are set from arguments external to the SQL statement or supplied when SQL functions are invoked. Some client libraries support specifying data values separately from the SQL command, in which case parameters refer to the out-of-line data values. A parameter reference has the form:

```
$number
```

For example:

```
CREATE FUNCTION dept(text) RETURNS dept
AS $$ SELECT * FROM dept WHERE name = $1 $$
```

```
LANGUAGE SQL;
```

Here, the `$1` references the value of the first function argument whenever the function is invoked.

Subscripts

If an expression yields a value of an array type, you can extract a specific element of the array value as follows:

```
<expression>[<subscript>]
```

You can extract multiple adjacent elements, called an array slice, as follows (including the brackets):

```
<expression>[<lower_subscript>:<upper_subscript>]
```

Each subscript is an expression and yields an integer value.

Array expressions usually must be in parentheses, but you can omit the parentheses when the expression to be subscripted is a column reference or positional parameter. You can concatenate multiple subscripts when the original array is multidimensional. For example (including the parentheses):

```
mytable.arraycolumn[4]
```

```
mytable.two_d_column[17][34]
```

```
$1[10:42]
```

```
(arrayfunction(a,b))[42]
```

Field Selection

If an expression yields a value of a composite type (row type), you can extract a specific field of the row as follows:

```
<expression>.<fieldname>
```

The row expression usually must be in parentheses, but you can omit these parentheses when the expression to be selected from is a table reference or positional parameter. For example:

```
mytable.mycolumn
```

```
$1.somecolumn
```

```
(rowfunction(a,b)).col3
```

A qualified column reference is a special case of field selection syntax.

Operator Invocations

Operator invocations have the following possible syntaxes:

```
<expression operator expression>(binary infix operator)
```

```
<operator expression>(unary prefix operator)
```

```
<expression operator>(unary postfix operator)
```

Where *operator* is an operator token, one of the key words **AND**, **OR**, or **NOT**, or qualified operator name in the form:

```
OPERATOR(<schema>.<operatorname>)
```

Available operators and whether they are unary or binary depends on the operators that the system or user defines. For more information about built-in operators, see [Built-in Functions and Operators](#).

Function Calls

The syntax for a function call is the name of a function (possibly qualified with a schema name), followed by its argument list enclosed in parentheses:

```
function ([expression [, expression ... ]])
```

For example, the following function call computes the square root of 2:

```
sqrt(2)
```

See [Summary of Built-in Functions](#) for lists of the built-in functions by category. You can add custom functions, too.

Aggregate Expressions

An aggregate expression applies an aggregate function across the rows that a query selects. An aggregate function performs a calculation on a set of values and returns a single value, such as the sum or average of the set of values. The syntax of an aggregate expression is one of the following:

- `aggregate_name(expression [, ...]) [FILTER (WHERE filter_clause)]` — operates across all input rows for which the expected result value is non-null. **ALL** is the default.
- `aggregate_name(ALL expression [, ...]) [FILTER (WHERE filter_clause)]` — operates identically to the first form because **ALL** is the default.
- `aggregate_name(DISTINCT expression [, ...]) [FILTER (WHERE filter_clause)]` — operates across all distinct non-null values of input rows.
- `aggregate_name(*) [FILTER (WHERE filter_clause)]` — operates on all rows with values both null and non-null. Generally, this form is most useful for the `count(*)` aggregate function.

Where *aggregate_name* is a previously defined aggregate (possibly schema-qualified) and *expression* is any value expression that does not contain an aggregate expression.

For example, `count(*)` yields the total number of input rows, `count(f1)` yields the number of input rows in which `f1` is non-null, and `count(distinct f1)` yields the number of distinct non-null values of `f1`.

If **FILTER** is specified, then only the input rows for which the `filter_clause` evaluates to true are fed to the aggregate function; other rows are discarded. For example:

```

SELECT
    count(*) AS unfiltered,
    count(*) FILTER (WHERE i < 5) AS filtered
FROM generate_series(1,10) AS s(i);
unfiltered | filtered
-----+-----
          10 |          4
(1 row)

```

For predefined aggregate functions, see [Built-in Functions and Operators](#). You can also add custom aggregate functions.

Greenplum Database provides the [MEDIAN](#) aggregate function, which returns the fiftieth percentile of the [PERCENTILE_CONT](#) result and special aggregate expressions for inverse distribution functions as follows:

```
PERCENTILE_CONT(_percentage_) WITHIN GROUP (ORDER BY _expression_)
```

```
PERCENTILE_DISC(_percentage_) WITHIN GROUP (ORDER BY _expression_)
```

Currently you can use only these two expressions with the keyword [WITHIN GROUP](#).

Limitations of Aggregate Expressions

The following are current limitations of the aggregate expressions:

- Greenplum Database does not support the following keywords: [ALL](#), [DISTINCT](#), and [OVER](#). See [Table 5](#) for more details.
- An aggregate expression can appear only in the result list or [HAVING](#) clause of a [SELECT](#) command. It is forbidden in other clauses, such as [WHERE](#), because those clauses are logically evaluated before the results of aggregates form. This restriction applies to the query level to which the aggregate belongs.
- When an aggregate expression appears in a subquery, the aggregate is normally evaluated over the rows of the subquery. If the aggregate's arguments (and filter_clause if any) contain only outer-level variables, the aggregate belongs to the nearest such outer level and evaluates over the rows of that query. The aggregate expression as a whole is then an outer reference for the subquery in which it appears, and the aggregate expression acts as a constant over any one evaluation of that subquery. The restriction about appearing only in the result list or [HAVING](#) clause applies with respect to the query level at which the aggregate appears. See [Scalar Subqueries](#) and [Table 3](#).
- Greenplum Database does not support specifying an aggregate function as an argument to another aggregate function.
- Greenplum Database does not support specifying a window function as an argument to an aggregate function.

Window Expressions

Window expressions allow application developers to more easily compose complex online analytical processing (OLAP) queries using standard SQL commands. For example, with window expressions, users can calculate moving averages or sums over various intervals, reset aggregations and ranks as selected column values change, and express complex ratios in simple terms.

A window expression represents the application of a *window function* to a *window frame*, which is

defined with an `OVER()` clause. This is comparable to the type of calculation that can be done with an aggregate function and a `GROUP BY` clause. Unlike aggregate functions, which return a single result value for each group of rows, window functions return a result value for every row, but that value is calculated with respect to the set of rows in the window frame to which the row belongs. The `OVER()` clause allows dividing the rows into *partitions* and then further restricting the window frame by specifying which rows preceding or following the current row within its partition to include in the calculation.

Greenplum Database does not support specifying a window function as an argument to another window function.

The syntax of a window expression is:

```
window_function ( [expression [, ...]] ) [ FILTER ( WHERE filter_clause ) ] OVER ( window_specification )
```

Where *window_function* is one of the functions listed in Table 4 or a user-defined window function, *expression* is any value expression that does not contain a window expression, and *window_specification* is:

```
[window_name]
[PARTITION BY expression [, ...]]
[[ORDER BY expression [ASC | DESC | USING operator] [NULLS {FIRST | LAST}} [, ...]]
  [{RANGE | ROWS}
    { UNBOUNDED PRECEDING
      | expression PRECEDING
      | CURRENT ROW
      | BETWEEN window_frame_bound AND window_frame_bound }]]
```

and where *window_frame_bound* can be one of:

```
UNBOUNDED PRECEDING
expression PRECEDING
CURRENT ROW
expression FOLLOWING
UNBOUNDED FOLLOWING
```

A window expression can appear only in the select list of a `SELECT` command. For example:

```
SELECT count(*) OVER(PARTITION BY customer_id), * FROM sales;
```

If `FILTER` is specified, then only the input rows for which the *filter_clause* evaluates to true are fed to the window function; other rows are discarded. In a window expression, a `FILTER` clause can be used only with a window_function that is an aggregate function.

In a window expression, the expression must contain an `OVER` clause. The `OVER` clause specifies the window frame—the rows to be processed by the window function. This syntactically distinguishes the function from a regular or aggregate function.

In a window aggregate function that is used in a window expression, Greenplum Database does not support a `DISTINCT` clause with multiple input expressions.

A window specification has the following characteristics:

- The `PARTITION BY` clause defines the window partitions to which the window function is applied. If omitted, the entire result set is treated as one partition.
- The `ORDER BY` clause defines the expression(s) for sorting rows within a window partition. The `ORDER BY` clause of a window specification is separate and distinct from the `ORDER BY` clause of

a regular query expression. The `ORDER BY` clause is required for the window functions that calculate rankings, as it identifies the measure(s) for the ranking values. For OLAP aggregations, the `ORDER BY` clause is required to use window frames (the `ROWS` or `RANGE` clause).

Note: Columns of data types without a coherent ordering, such as `time`, are not good candidates for use in the `ORDER BY` clause of a window specification. `Time`, with or without a specified time zone, lacks a coherent ordering because addition and subtraction do not have the expected effects. For example, the following is not generally true: `x::time < x::time + '2 hour'::interval`

- The `ROWS` or `RANGE` clause defines a window frame for aggregate (non-ranking) window functions. A window frame defines a set of rows within a window partition. When a window frame is defined, the window function computes on the contents of this moving frame rather than the fixed contents of the entire window partition. Window frames are row-based (`ROWS`) or value-based (`RANGE`).

Window Examples

The following examples demonstrate using window functions with partitions and window frames.

Example 1 – Aggregate Window Function Over a Partition

The `PARTITION BY` list in the `OVER` clause divides the rows into groups, or partitions, that have the same values as the specified expressions.

This example compares employees' salaries with the average salaries for their departments:

```
SELECT depname, empno, salary, avg(salary) OVER(PARTITION BY depname)
FROM empsalary;
```

depname	empno	salary	avg
develop	9	4500	5020.0000000000000000
develop	10	5200	5020.0000000000000000
develop	11	5200	5020.0000000000000000
develop	7	4200	5020.0000000000000000
develop	8	6000	5020.0000000000000000
personnel	5	3500	3700.0000000000000000
personnel	2	3900	3700.0000000000000000
sales	1	5000	4866.6666666666666667
sales	3	4800	4866.6666666666666667
sales	4	4800	4866.6666666666666667

(10 rows)

The first three output columns come from the table `empsalary`, and there is one output row for each row in the table. The fourth column is the average calculated on all rows that have the same `depname` value as the current row. Rows that share the same `depname` value constitute a partition, and there are three partitions in this example. The `avg` function is the same as the regular `avg` aggregate function, but the `OVER` clause causes it to be applied as a window function.

You can also put the window specification in a `WINDOW` clause and reference it in the select list. This example is equivalent to the previous query:

```
SELECT depname, empno, salary, avg(salary) OVER(mywindow)
FROM empsalary
WINDOW mywindow AS (PARTITION BY depname);
```

Defining a named window is useful when the select list has multiple window functions using the same window specification.

Example 2 – Ranking Window Function With an ORDER BY Clause

An **ORDER BY** clause within the **OVER** clause controls the order in which rows are processed by window functions. The **ORDER BY** list for the window function does not have to match the output order of the query. This example uses the **rank()** window function to rank employees' salaries within their departments:

```
SELECT depname, empno, salary,
       rank() OVER (PARTITION BY depname ORDER BY salary DESC)
FROM empsalary;
 depname | empno | salary | rank
-----+-----+-----+-----
develop  |      8 |   6000 |      1
develop  |     11 |   5200 |      2
develop  |     10 |   5200 |      2
develop  |      9 |   4500 |      4
develop  |      7 |   4200 |      5
personnel |      2 |   3900 |      1
personnel |      5 |   3500 |      2
sales     |      1 |   5000 |      1
sales     |      4 |   4800 |      2
sales     |      3 |   4800 |      2
(10 rows)
```

Example 3 – Aggregate Function over a Row Window Frame

A **RANGE** or **ROWS** clause defines the window frame—a set of rows within a partition—that the window function includes in the calculation. **ROWS** specifies a physical set of rows to process, for example all rows from the beginning of the partition to the current row.

This example calculates a running total of employee' s salaries by department using the **sum()** function to total rows from the start of the partition to the current row:

```
SELECT depname, empno, salary,
       sum(salary) OVER (PARTITION BY depname ORDER BY salary
                        ROWS between UNBOUNDED PRECEDING AND CURRENT ROW)
FROM empsalary ORDER BY depname, sum;
 depname | empno | salary | sum
-----+-----+-----+-----
develop  |      7 |   4200 |  4200
develop  |      9 |   4500 |  8700
develop  |     11 |   5200 | 13900
develop  |     10 |   5200 | 19100

(10 rows)
```

Example 4 – Aggregate Function for a Range Window Frame

RANGE specifies logical values based on values of the **ORDER BY** expression in the **OVER** clause. This example demonstrates the difference between **ROWS** and **RANGE**. The frame contains all rows with salary values less than or equal to the current row. Unlike the previous example, for employees with the same salary, the sum is the same and includes the salaries of all of those employees.

```
SELECT depname, empno, salary,
       sum(salary) OVER (PARTITION BY depname ORDER BY salary
                        RANGE between UNBOUNDED PRECEDING AND CURRENT ROW)
FROM empsalary ORDER BY depname, sum;
 depname | empno | salary | sum
-----+-----+-----+-----
develop  |      7 |   4200 |  4200
develop  |      9 |   4500 |  8700
develop  |     11 |   5200 | 19100
develop  |     10 |   5200 | 19100
develop  |      8 |   6000 | 25100
personnel |      5 |   3500 |  3500
personnel |      2 |   3900 |  7400
sales     |      4 |   4800 |  9600
sales     |      3 |   4800 |  9600
sales     |      1 |   5000 | 14600
(10 rows)
```

Type Casts

A type cast specifies a conversion from one data type to another. A cast applied to a value expression of a known type is a run-time type conversion. The cast succeeds only if a suitable type conversion is defined. This differs from the use of casts with constants. A cast applied to a string literal represents the initial assignment of a type to a literal constant value, so it succeeds for any type if the contents of the string literal are acceptable input syntax for the data type.

Greenplum Database supports three types of casts applied to a value expression:

- *Explicit cast* - Greenplum Database applies a cast when you explicitly specify a cast between two data types. Greenplum Database accepts two equivalent syntaxes for explicit type casts:

```
CAST ( expression AS type )
expression::type
```

The `CAST` syntax conforms to SQL; the syntax using `::` is historical PostgreSQL usage.

- *Assignment cast* - Greenplum Database implicitly invokes a cast in assignment contexts, when assigning a value to a column of the target data type. For example, a `CREATE CAST` command with the `AS ASSIGNMENT` clause creates a cast that is applied implicitly in the assignment context. This example assignment cast assumes that `tbl1.f1` is a column of type `text`. The `INSERT` command is allowed because the value is implicitly cast from the `integer` to `text` type.

```
INSERT INTO tbl1 (f1) VALUES (42);
```

- *Implicit cast* - Greenplum Database implicitly invokes a cast in assignment or expression contexts. For example, a `CREATE CAST` command with the `AS IMPLICIT` clause creates an implicit cast, a cast that is applied implicitly in both the assignment and expression context. This example implicit cast assumes that `tbl1.c1` is a column of type `int`. For the calculation in the predicate, the value of `c1` is implicitly cast from `int` to a `decimal` type.

```
SELECT * FROM tbl1 WHERE tbl1.c2 = (4.3 + tbl1.c1) ;
```

You can usually omit an explicit type cast if there is no ambiguity about the type a value expression must produce (for example, when it is assigned to a table column); the system automatically applies a type cast. Greenplum Database implicitly applies casts only to casts defined with a cast context of assignment or explicit in the system catalogs. Other casts must be invoked with explicit casting syntax to prevent unexpected conversions from being applied without the user's knowledge.

You can display cast information with the `psql` meta-command `\dc`. Cast information is stored in the catalog table `pg_cast`, and type information is stored in the catalog table `pg_type`.

Scalar Subqueries

A scalar subquery is a `SELECT` query in parentheses that returns exactly one row with one column. Do not use a `SELECT` query that returns multiple rows or columns as a scalar subquery. The query runs and uses the returned value in the surrounding value expression. A correlated scalar subquery contains references to the outer query block.

Correlated Subqueries

A correlated subquery (CSQ) is a `SELECT` query with a `WHERE` clause or target list that contains references to the parent outer clause. CSQs efficiently express results in terms of results of another query. Greenplum Database supports correlated subqueries that provide compatibility with many existing applications. A CSQ is a scalar or table subquery, depending on whether it returns one or multiple rows. Greenplum Database does not support correlated subqueries with skip-level correlations.

Correlated Subquery Examples

Example 1 – Scalar correlated subquery

```
SELECT * FROM t1 WHERE t1.x
      > (SELECT MAX(t2.x) FROM t2 WHERE t2.y = t1.y);
```

Example 2 – Correlated EXISTS subquery

```
SELECT * FROM t1 WHERE
EXISTS (SELECT 1 FROM t2 WHERE t2.x = t1.x);
```

Greenplum Database uses one of the following methods to run CSQs:

- Unnest the CSQ into join operations – This method is most efficient, and it is how Greenplum Database runs most CSQs, including queries from the TPC-H benchmark.
- Run the CSQ on every row of the outer query – This method is relatively inefficient, and it is how Greenplum Database runs queries that contain CSQs in the `SELECT` list or are connected by `OR` conditions.

The following examples illustrate how to rewrite some of these types of queries to improve performance.

Example 3 - CSQ in the Select List

Original Query

```
SELECT T1.a,
      (SELECT COUNT(DISTINCT T2.z) FROM t2 WHERE t1.x = t2.y) dt2
FROM t1;
```

Rewrite this query to perform an inner join with `t1` first and then perform a left join with `t1` again. The rewrite applies for only an equijoin in the correlated condition.

Rewritten Query

```
SELECT t1.a, dt2 FROM t1
  LEFT JOIN
    (SELECT t2.y AS csq_y, COUNT(DISTINCT t2.z) AS dt2
     FROM t1, t2 WHERE t1.x = t2.y
     GROUP BY t1.x)
  ON (t1.x = csq_y);
```

Example 4 - CSQs connected by OR Clauses

Original Query

```
SELECT * FROM t1
WHERE
x > (SELECT COUNT(*) FROM t2 WHERE t1.x = t2.x)
OR x < (SELECT COUNT(*) FROM t3 WHERE t1.y = t3.y)
```

Rewrite this query to separate it into two parts with a union on the [OR](#) conditions.

Rewritten Query

```
SELECT * FROM t1
WHERE x > (SELECT count(*) FROM t2 WHERE t1.x = t2.x)
UNION
SELECT * FROM t1
WHERE x < (SELECT count(*) FROM t3 WHERE t1.y = t3.y)
```

To view the query plan, use [EXPLAIN SELECT](#) or [EXPLAIN ANALYZE SELECT](#). Subplan nodes in the query plan indicate that the query will run on every row of the outer query, and the query is a candidate for rewriting. For more information about these statements, see [Query Profiling](#).

Array Constructors

An array constructor is an expression that builds an array value from values for its member elements. A simple array constructor consists of the key word [ARRAY](#), a left square bracket [\[](#), one or more expressions separated by commas for the array element values, and a right square bracket [\]](#). For example,

```
SELECT ARRAY[1,2,3+4];
   array
-----
{1,2,7}
```

The array element type is the common type of its member expressions, determined using the same rules as for [UNION](#) or [CASE](#) constructs.

You can build multidimensional array values by nesting array constructors. In the inner constructors, you can omit the keyword [ARRAY](#). For example, the following two [SELECT](#) statements produce the same result:

```
SELECT ARRAY[ARRAY[1,2], ARRAY[3,4]];
SELECT ARRAY[[1,2],[3,4]];
   array
-----
{{1,2},{3,4}}
```

Since multidimensional arrays must be rectangular, inner constructors at the same level must produce sub-arrays of identical dimensions.

Multidimensional array constructor elements are not limited to a sub-**ARRAY** construct; they are anything that produces an array of the proper kind. For example:

```
CREATE TABLE arr(f1 int[], f2 int[]);
INSERT INTO arr VALUES (ARRAY[[1,2],[3,4]],
ARRAY[[5,6],[7,8]]);
SELECT ARRAY[f1, f2, '{{9,10},{11,12}}'::int[]] FROM arr;
      array
-----
{{{1,2},{3,4}},{5,6},{7,8}},{9,10},{11,12}}
```

You can construct an array from the results of a subquery. Write the array constructor with the keyword **ARRAY** followed by a subquery in parentheses. For example:

```
SELECT ARRAY(SELECT oid FROM pg_proc WHERE proname LIKE 'bytea%');
      ?column?
-----
{2011,1954,1948,1952,1951,1244,1950,2005,1949,1953,2006,31}
```

The subquery must return a single column. The resulting one-dimensional array has an element for each row in the subquery result, with an element type matching that of the subquery's output column. The subscripts of an array value built with **ARRAY** always begin with 1.

Row Constructors

A row constructor is an expression that builds a row value (also called a composite value) from values for its member fields. For example,

```
SELECT ROW(1,2.5,'this is a test');
```

Row constructors have the syntax **rowvalue.***, which expands to a list of the elements of the row value, as when you use the syntax **.*** at the top level of a **SELECT** list. For example, if table **t** has columns **f1** and **f2**, the following queries are the same:

```
SELECT ROW(t.*, 42) FROM t;
SELECT ROW(t.f1, t.f2, 42) FROM t;
```

By default, the value created by a **ROW** expression has an anonymous record type. If necessary, it can be cast to a named composite type — either the row type of a table, or a composite type created with **CREATE TYPE AS**. To avoid ambiguity, you can explicitly cast the value if necessary. For example:

```
CREATE TABLE mytable(f1 int, f2 float, f3 text);
CREATE FUNCTION getf1(mytable) RETURNS int AS 'SELECT $1.f1'
LANGUAGE SQL;
```

In the following query, you do not need to cast the value because there is only one **getf1()** function and therefore no ambiguity:

```
SELECT getf1(ROW(1,2.5,'this is a test'));
      getf1
```

```

-----
1
CREATE TYPE myrowtype AS (f1 int, f2 text, f3 numeric);
CREATE FUNCTION getf1(myrowtype) RETURNS int AS 'SELECT
$f1.f1' LANGUAGE SQL;

```

Now we need a cast to indicate which function to call:

```

SELECT getf1(ROW(1,2.5,'this is a test'));
ERROR:  function getf1(record) is not unique

```

```

SELECT getf1(ROW(1,2.5,'this is a test')::mytable);
getf1
-----
1
SELECT getf1(CAST(ROW(11,'this is a test',2.5) AS
myrowtype));
getf1
-----
11

```

You can use row constructors to build composite values to be stored in a composite-type table column or to be passed to a function that accepts a composite parameter.

Expression Evaluation Rules

The order of evaluation of subexpressions is undefined. The inputs of an operator or function are not necessarily evaluated left-to-right or in any other fixed order.

If you can determine the result of an expression by evaluating only some parts of the expression, then other subexpressions might not be evaluated at all. For example, in the following expression:

```
SELECT true OR somefunc();
```

`somefunc()` would probably not be called at all. The same is true in the following expression:

```
SELECT somefunc() OR true;
```

This is not the same as the left-to-right evaluation order that Boolean operators enforce in some programming languages.

Do not use functions with side effects as part of complex expressions, especially in `WHERE` and `HAVING` clauses, because those clauses are extensively reprocessed when developing an execution plan. Boolean expressions (`AND/OR/NOT` combinations) in those clauses can be reorganized in any manner that Boolean algebra laws allow.

Use a `CASE` construct to force evaluation order. The following example is an untrustworthy way to avoid division by zero in a `WHERE` clause:

```
SELECT ... WHERE x <> 0 AND y/x > 1.5;
```

The following example shows a trustworthy evaluation order:

```
SELECT ... WHERE CASE WHEN x <> 0 THEN y/x > 1.5 ELSE false
```

```
END;
```

This `CASE` construct usage defeats optimization attempts; use it only when necessary.

WITH Queries (Common Table Expressions)

The `WITH` clause provides a way to use subqueries or perform a data modifying operation in a larger `SELECT` query. You can also use the `WITH` clause in an `INSERT`, `UPDATE`, or `DELETE` command.

See [SELECT in a WITH Clause](#) for information about using `SELECT` in a `WITH` clause.

See [Data-Modifying Statements in a WITH clause](#), for information about using `INSERT`, `UPDATE`, or `DELETE` in a `WITH` clause.

Note: These are limitations for using a `WITH` clause.

- For a `SELECT` command that includes a `WITH` clause, the clause can contain at most a single clause that modifies table data (`INSERT`, `UPDATE`, or `DELETE` command).
- For a data-modifying command (`INSERT`, `UPDATE`, or `DELETE`) that includes a `WITH` clause, the clause can only contain a `SELECT` command, the `WITH` clause cannot contain a data-modifying command.

By default, the `RECURSIVE` keyword for the `WITH` clause is enabled. `RECURSIVE` can be disabled by setting the server configuration parameter `gp_recursive_cte` to `false`.

Parent topic: [Querying Data](#)

SELECT in a WITH Clause

The subqueries, which are often referred to as Common Table Expressions or CTEs, can be thought of as defining temporary tables that exist just for the query. These examples show the `WITH` clause being used with a `SELECT` command. The example `WITH` clauses can be used the same way with `INSERT`, `UPDATE`, or `DELETE`. In each case, the `WITH` clause effectively provides temporary tables that can be referred to in the main command.

A `SELECT` command in the `WITH` clause is evaluated only once per execution of the parent query, even if it is referred to more than once by the parent query or sibling `WITH` clauses. Thus, expensive calculations that are needed in multiple places can be placed within a `WITH` clause to avoid redundant work. Another possible application is to prevent unwanted multiple evaluations of functions with side-effects. However, the other side of this coin is that the optimizer is less able to push restrictions from the parent query down into a `WITH` query than an ordinary sub-query. The `WITH` query will generally be evaluated as written, without suppression of rows that the parent query might discard afterwards. However, evaluation might stop early if the references to the query demand only a limited number of rows.

One use of this feature is to break down complicated queries into simpler parts. This example query displays per-product sales totals in only the top sales regions:

```
WITH regional_sales AS (
  SELECT region, SUM(amount) AS total_sales
  FROM orders
  GROUP BY region
), top_regions AS (
  SELECT region
  FROM regional_sales
  WHERE total_sales > (SELECT SUM(total_sales)/10 FROM regional_sales)
)
```

```
SELECT region,
       product,
       SUM(quantity) AS product_units,
       SUM(amount) AS product_sales
FROM orders
WHERE region IN (SELECT region FROM top_regions)
GROUP BY region, product;
```

The query could have been written without the `WITH` clause, but would have required two levels of nested sub-SELECTs. It is easier to follow with the `WITH` clause.

When the optional `RECURSIVE` keyword is enabled, the `WITH` clause can accomplish things not otherwise possible in standard SQL. Using `RECURSIVE`, a query in the `WITH` clause can refer to its own output. This is a simple example that computes the sum of integers from 1 through 100:

```
WITH RECURSIVE t(n) AS (
    VALUES (1)
    UNION ALL
    SELECT n+1 FROM t WHERE n < 100
)
SELECT sum(n) FROM t;
```

The general form of a recursive `WITH` clause (a `WITH` clause that uses a the `RECURSIVE` keyword) is a *non-recursive term*, followed by a `UNION` (or `UNION ALL`), and then a *recursive term*, where only the *recursive term* can contain a reference to the query output.

```
<non_recursive_term> UNION [ ALL ] <recursive_term>
```

A recursive `WITH` query that contains a `UNION [ALL]` is run as follows:

1. Evaluate the non-recursive term. For `UNION` (but not `UNION ALL`), discard duplicate rows. Include all remaining rows in the result of the recursive query, and also place them in a temporary *working table*.
2. As long as the working table is not empty, repeat these steps:
 1. Evaluate the recursive term, substituting the current contents of the working table for the recursive self-reference. For `UNION` (but not `UNION ALL`), discard duplicate rows and rows that duplicate any previous result row. Include all remaining rows in the result of the recursive query, and also place them in a temporary *intermediate table*.
 2. Replace the contents of the *working table* with the contents of the *intermediate table*, then empty the *intermediate table*.

Note: Strictly speaking, the process is iteration not recursion, but `RECURSIVE` is the terminology chosen by the SQL standards committee.

Recursive `WITH` queries are typically used to deal with hierarchical or tree-structured data. An example is this query to find all the direct and indirect sub-parts of a product, given only a table that shows immediate inclusions:

```
WITH RECURSIVE included_parts(sub_part, part, quantity) AS (
    SELECT sub_part, part, quantity FROM parts WHERE part = 'our_product'
    UNION ALL
    SELECT p.sub_part, p.part, p.quantity
    FROM included_parts pr, parts p
    WHERE p.part = pr.sub_part
)
SELECT sub_part, SUM(quantity) as total_quantity
FROM included_parts
```

```
GROUP BY sub_part ;
```

When working with recursive **WITH** queries, you must ensure that the recursive part of the query eventually returns no tuples, or else the query loops indefinitely. In the example that computes the sum of integers, the working table contains a single row in each step, and it takes on the values from 1 through 100 in successive steps. In the 100th step, there is no output because of the **WHERE** clause, and the query terminates.

For some queries, using **UNION** instead of **UNION ALL** can ensure that the recursive part of the query eventually returns no tuples by discarding rows that duplicate previous output rows. However, often a cycle does not involve output rows that are complete duplicates: it might be sufficient to check just one or a few fields to see if the same point has been reached before. The standard method for handling such situations is to compute an array of the visited values. For example, consider the following query that searches a table graph using a link field:

```
WITH RECURSIVE search_graph(id, link, data, depth) AS (
    SELECT g.id, g.link, g.data, 1
    FROM graph g
    UNION ALL
    SELECT g.id, g.link, g.data, sg.depth + 1
    FROM graph g, search_graph sg
    WHERE g.id = sg.link
)
SELECT * FROM search_graph;
```

This query loops if the link relationships contain cycles. Because the query requires a **depth** output, changing **UNION ALL** to **UNION** does not eliminate the looping. Instead the query needs to recognize whether it has reached the same row again while following a particular path of links. This modified query adds two columns, **path** and **cycle**, to the loop-prone query:

```
WITH RECURSIVE search_graph(id, link, data, depth, path, cycle) AS (
    SELECT g.id, g.link, g.data, 1,
        ARRAY[g.id],
        false
    FROM graph g
    UNION ALL
    SELECT g.id, g.link, g.data, sg.depth + 1,
        path || g.id,
        g.id = ANY(path)
    FROM graph g, search_graph sg
    WHERE g.id = sg.link AND NOT cycle
)
SELECT * FROM search_graph;
```

Aside from detecting cycles, the array value of **path** is useful in its own right since it represents the path taken to reach any particular row.

In the general case where more than one field needs to be checked to recognize a cycle, an array of rows can be used. For example, if we needed to compare fields **f1** and **f2**:

```
WITH RECURSIVE search_graph(id, link, data, depth, path, cycle) AS (
    SELECT g.id, g.link, g.data, 1,
        ARRAY[ROW(g.f1, g.f2)],
        false
    FROM graph g
    UNION ALL
    SELECT g.id, g.link, g.data, sg.depth + 1,
```

```

        path || ROW(g.f1, g.f2),
        ROW(g.f1, g.f2) = ANY(path)
FROM graph g, search_graph sg
WHERE g.id = sg.link AND NOT cycle
)
SELECT * FROM search_graph;

```

Tip: Omit the `ROW()` syntax in the case where only one field needs to be checked to recognize a cycle. This uses a simple array rather than a composite-type array, gaining efficiency.

Tip: The recursive query evaluation algorithm produces its output in breadth-first search order. You can display the results in depth-first search order by making the outer query `ORDER BY` a path column constructed in this way.

A helpful technique for testing a query when you are not certain if it might loop indefinitely is to place a `LIMIT` in the parent query. For example, this query would loop forever without the `LIMIT` clause:

```

WITH RECURSIVE t(n) AS (
    SELECT 1
    UNION ALL
    SELECT n+1 FROM t
)
SELECT n FROM t LIMIT 100;

```

The technique works because the recursive `WITH` implementation evaluates only as many rows of a `WITH` query as are actually fetched by the parent query. Using this technique in production is not recommended, because other systems might work differently. Also, the technique might not work if the outer query sorts the recursive `WITH` results or join the results to another table.

Data-Modifying Statements in a WITH clause

For a `SELECT` command, you can use the data-modifying commands `INSERT`, `UPDATE`, or `DELETE` in a `WITH` clause. This allows you to perform several different operations in the same query.

A data-modifying statement in a `WITH` clause is run exactly once, and always to completion, independently of whether the primary query reads all (or indeed any) of the output. This is different from the rule when using `SELECT` in a `WITH` clause, the execution of a `SELECT` continues only as long as the primary query demands its output.

This simple CTE query deletes rows from `products`. The `DELETE` in the `WITH` clause deletes the specified rows from `products`, returning their contents by means of its `RETURNING` clause.

```

WITH deleted_rows AS (
    DELETE FROM products
    WHERE
        "date" >= '2010-10-01' AND
        "date" < '2010-11-01'
    RETURNING *
)
SELECT * FROM deleted_rows;

```

Data-modifying statements in a `WITH` clause must have `RETURNING` clauses, as shown in the previous example. It is the output of the `RETURNING` clause, not the target table of the data-modifying statement, that forms the temporary table that can be referred to by the rest of the query. If a data-modifying statement in a `WITH` lacks a `RETURNING` clause, an error is returned.

If the optional `RECURSIVE` keyword is enabled, recursive self-references in data-modifying statements

are not allowed. In some cases it is possible to work around this limitation by referring to the output of a recursive [WITH](#). For example, this query would remove all direct and indirect subparts of a product.

```
WITH RECURSIVE included_parts(sub_part, part) AS (
    SELECT sub_part, part FROM parts WHERE part = 'our_product'
    UNION ALL
    SELECT p.sub_part, p.part
    FROM included_parts pr, parts p
    WHERE p.part = pr.sub_part
)
DELETE FROM parts
WHERE part IN (SELECT part FROM included_parts);
```

The sub-statements in a [WITH](#) clause are run concurrently with each other and with the main query. Therefore, when using a data-modifying statement in a [WITH](#), the statement is run in a *snapshot*. The effects of the statement are not visible on the target tables. The [RETURNING](#) data is the only way to communicate changes between different [WITH](#) sub-statements and the main query. In this example, the outer [SELECT](#) returns the original prices before the action of the [UPDATE](#) in the [WITH](#) clause.

```
WITH t AS (
    UPDATE products SET price = price * 1.05
    RETURNING *
)
SELECT * FROM products;
```

In this example the outer [SELECT](#) returns the updated data.

```
WITH t AS (
    UPDATE products SET price = price * 1.05
    RETURNING *
)
SELECT * FROM t;
```

Updating the same row twice in a single statement is not supported. The effects of such a statement will not be predictable. Only one of the modifications takes place, but it is not easy (and sometimes not possible) to predict which modification occurs.

Any table used as the target of a data-modifying statement in a [WITH](#) clause must not have a conditional rule, or an [ALSO](#) rule, or an [INSTEAD](#) rule that expands to multiple statements.

Using Functions and Operators

Description of user-defined and built-in functions and operators in Greenplum Database.

- [Advanced Aggregate Functions](#)

Parent topic: [Querying Data](#)

Using Functions in Greenplum Database

When you invoke a function in Greenplum Database, function attributes control the execution of the function. The volatility attributes ([IMMUTABLE](#), [STABLE](#), [VOLATILE](#)) and the [EXECUTE ON](#) attributes control

two different aspects of function execution. In general, volatility indicates when the function is run, and `EXECUTE ON` indicates where it is run. The volatility attributes are PostgreSQL based attributes, the `EXECUTE ON` attributes are Greenplum Database attributes.

For example, a function defined with the `IMMUTABLE` attribute can be run at query planning time, while a function with the `VOLATILE` attribute must be run for every row in the query. A function with the `EXECUTE ON MASTER` attribute runs only on the master instance, and a function with the `EXECUTE ON ALL SEGMENTS` attribute runs on all primary segment instances (not the master).

These tables summarize what Greenplum Database assumes about function execution based on the attribute.

Function Attribute	Greenplum Support	Description	Comments
IMMUTABLE	Yes	Relies only on information directly in its argument list. Given the same argument values, always returns the same result.	
STABLE	Yes, in most cases	Within a single table scan, returns the same result for same argument values, but results change across SQL statements.	Results depend on database lookups or parameter values. <code>current_timestamp</code> family of functions is <code>STABLE</code> ; values do not change within an execution.
VOLATILE	Restricted	Function values can change within a single table scan. For example: <code>random()</code> , <code>timeofday()</code> . This is the default attribute.	Any function with side effects is volatile, even if its result is predictable. For example: <code>setval()</code> .

Function Attribute	Description	Comments
EXECUTE ON ANY	Indicates that the function can be run on the master, or any segment instance, and it returns the same result regardless of where it runs. This is the default attribute.	Greenplum Database determines where the function runs.
EXECUTE ON MASTER	Indicates that the function must be run on the master instance.	Specify this attribute if the user-defined function runs queries to access tables.
EXECUTE ON ALL SEGMENTS	Indicates that for each invocation, the function must be run on all primary segment instances, but not the master.	
EXECUTE ON INITPLAN	Indicates that the function contains an SQL command that dispatches queries to the segment instances and requires special processing on the master instance by Greenplum Database when possible.	

You can display the function volatility and `EXECUTE ON` attribute information with the `psql \df+ function` command.

Refer to the PostgreSQL [Function Volatility Categories](#) documentation for additional information about the Greenplum Database function volatility classifications.

For more information about `EXECUTE ON` attributes, see [CREATE FUNCTION](#).

In Greenplum Database, data is divided up across segments — each segment is a distinct PostgreSQL database. To prevent inconsistent or unexpected results, do not run functions classified as `VOLATILE` at the segment level if they contain SQL commands or modify the database in any way. For example, functions such as `setval()` are not allowed to run on distributed data in Greenplum Database because they can cause inconsistent data between segment instances.

A function can run read-only queries on replicated tables (`DISTRIBUTED REPLICATED`) on the

segments, but any SQL command that modifies data must run on the master instance.

Note: The hidden system columns (`ctid`, `cmin`, `cmax`, `xmin`, `xmax`, and `gp_segment_id`) cannot be referenced in user queries on replicated tables because they have no single, unambiguous value. Greenplum Database returns a `column does not exist` error for the query.

To ensure data consistency, you can safely use `VOLATILE` and `STABLE` functions in statements that are evaluated on and run from the master. For example, the following statements run on the master (statements without a `FROM` clause):

```
SELECT setval('myseq', 201);
SELECT foo();
```

If a statement has a `FROM` clause containing a distributed table *and* the function in the `FROM` clause returns a set of rows, the statement can run on the segments:

```
SELECT * from foo();
```

Greenplum Database does not support functions that return a table reference (`rangeFuncs`) or functions that use the `refCursor` data type.

Function Volatility and Plan Caching

There is relatively little difference between the `STABLE` and `IMMUTABLE` function volatility categories for simple interactive queries that are planned and immediately run. It does not matter much whether a function is run once during planning or once during query execution start up. But there is a big difference when you save the plan and reuse it later. If you mislabel a function `IMMUTABLE`, Greenplum Database may prematurely fold it to a constant during planning, possibly reusing a stale value during subsequent execution of the plan. You may run into this hazard when using `PREPARED` statements, or when using languages such as PL/pgSQL that cache plans.

User-Defined Functions

Greenplum Database supports user-defined functions. See [Extending SQL](#) in the PostgreSQL documentation for more information.

Use the `CREATE FUNCTION` statement to register user-defined functions that are used as described in [Using Functions in Greenplum Database](#). By default, user-defined functions are declared as `VOLATILE`, so if your user-defined function is `IMMUTABLE` or `STABLE`, you must specify the correct volatility level when you register your function.

By default, user-defined functions are declared as `EXECUTE ON ANY`. A function that runs queries to access tables is supported only when the function runs on the master instance, except that a function can run `SELECT` commands that access only replicated tables on the segment instances. A function that accesses hash-distributed or randomly distributed tables must be defined with the `EXECUTE ON MASTER` attribute. Otherwise, the function might return incorrect results when the function is used in a complicated query. Without the attribute, planner optimization might determine it would be beneficial to push the function invocation to segment instances.

When you create user-defined functions, avoid using fatal errors or destructive calls. Greenplum Database may respond to such errors with a sudden shutdown or restart.

In Greenplum Database, the shared library files for user-created functions must reside in the same library path location on every host in the Greenplum Database array (masters, segments, and mirrors).

You can also create and run anonymous code blocks that are written in a Greenplum Database

procedural language such as PL/pgSQL. The anonymous blocks run as transient anonymous functions. For information about creating and running anonymous blocks, see the [DO](#) command.

Built-in Functions and Operators

The following table lists the categories of built-in functions and operators supported by PostgreSQL. All functions and operators are supported in Greenplum Database as in PostgreSQL with the exception of [STABLE](#) and [VOLATILE](#) functions, which are subject to the restrictions noted in [Using Functions in Greenplum Database](#). See the [Functions and Operators](#) section of the PostgreSQL documentation for more information about these built-in functions and operators.

Greenplum Database includes JSON processing functions that manipulate values the [json](#) data type. For information about JSON data, see [Working with JSON Data](#).

Table 3. Built-in functions and operators

Operator/Function Category	VOLATILE Functions	STABLE Functions	Restrictions
Logical Operators			
Comparison Operators			
Mathematical Functions and Operators	random setseed		
String Functions and Operators	<i>All built-in conversion functions</i>	convert pg_client_encoding	
Binary String Functions and Operators			
Bit String Functions and Operators

Window Functions

The following built-in window functions are Greenplum extensions to the PostgreSQL database. All window functions are *immutable*. For more information about window functions, see [Window Expressions](#).

Table 4. Window functions

Function	Return Type	Full Syntax	Description
<code>cume_dist()</code>	<code>double precision</code>	<code>CUME_DIST() OVER ([PARTITION BY expr] ORDER BY expr)</code>	Calculates the cumulative distribution of a value in a group of values. Rows with equal values always evaluate to the same cumulative distribution value.
<code>dense_rank()</code>	<code>bigint</code>	<code>DENSE_RANK () OVER ([PARTITION BY expr] ORDER BY expr)</code>	Computes the rank of a row in an ordered group of rows without skipping rank values. Rows with equal values are given the same rank value.
<code>first_value(expr)</code>	same as input <code>expr</code> type	<code>FIRST_VALUE(expr) OVER ([PARTITION BY expr] ORDER BY expr [ROWS RANGE frame_expr])</code>	Returns the first value in an ordered set of values.
<code>lag(expr [,offset] [,default])</code>	same as input <code>expr</code> type	<code>LAG(expr [, offset] [, default]) OVER ([PARTITION BY expr] ORDER BY expr)</code>	Provides access to more than one row of the same table without doing a self join. Given a series of rows returned from a query and a position of the cursor, <code>LAG</code> provides access to a row at a given physical offset prior to that position. The default <code>offset</code> is 1. <code>default</code> sets the value that is returned if the offset goes beyond the scope of the window. If <code>default</code> is not specified, the default value is null.
<code>last_value(expr)</code>	same as input <code>expr</code> type	<code>LAST_VALUE(expr) OVER ([PARTITION BY expr] ORDER BY expr [ROWS RANGE frame_expr])</code>	Returns the last value in an ordered set of values.

Table 4. Window functions

Function	Return Type	Full Syntax	Description
<code>lead(expr [,offset] [,default])</code>	same as input <i>expr</i> type	<code>LEAD(expr [,offset] [,exprdefault]) OVER ([PARTITION BY expr] ORDER BY expr)</code>	Provides access to more than one row of the same table without doing a self join. Given a series of rows returned from a query and a position of the cursor, <code>lead</code> provides access to a row at a given physical offset after that position. If <i>offset</i> is not specified, the default offset is 1. <i>default</i> sets the value that is returned if the offset goes beyond the scope of the window. If <i>default</i> is not specified, the default value is null.
<code>ntile(expr)</code>	<code>bigint</code>	<code>NTILE(expr) OVER ([PARTITION BY expr] ORDER BY expr)</code>	Divides an ordered data set into a number of buckets (as defined by <i>expr</i>) and assigns a bucket number to each row.
<code>percent_rank()</code>	<code>double precision</code>	<code>PERCENT_RANK () OVER ([PARTITION BY expr] ORDER BY expr)</code>	Calculates the rank of a hypothetical row <i>R</i> minus 1, divided by 1 less than the number of rows being evaluated (within a window partition).
<code>rank()</code>	<code>bigint</code>	<code>RANK () OVER ([PARTITION BY expr] ORDER BY expr)</code>	Calculates the rank of a row in an ordered group of values. Rows with equal values for the ranking criteria receive the same rank. The number of tied rows are added to the rank number to calculate the next rank value. Ranks may not be consecutive numbers in this case.
<code>row_number()</code>	<code>bigint</code>	<code>ROW_NUMBER () OVER ([PARTITION BY expr] ORDER BY expr)</code>	Assigns a unique number to each row to which it is applied (either each row in a window partition or each row of the query).

Advanced Aggregate Functions

The following built-in advanced aggregate functions are Greenplum extensions of the PostgreSQL database. These functions are *immutable*.

Note: The Greenplum MADlib Extension for Analytics provides additional advanced functions to

perform statistical analysis and machine learning with Greenplum Database data. See [Greenplum MADlib Extension for Analytics](#) in the *Greenplum Database Reference Guide*.

Table 5. Advanced Aggregate Functions

Function	Return Type	Full Syntax	Description
<code>MEDIAN (expr)</code>	<code>timestamp,</code> <code>timestampz,</code> <code>interval, float</code>	<code>MEDIAN (expression)</code> <i>Example:</i> <pre>SELECT departmzent_id, MEDIAN(salary) FROM emp loyees GROUP BY departm ent_id;</pre>	Can take a two-dimensional array as input. Treats such arrays as matrices.
<code>sum(array[])</code>	<code>smallint[],</code> <code>int[], bigint[],</code> <code>float[]</code>	<code>sum(array[[1,2],[3,4]])</code> <i>Example:</i> <pre>CREATE TABLE mymatrix (myvalue int[]); INSERT INTO mymatrix VALUES (a rray[[1,2],[3,4]]); INS ERT INTO mymatrix VALUE S (array[[0,1],[1,0]]); SELECT sum(myvalue) FR OM mymatrix; sum {{1,3},{4,4}}</pre>	Performs matrix summation. Can take as input a two-dimensional array that is treated as a matrix.
<code>pivot_sum (label[], label, expr)</code>	<code>int[], bigint[],</code> <code>float[]</code>	<code>pivot_sum(array['A1' , 'A2'], attr, value)</code>	A pivot aggregation using sum to resolve duplicate entries.
<code>unnest (array[])</code>	set of anyelement	<code>unnest(array['one' , 'row' , 'per' , 'item'])</code>	Transforms a one dimensional array into rows. Returns a set of anyelement , a polymorphic pseudo-type in PostgreSQL.

Working with JSON Data

Greenplum Database supports the `json` and `jsonb` data types that store JSON (JavaScript Object Notation) data.

Greenplum Database supports JSON as specified in the [RFC 7159](#) document and enforces data validity according to the JSON rules. There are also JSON-specific functions and operators available for the `json` and `jsonb` data types. See [JSON Functions and Operators](#).

This section contains the following topics:

- [About JSON Data](#)
- [JSON Input and Output Syntax](#)
- [Designing JSON documents](#)
- [jsonb Containment and Existence](#)
- [jsonb Indexing](#)
- [JSON Functions and Operators](#)

Parent topic: [Querying Data](#)

About JSON Data

Greenplum Database supports two JSON data types: `json` and `jsonb`. They accept almost identical sets of values as input. The major difference is one of efficiency.

- The `json` data type stores an exact copy of the input text. This requires JSON processing functions to reparse `json` data on each execution. The `json` data type does not alter the input text.
 - ◊ Semantically-insignificant white space between tokens is retained, as well as the order of keys within JSON objects.
 - ◊ All key/value pairs are kept even if a JSON object contains duplicate keys. For duplicate keys, JSON processing functions consider the last value as the operative one.
- The `jsonb` data type stores a decomposed binary format of the input text. The conversion overhead makes data input slightly slower than the `json` data type. However, The JSON processing functions are significantly faster because reparsing `jsonb` data is not required. The `jsonb` data type alters the input text.
 - ◊ White space is not preserved.
 - ◊ The order of object keys is not preserved.
 - ◊ Duplicate object keys are not kept. If the input includes duplicate keys, only the last value is kept. The `jsonb` data type supports indexing. See [jsonb Indexing](#).

In general, JSON data should be stored as the `jsonb` data type unless there are specialized needs, such as legacy assumptions about ordering of object keys.

About Unicode Characters in JSON Data

The [RFC 7159](#) document permits JSON strings to contain Unicode escape sequences denoted by `\uXXXX`. However, Greenplum Database allows only one character set encoding per database. It is not possible for the `json` data type to conform rigidly to the JSON specification unless the database encoding is UTF8. Attempts to include characters that cannot be represented in the database encoding will fail. Characters that can be represented in the database encoding, but not in UTF8, are allowed.

- The Greenplum Database input function for the `json` data type allows Unicode escapes regardless of the database encoding and checks Unicode escapes only for syntactic correctness (a `\u` followed by four hex digits).
- The Greenplum Database input function for the `jsonb` data type is more strict. It does not allow Unicode escapes for non-ASCII characters (those above `U+007F`) unless the database encoding is UTF8. It also rejects `\u0000`, which cannot be represented in the Greenplum Database `text` type, and it requires that any use of Unicode surrogate pairs to designate characters outside the Unicode Basic Multilingual Plane be correct. Valid Unicode escapes, except for `\u0000`, are converted to the equivalent ASCII or UTF8 character for storage; this includes folding surrogate pairs into a single character.

Note: Many of the JSON processing functions described in [JSON Functions and Operators](#) convert Unicode escapes to regular characters. The functions throw an error for characters that cannot be represented in the database encoding. You should avoid mixing Unicode escapes in JSON with a non-UTF8 database encoding, if possible.

Mapping JSON Data Types to Greenplum Data Types

When converting JSON text input into `jsonb` data, the primitive data types described by RFC 7159 are effectively mapped onto native Greenplum Database data types, as shown in the following table.

JSON primitive data type	Greenplum Database data type	Notes
<code>string</code>	<code>text</code>	<code>\u0000</code> is not allowed. Non-ASCII Unicode escapes are allowed only if database encoding is UTF8
<code>number</code>	<code>numeric</code>	<code>NaN</code> and <code>infinity</code> values are disallowed
<code>boolean</code>	<code>boolean</code>	Only lowercase <code>true</code> and <code>false</code> spellings are accepted
<code>null</code>	(none)	The JSON <code>null</code> primitive type is different than the SQL <code>NULL</code> .

There are some minor constraints on what constitutes valid `jsonb` data that do not apply to the `json` data type, nor to JSON in the abstract, corresponding to limits on what can be represented by the underlying data type. Notably, when converting data to the `jsonb` data type, numbers that are outside the range of the Greenplum Database `numeric` data type are rejected, while the `json` data type does not reject such numbers.

Such implementation-defined restrictions are permitted by RFC 7159. However, in practice such problems might occur in other implementations, as it is common to represent the JSON `number` primitive type as IEEE 754 double precision floating point (which RFC 7159 explicitly anticipates and allows for).

When using JSON as an interchange format with other systems, be aware of the possibility of losing numeric precision compared to data originally stored by Greenplum Database.

Also, as noted in the previous table, there are some minor restrictions on the input format of JSON primitive types that do not apply to the corresponding Greenplum Database data types.

JSON Input and Output Syntax

The input and output syntax for the `json` data type is as specified in RFC 7159.

The following are all valid `json` expressions:

```
-- Simple scalar/primitive value
-- Primitive values can be numbers, quoted strings, true, false, or null
SELECT '5'::json;

-- Array of zero or more elements (elements need not be of same type)
SELECT '[1, 2, "foo", null]'::json;

-- Object containing pairs of keys and values
-- Note that object keys must always be quoted strings
SELECT '{"bar": "baz", "balance": 7.77, "active": false}'::json;

-- Arrays and objects can be nested arbitrarily
SELECT '{"foo": [true, "bar"], "tags": {"a": 1, "b": null}}'::json;
```

As previously stated, when a JSON value is input and then printed without any additional processing, the `json` data type outputs the same text that was input, while the `jsonb` data type does not preserve semantically-insignificant details such as whitespace. For example, note the differences here:

```
SELECT '{"bar": "baz", "balance": 7.77, "active": false}'::json;
           json
-----
{"bar": "baz", "balance": 7.77, "active": false}
(1 row)
```

```
SELECT '{"bar": "baz", "balance": 7.77, "active":false}':::jsonb;
           jsonb
-----
{"bar": "baz", "active": false, "balance": 7.77}
(1 row)
```

One semantically-insignificant detail worth noting is that with the `jsonb` data type, numbers will be printed according to the behavior of the underlying numeric type. In practice, this means that numbers entered with E notation will be printed without it, for example:

```
SELECT '{"reading": 1.230e-5}':::json, '{"reading": 1.230e-5}':::jsonb;
           json           |           jsonb
-----+-----
{"reading": 1.230e-5} | {"reading": 0.00001230}
(1 row)
```

However, the `jsonb` data type preserves trailing fractional zeroes, as seen in previous example, even though those are semantically insignificant for purposes such as equality checks.

Designing JSON documents

Representing data as JSON can be considerably more flexible than the traditional relational data model, which is compelling in environments where requirements are fluid. It is quite possible for both approaches to co-exist and complement each other within the same application. However, even for applications where maximal flexibility is desired, it is still recommended that JSON documents have a somewhat fixed structure. The structure is typically unenforced (though enforcing some business rules declaratively is possible), but having a predictable structure makes it easier to write queries that usefully summarize a set of JSON documents (datums) in a table.

JSON data is subject to the same concurrency-control considerations as any other data type when stored in a table. Although storing large documents is practicable, keep in mind that any update acquires a row-level lock on the whole row. Consider limiting JSON documents to a manageable size in order to decrease lock contention among updating transactions. Ideally, JSON documents should each represent an atomic datum that business rules dictate cannot reasonably be further subdivided into smaller datums that could be modified independently.

jsonb Containment and Existence

Testing *containment* is an important capability of `jsonb`. There is no parallel set of facilities for the `json` type. Containment tests whether one `jsonb` document has contained within it another one. These examples return true except as noted:

```
-- Simple scalar/primitive values contain only the identical value:
SELECT '"foo"':::jsonb @> '"foo"':::jsonb;

-- The array on the right side is contained within the one on the left:
SELECT '[1, 2, 3]':::jsonb @> '[1, 3]':::jsonb;

-- Order of array elements is not significant, so this is also true:
SELECT '[1, 2, 3]':::jsonb @> '[3, 1]':::jsonb;

-- Duplicate array elements don't matter either:
SELECT '[1, 2, 3]':::jsonb @> '[1, 2, 2]':::jsonb;

-- The object with a single pair on the right side is contained
-- within the object on the left side:
SELECT '{"product": "Greenplum", "version": "6.0.0", "jsonb":true}':::jsonb @> '{"versi
on":"6.0.0"}':::jsonb;
```

```
-- The array on the right side is not considered contained within the
-- array on the left, even though a similar array is nested within it:
SELECT '[1, 2, [1, 3]]'::jsonb @> '[1, 3]'::jsonb; -- yields false

-- But with a layer of nesting, it is contained:
SELECT '[1, 2, [1, 3]]'::jsonb @> '[[1, 3]]'::jsonb;

-- Similarly, containment is not reported here:
SELECT '{"foo": {"bar": "baz", "zig": "zag"}}'::jsonb @> '{"bar": "baz"}'::jsonb; -- y
ields false

-- But with a layer of nesting, it is contained:
SELECT '{"foo": {"bar": "baz", "zig": "zag"}}'::jsonb @> '{"foo": {"bar": "baz"}}'::js
onb;
```

The general principle is that the contained object must match the containing object as to structure and data contents, possibly after discarding some non-matching array elements or object key/value pairs from the containing object. For containment, the order of array elements is not significant when doing a containment match, and duplicate array elements are effectively considered only once.

As an exception to the general principle that the structures must match, an array may contain a primitive value:

```
-- This array contains the primitive string value:
SELECT '["foo", "bar"]'::jsonb @> '"bar"'::jsonb;

-- This exception is not reciprocal -- non-containment is reported here:
SELECT '"bar"'::jsonb @> '["bar"]'::jsonb; -- yields false
```

`jsonb` also has an *existence* operator, which is a variation on the theme of containment: it tests whether a string (given as a text value) appears as an object key or array element at the top level of the `jsonb` value. These examples return true except as noted:

```
-- String exists as array element:
SELECT '["foo", "bar", "baz"]'::jsonb ? 'bar';

-- String exists as object key:
SELECT '{"foo": "bar"}'::jsonb ? 'foo';

-- Object values are not considered:
SELECT '{"foo": "bar"}'::jsonb ? 'bar'; -- yields false

-- As with containment, existence must match at the top level:
SELECT '{"foo": {"bar": "baz"}}'::jsonb ? 'bar'; -- yields false

-- A string is considered to exist if it matches a primitive JSON string:
SELECT '"foo"'::jsonb ? 'foo';
```

JSON objects are better suited than arrays for testing containment or existence when there are many keys or elements involved, because unlike arrays they are internally optimized for searching, and do not need to be searched linearly.

The various containment and existence operators, along with all other JSON operators and functions are documented in [JSON Functions and Operators](#).

Because JSON containment is nested, an appropriate query can skip explicit selection of sub-objects. As an example, suppose that we have a doc column containing objects at the top level, with most objects containing tags fields that contain arrays of sub-objects. This query finds entries in which sub-objects containing both `"term": "paris"` and `"term": "food"` appear, while ignoring any such keys outside the tags array:

```
SELECT doc->'site_name' FROM websites
WHERE doc @> '{"tags":[{"term":"paris"}, {"term":"food"}]}';
```

The query with this predicate could accomplish the same thing.

```
SELECT doc->'site_name' FROM websites
WHERE doc->'tags' @> ' [{"term":"paris"}, {"term":"food"}]';
```

However, the second approach is less flexible and is often less efficient as well.

On the other hand, the JSON existence operator is not nested: it will only look for the specified key or array element at top level of the JSON value.

jsonb Indexing

The Greenplum Database `jsonb` data type, supports GIN, btree, and hash indexes.

- [GIN Indexes on jsonb Data](#)
- [Btree and Hash Indexes on jsonb Data](#)

GIN Indexes on jsonb Data

GIN indexes can be used to efficiently search for keys or key/value pairs occurring within a large number of `jsonb` documents (datums). Two GIN operator classes are provided, offering different performance and flexibility trade-offs.

The default GIN operator class for `jsonb` supports queries with the `@>`, `?`, `?&` and `?|` operators. (For details of the semantics that these operators implement, see the table [Table 3](#).) An example of creating an index with this operator class is:

```
CREATE INDEX idxgin ON api USING gin (jdoc);
```

The non-default GIN operator class `jsonb_path_ops` supports indexing the `@>` operator only. An example of creating an index with this operator class is:

```
CREATE INDEX idxginp ON api USING gin (jdoc jsonb_path_ops);
```

Consider the example of a table that stores JSON documents retrieved from a third-party web service, with a documented schema definition. This is a typical document:

```
{
  "guid": "9c36adc1-7fb5-4d5b-83b4-90356a46061a",
  "name": "Angela Barton",
  "is_active": true,
  "company": "MagnaFone",
  "address": "178 Howard Place, Gulf, Washington, 702",
  "registered": "2009-11-07T08:53:22 +08:00",
  "latitude": 19.793713,
  "longitude": 86.513373,
  "tags": [
    "enim",
    "aliquip",
    "qui"
  ]
}
```

The JSON documents are stored a table named `api`, in a `jsonb` column named `jdoc`. If a GIN index is created on this column, queries like the following can make use of the index:

```
-- Find documents in which the key "company" has value "MagnaFone"
SELECT jdoc->'guid', jdoc->'name' FROM api WHERE jdoc @> '{"company": "MagnaFone"}';
```

However, the index could not be used for queries like the following. The operator `?>` is indexable, however, the comparison is not applied directly to the indexed column `jdoc`:

```
-- Find documents in which the key "tags" contains key or array element "qui"
SELECT jdoc->'guid', jdoc->'name' FROM api WHERE jdoc -> 'tags' ?> 'qui';
```

With appropriate use of expression indexes, the above query can use an index. If querying for particular items within the `tags` key is common, defining an index like this might be worthwhile:

```
CREATE INDEX idxgintags ON api USING gin ((jdoc -> 'tags'));
```

Now, the `WHERE` clause `jdoc -> 'tags' ?> 'qui'` is recognized as an application of the indexable operator `?>` to the indexed expression `jdoc -> 'tags'`. For information about expression indexes, see [Indexes on Expressions](#).

Another approach to querying JSON documents is to exploit containment, for example:

```
-- Find documents in which the key "tags" contains array element "qui"
SELECT jdoc->'guid', jdoc->'name' FROM api WHERE jdoc @> '{"tags": ["qui"]}';
```

A simple GIN index on the `jdoc` column can support this query. However, the index will store copies of every key and value in the `jdoc` column, whereas the expression index of the previous example stores only data found under the `tags` key. While the simple-index approach is far more flexible (since it supports queries about any key), targeted expression indexes are likely to be smaller and faster to search than a simple index.

Although the `jsonb_path_ops` operator class supports only queries with the `@>` operator, it has performance advantages over the default operator class `jsonb_ops`. A `jsonb_path_ops` index is usually much smaller than a `jsonb_ops` index over the same data, and the specificity of searches is better, particularly when queries contain keys that appear frequently in the data. Therefore search operations typically perform better than with the default operator class.

The technical difference between a `jsonb_ops` and a `jsonb_path_ops` GIN index is that the former creates independent index items for each key and value in the data, while the latter creates index items only for each value in the data.

Note: For this discussion, the term *value* includes array elements, though JSON terminology sometimes considers array elements distinct from values within objects.

Basically, each `jsonb_path_ops` index item is a hash of the value and the key(s) leading to it; for example to index `{"foo": {"bar": "baz"}}`, a single index item would be created incorporating all three of `foo`, `bar`, and `baz` into the hash value. Thus a containment query looking for this structure would result in an extremely specific index search; but there is no way at all to find out whether `foo` appears as a key. On the other hand, a `jsonb_ops` index would create three index items representing `foo`, `bar`, and `baz` separately; then to do the containment query, it would look for rows containing all three of these items. While GIN indexes can perform such an `AND` search fairly efficiently, it will still be less specific and slower than the equivalent `jsonb_path_ops` search, especially if there are a very large number of rows containing any single one of the three index items.

A disadvantage of the `jsonb_path_ops` approach is that it produces no index entries for JSON structures not containing any values, such as `{"a": {}}`. If a search for documents containing such a structure is requested, it will require a full-index scan, which is quite slow. `jsonb_path_ops` is ill-suited for applications that often perform such searches.

Btree and Hash Indexes on jsonb Data

`jsonb` also supports `btree` and `hash` indexes. These are usually useful only when it is important to check the equality of complete JSON documents.

For completeness the `btree` ordering for `jsonb` datums is:

```
Object > Array > Boolean > Number > String > Null

Object with n pairs > object with n - 1 pairs

Array with n elements > array with n - 1 elements
```

Objects with equal numbers of pairs are compared in the order:

```
key-1, value-1, key-2 ...
```

Object keys are compared in their storage order. In particular, since shorter keys are stored before longer keys, this can lead to orderings that might not be intuitive, such as:

```
{ "aa": 1, "c": 1 } > { "b": 1, "d": 1 }
```

Similarly, arrays with equal numbers of elements are compared in the order:

```
element-1, element-2 ...
```

Primitive JSON values are compared using the same comparison rules as for the underlying Greenplum Database data type. Strings are compared using the default database collation.

JSON Functions and Operators

Greenplum Database includes built-in functions and operators that create and manipulate JSON data.

- [JSON Operators](#)
- [JSON Creation Functions](#)
- [JSON Aggregate Functions](#)
- [JSON Processing Functions](#)

Note: For `json` data type values, all key/value pairs are kept even if a JSON object contains duplicate keys. For duplicate keys, JSON processing functions consider the last value as the operative one.

For the `jsonb` data type, duplicate object keys are not kept. If the input includes duplicate keys, only the last value is kept. See [About JSON Data](#).

JSON Operators

This table describes the operators that are available for use with the `json` and `jsonb` data types.

Operator	Right Operand Type	Description	Example	Example Result
<code>-></code>	<code>int</code>	Get the JSON array element (indexed from zero).	<code>'[{"a": "foo"}, {"b": "bar"}, {"c": "baz"}]'::json->2</code>	<code>{"c": "baz"}</code>
<code>-></code>	<code>text</code>	Get the JSON object field by key.	<code>'{"a": {"b": "foo"}}'::json->'a'</code>	<code>{"b": "foo"}</code>

Operator	Right Operand Type	Description	Example	Example Result
->>	int	Get the JSON array element as <code>text</code> .	'[1,2,3]'::json->>2	3
->>	text	Get the JSON object field as <code>text</code> .	'{"a":1,"b":2}'::json->>'b'	2
#>	text[]	Get the JSON object at specified path.	'{"a": {"b":{"c":"foo"}}}'::json#>'a,b'	{ "c": "foo" }
#>>	text[]	Get the JSON object at specified path as <code>text</code> .	'{"a": [1,2,3], "b": [4,5,6]}'::json#>>'a,2'	3

Note: There are parallel variants of these operators for both the `json` and `jsonb` data types. The field, element, and path extraction operators return the same data type as their left-hand input (either `json` or `jsonb`), except for those specified as returning `text`, which coerce the value to `text`. The field, element, and path extraction operators return `NULL`, rather than failing, if the JSON input does not have the right structure to match the request; for example if no such element exists.

Operators that require the `jsonb` data type as the left operand are described in the following table. Many of these operators can be indexed by `jsonb` operator classes. For a full description of `jsonb` containment and existence semantics, see [jsonb Containment and Existence](#). For information about how these operators can be used to effectively index `jsonb` data, see [jsonb Indexing](#).

Table 3. jsonb Operators

Operator	Right Operand Type	Description	Example
@>	jsonb	Does the left JSON value contain within it the right value?	'{ "a" :1, "b" :2}'::jsonb @> '{ "b" :2}'::jsonb
<@	jsonb	Is the left JSON value contained within the right value?	'{ "b" :2}'::jsonb <@ '{ "a" :1, "b" :2}'::jsonb
?	text	Does the key/element string exist within the JSON value?	'{ "a" :1, "b" :2}'::jsonb ? 'b'
?	text[]	Do any of these key/element strings exist?	'{ "a" :1, "b" :2, "c" :3}'::jsonb ? array['b' , 'c']
?&	text[]	Do all of these key/element strings exist?	'["a" , "b"]'::jsonb ?& array['a' , 'b']

The standard comparison operators in the following table are available only for the `jsonb` data type, not for the `json` data type. They follow the ordering rules for B-tree operations described in [jsonb Indexing](#).

Operator	Description
<	less than
>	greater than
<=	less than or equal to
>=	greater than or equal to
=	equal

Operator	Description
<code><></code> or <code>!=</code>	not equal

Note: The `!=` operator is converted to `<>` in the parser stage. It is not possible to implement `!=` and `<>` operators that do different things.

JSON Creation Functions

This table describes the functions that create `json` data type values. (Currently, there are no equivalent functions for `jsonb`, but you can cast the result of one of these functions to `jsonb`.)

Table 5. JSON Creation Functions

Function	Description	Example	Example Result
<code>to_json(anyelement)</code>	Returns the value as a JSON object. Arrays and composites are processed recursively and are converted to arrays and objects. If the input contains a cast from the type to <code>json</code> , the cast function is used to perform the conversion; otherwise, a JSON scalar value is produced. For any scalar type other than a number, a Boolean, or a null value, the text representation will be used, properly quoted and escaped so that it is a valid JSON string.	<code>to_json('Fred said "Hi."' ::text)</code>	<code>"Fred said \"Hi.\""</code>
<code>array_to_json(anyarray [, pretty_bool])</code>	Returns the array as a JSON array. A multidimensional array becomes a JSON array of arrays. Line feeds will be added between dimension-1 elements if <code>pretty_bool</code> is true.	<code>array_to_json('{{1,5},{99,100}}' ::int[])</code>	<code>[[1,5],[99,100]]</code>

Table 5. JSON Creation Functions

Function	Description	Example	Example Result
<code>row_to_json(record [, pretty_bool])</code>	Returns the row as a JSON object. Line feeds will be added between level-1 elements if <code>pretty_bool</code> is true.	<code>row_to_json(row(1, 'foo'))</code>	<code>{ "f1" :1, "f2" : "foo" }</code>
<code>json_build_array(VARIADIC "any")</code>	Builds a possibly-heterogeneously-typed JSON array out of a <code>VARIADIC</code> argument list.	<code>json_build_array(1,2, '3' ,4,5)</code>	<code>[1, 2, "3" , 4, 5]</code>
<code>json_build_object(VARIADIC "any")</code>	Builds a JSON object out of a <code>VARIADIC</code> argument list. The argument list is taken in order and converted to a set of key/value pairs.	<code>json_build_object('foo' ,1, 'bar' ,2)</code>	<code>{ "foo" : 1, "bar" : 2}</code>
<code>json_object(text[])</code>	Builds a JSON object out of a text array. The array must be either a one or a two dimensional array. The one dimensional array must have an even number of elements. The elements are taken as key/value pairs. For a two dimensional array, each inner array must have exactly two elements, which are taken as a key/value pair.	<code>json_object('{a, 1, b, "def" , c, 3.5}')</code> <code>json_object('{{a, 1},{b, "def" }, {c, 3.5}}')</code>	<code>{ "a" : "1" , "b" : "def" , "c" : "3.5" }</code>

Table 5. JSON Creation Functions

Function	Description	Example	Example Result
<code>json_object(keys text[], values text[])</code>	Builds a JSON object out of a text array. This form of <code>json_object</code> takes keys and values pairwise from two separate arrays. In all other respects it is identical to the one-argument form.	<code>json_object('{a, b}', '{1,2}')</code>	<code>{ "a" : "1" , "b" : "2" }</code>

Note: `array_to_json` and `row_to_json` have the same behavior as `to_json` except for offering a pretty-printing option. The behavior described for `to_json` likewise applies to each individual value converted by the other JSON creation functions.

Note: The `hstore` module contains functions that cast from `hstore` to `json`, so that `hstore` values converted via the JSON creation functions will be represented as JSON objects, not as primitive string values.

JSON Aggregate Functions

This table shows the functions aggregate records to an array of JSON objects and pairs of values to a JSON object

Function	Argument Types	Return Type	Description
<code>json_agg(record)</code>	<code>record</code>	<code>json</code>	Aggregates records as a JSON array of objects.
<code>json_object_agg(name, value)</code>	<code>("any", "any")</code>	<code>json</code>	Aggregates name/value pairs as a JSON object.

JSON Processing Functions

This table shows the functions that are available for processing `json` and `jsonb` values.

Many of these processing functions and operators convert Unicode escapes in JSON strings to the appropriate single character. This is a not an issue if the input data type is `jsonb`, because the conversion was already done. However, for `json` data type input, this might result in an error being thrown. See [About JSON Data](#).

Table 7. JSON Processing Functions

Function	Return Type	Description	Example	Example Result
<code>json_array_length(json)</code> <code>jsonb_array_length(jsonb)</code>	<code>int</code>	Returns the number of elements in the outermost JSON array.	<code>json_array_length('[1,2,3,{ "f1" :1, "f2" : 5 [5,6]},4]')</code>	

Table 7. JSON Processing Functions

Function	Return Type	Description	Example	Example Result
<code>json_each(json)</code> <code>jsonb_each(jsonb)</code>	setof key text, value json setof key text, value jsonb	Expands the outermost JSON object into a set of key/value pairs.	<pre>select * from json_each('{ "a" : "foo" , "b" : "bar" }')</pre>	<pre>key value --+ --- a "foo" b "bar"</pre>
<code>json_each_text(json)</code> <code>jsonb_each_text(jsonb)</code>	setof key text, value text	Expands the outermost JSON object into a set of key/value pairs. The returned values will be of type text.	<pre>select * from json_each_text('{ "a" : "foo" , "b" : "bar" }')</pre>	<pre>key value --+ --- a foo b bar</pre>
<code>json_extract_path(from_json json, VARIADIC path_elems text[])</code> <code>jsonb_extract_path(from_json jsonb, VARIADIC path_elems text[])</code>	json jsonb	Returns the JSON value pointed to by <code>path_elems</code> (equivalent to <code>#></code> operator).	<pre>json_extract_path('{ "f2" : { "f3" :1, "f4" : { "f5" :99, "f6" : "foo" }}' , 'f4')</pre>	<pre>{ "f5" :99, "f6" : "foo" }</pre>
<code>json_extract_path_text(from_json json, VARIADIC path_elems text[])</code> <code>jsonb_extract_path_text(from_json jsonb, VARIADIC path_elems text[])</code>	text	Returns the JSON value pointed to by <code>path_elems</code> as text. Equivalent to <code>#>></code> operator.	<pre>json_extract_path_text('{ "f2" : { "f3" :1, "f4" : { "f5" :99, "f6" : "foo" }}' , 'f4' , 'f6')</pre>	<pre>foo</pre>
<code>json_object_keys(json)</code> <code>jsonb_object_keys(jsonb)</code>	setof text	Returns set of keys in the outermost JSON object.	<pre>json_object_keys('{ "f1" : "abc" , "f2" : { "f3" : "a" , "f4" : "b" } }')</pre>	<pre>json_object_keys f1 f2</pre>
<code>json_populate_record(base anyelement, from_json json)</code> <code>jsonb_populate_record(base anyelement, from_json jsonb)</code>	anyelement	Expands the object in <code>from_json</code> to a row whose columns match the record type defined by <code>base</code> . See Note 1 .	<pre>select * from json_populate_record(null::myrowtype, '{ "a" :1, "b" :2}')</pre>	<pre>a b --+ 1 2</pre>

Table 7. JSON Processing Functions

Function	Return Type	Description	Example	Example Result
<code>json_populate_recordset(base anyelement, from_json json)</code> <code>jsonb_populate_recordset(base anyelement, from_json jsonb)</code>	<code>setof anyelement</code>	Expands the outermost array of objects in <code>from_json</code> to a set of rows whose columns match the record type defined by <code>base</code> . See Note 1 .	<pre>select * from json_populate_recordset(null::myrowtype, '[{ "a" :1, "b" :2},{ "a" :3, "b" :4}]')</pre>	<pre>a b 1 2 3 4</pre>
<code>json_array_elements(json)</code> <code>jsonb_array_elements(jsonb)</code>	<code>setof json</code> <code>setof jsonb</code>	Expands a JSON array to a set of JSON values.	<pre>select * from json_array_elements('[1,true, [2,false]]')</pre>	<pre>value 1 true [2,false]</pre>
<code>json_array_elements_text(json)</code> <code>jsonb_array_elements_text(jsonb)</code>	<code>setof text</code>	Expands a JSON array to a set of <code>text</code> values.	<pre>select * from json_array_elements_text('["foo" , "bar"]')</pre>	<pre>value foo bar</pre>
<code>json_typeof(json)</code> <code>jsonb_typeof(jsonb)</code>	<code>text</code>	Returns the type of the outermost JSON value as a text string. Possible types are <code>object</code> , <code>array</code> , <code>string</code> , <code>number</code> , <code>boolean</code> , and <code>null</code> . See Note 2 .	<pre>json_typeof('-123.4')</pre>	<pre>number</pre>

Table 7. JSON Processing Functions

Function	Return Type	Description	Example	Example Result
<code>json_to_record(json)</code> <code>jsonb_to_record(jsonb)</code>	<code>record</code>	<p>Builds an arbitrary record from a JSON object. See Note 1.</p> <p>As with all functions returning record, the caller must explicitly define the structure of the record with an <code>AS</code> clause.</p>	<pre>select * from json_to_record('{ "a" :1, "b" : [1,2,3], "c" : "bar" }') as x(a int, b text, d text)</pre>	<pre>a b d --+-----+-- 1 [1, 2,3] </pre>
<code>json_to_recordset(json)</code> <code>jsonb_to_recordset(jsonb)</code>	<code>setof</code> <code>record</code>	<p>Builds an arbitrary set of records from a JSON array of objects. See Note 1.</p> <p>As with all functions returning record, the caller must explicitly define the structure of the record with an <code>AS</code> clause.</p>	<pre>select * from json_to_recordset(' [{ "a" :1, "b" : "foo" }, { "a" : "2" , "c" : "bar" }] ') as x(a int, b text);</pre>	<pre>a b +--+ 1 foo 2 </pre>

Note:

1. The examples for the functions `json_populate_record()`, `json_populate_recordset()`, `json_to_record()` and `json_to_recordset()` use constants. However, the typical use would be to reference a table in the `FROM` clause and use one of its `json` or `jsonb` columns as an argument to the function. The extracted key values can then be referenced in other parts of the query. For example the value can be referenced in `WHERE` clauses and target lists. Extracting multiple values in this way can improve performance over extracting them separately with per-key operators.

JSON keys are matched to identical column names in

the target row type. JSON type coercion for these functions might not result in desired values for some types. JSON fields that do not appear in the target row type will be omitted from the output, and target columns that do not match any JSON field will be `NULL`.

2. The `json_typeof` function null return value of `null` should not be confused with a SQL `NULL`. While calling `json_typeof('null'::json)` will return `null`, calling `json_typeof(NULL::json)` will return a SQL `NULL`.

Working with XML Data

Greenplum Database supports the `xml` data type that stores XML data.

The `xml` data type checks the input values for well-formedness, providing an advantage over simply storing XML data in a text field. Additionally, support functions allow you to perform type-safe operations on this data; refer to [XML Function Reference](#), below.

Use of this data type requires the installation to have been built with `configure --with-libxml`. This is enabled by default for VMware Tanzu Greenplum builds.

The `xml` type can store well-formed “documents”, as defined by the XML standard, as well as “content” fragments, which are defined by reference to the more permissive [document node](#) of the XQuery and XPath model. Roughly, this means that content fragments can have more than one top-level element or character node. The expression `xmlvalue IS DOCUMENT` can be used to evaluate whether a particular `xml` value is a full document or only a content fragment.

This section contains the following topics:

- [Creating XML Values](#)
- [Encoding Handling](#)
- [Accessing XML Values](#)
- [Processing XML](#)
- [Mapping Tables to XML](#)
- [Using XML Functions and Expressions](#)

Parent topic: [Querying Data](#)

Creating XML Values

To produce a value of type `xml` from character data, use the function `xmlparse`:

```
xmlparse ( { DOCUMENT | CONTENT } value)
```

For example:

```
XMLPARSE (DOCUMENT '<?xml version="1.0"?><book><title>Manual</title><chapter>...</chapter></book>')
XMLPARSE (CONTENT 'abc<foo>bar</foo><bar>foo</bar>')
```

The above method converts character strings into XML values according to the SQL standard, but you can also use Greenplum Database syntax like the following:

```
xml '<foo>bar</foo>'
'<foo>bar</foo>'::xml
```

The `xml` type does not validate input values against a document type declaration (DTD), even when the input value specifies a DTD. There is also currently no built-in support for validating against other XML schema languages such as XML schema.

The inverse operation, producing a character string value from `xml`, uses the function `xmlserialize`:

```
xmlserialize ( { DOCUMENT | CONTENT } <value> AS <type> )
```

type can be `character`, `character varying`, or `text` (or an alias for one of those). Again, according to the SQL standard, this is the only way to convert between type `xml` and character types, but Greenplum Database also allows you to simply cast the value.

When a character string value is cast to or from type `xml` without going through `XMLPARSE` or `XMLSERIALIZE`, respectively, the choice of `DOCUMENT` versus `CONTENT` is determined by the `XML OPTION` session configuration parameter, which can be set using the standard command:

```
SET XML OPTION { DOCUMENT | CONTENT };
```

or simply like Greenplum Database:

```
SET XML OPTION TO { DOCUMENT | CONTENT };
```

The default is `CONTENT`, so all forms of XML data are allowed.

Encoding Handling

Be careful when dealing with multiple character encodings on the client, server, and in the XML data passed through them. When using the text mode to pass queries to the server and query results to the client (which is the normal mode), Greenplum Database converts all character data passed between the client and the server, and vice versa, to the character encoding of the respective endpoint; see [Character Set Support](#). This includes string representations of XML values, such as in the above examples. Ordinarily, this means that encoding declarations contained in XML data can become invalid, as the character data is converted to other encodings while travelling between client and server, because the embedded encoding declaration is not changed. To cope with this behavior, encoding declarations contained in character strings presented for input to the `xml` type are ignored, and content is assumed to be in the current server encoding. Consequently, for correct processing, character strings of XML data must be sent from the client in the current client encoding. It is the responsibility of the client to either convert documents to the current client encoding before sending them to the server, or to adjust the client encoding appropriately. On output, values of type `xml` will not have an encoding declaration, and clients should assume all data is in the current client encoding.

When using binary mode to pass query parameters to the server and query results back to the client, no character set conversion is performed, so the situation is different. In this case, an encoding declaration in the XML data will be observed, and if it is absent, the data will be assumed to be in UTF-8 (as required by the XML standard; note that Greenplum Database does not support UTF-16). On output, data will have an encoding declaration specifying the client encoding, unless the client encoding is UTF-8, in which case it will be omitted.

Note:

Processing XML data with Greenplum Database will be less error-prone and more efficient if the

XML data encoding, client encoding, and server encoding are the same. Because XML data is internally processed in UTF-8, computations will be most efficient if the server encoding is also UTF-8.

Accessing XML Values

The `xml` data type is unusual in that it does not provide any comparison operators. This is because there is no well-defined and universally useful comparison algorithm for XML data. One consequence of this is that you cannot retrieve rows by comparing an `xml` column against a search value. XML values should therefore typically be accompanied by a separate key field such as an ID. An alternative solution for comparing XML values is to convert them to character strings first, but note that character string comparison has little to do with a useful XML comparison method.

Because there are no comparison operators for the `xml` data type, it is not possible to create an index directly on a column of this type. If speedy searches in XML data are desired, possible workarounds include casting the expression to a character string type and indexing that, or indexing an XPath expression. Of course, the actual query would have to be adjusted to search by the indexed expression.

Processing XML

To process values of data type `xml`, Greenplum Database offers the functions `xpath` and `xpath_exists`, which evaluate XPath 1.0 expressions.

```
xpath(<xpath>, <xml> [, <nsarray>])
```

The function `xpath` evaluates the XPath expression `xpath` (a text value) against the XML value `xml`. It returns an array of XML values corresponding to the node set produced by the XPath expression.

The second argument must be a well formed XML document. In particular, it must have a single root node element.

The optional third argument of the function is an array of namespace mappings. This array should be a two-dimensional text array with the length of the second axis being equal to 2 (i.e., it should be an array of arrays, each of which consists of exactly 2 elements). The first element of each array entry is the namespace name (alias), the second the namespace URI. It is not required that aliases provided in this array be the same as those being used in the XML document itself (in other words, both in the XML document and in the `xpath` function context, aliases are local).

Example:

```
SELECT xpath('/my:a/<text>()', '<my:a xmlns:my="http://example.com">test</my:a>',
            ARRAY[ARRAY['my', 'http://example.com']]);

 xpath
-----
 {test}
(1 row)
```

To deal with default (anonymous) namespaces, do something like this:

```
SELECT xpath('//mydefns:b/<text>()', '<a xmlns="http://example.com"><b>test</b></a>',
            ARRAY[ARRAY['mydefns', 'http://example.com']]);

 xpath
-----
```

```
{test}
(1 row)
```

```
xpath_exists(<xpath>, <xml> [, <nsarray>])
```

The function `xpath_exists` is a specialized form of the `xpath` function. Instead of returning the individual XML values that satisfy the XPath, this function returns a Boolean indicating whether the query was satisfied or not. This function is equivalent to the standard `XMLEXISTS` predicate, except that it also offers support for a namespace mapping argument.

Example:

```
SELECT xpath_exists('/my:a/<text>()', ' <my:a xmlns:my="http://example.com">test</my:a>
',
                        ARRAY[ARRAY['my', 'http://example.com']]);

 xpath_exists
-----
t
(1 row)
```

Mapping Tables to XML

The following functions map the contents of relational tables to XML values. They can be thought of as XML export functionality:

```
table_to_xml(tbl regclass, nulls boolean, tableforest boolean, targetns text)
query_to_xml(query <text>, nulls boolean, tableforest boolean, targetns text)
cursor_to_xml(cursor refcursor, count int, nulls boolean,
              tableforest boolean, targetns text)
```

The return type of each function is `xml`.

`table_to_xml` maps the content of the named table, passed as parameter `tbl`. The `regclass` type accepts strings identifying tables using the usual notation, including optional schema qualifications and double quotes. `query_to_xml` runs the query whose text is passed as parameter `query` and maps the result set. `cursor_to_xml` fetches the indicated number of rows from the cursor specified by the parameter `cursor`. This variant is recommended if large tables have to be mapped, because the result value is built up in memory by each function.

If `tableforest` is false, then the resulting XML document looks like this:

```
<tablename>
  <row>
    <columnname1>data</columnname1>
    <columnname2>data</columnname2>
  </row>

  <row>
    ...
  </row>

  ...
</tablename>
```

If `tableforest` is true, the result is an XML content fragment that looks like this:

```

<tablename>
  <columnname1>data</columnname1>
  <columnname2>data</columnname2>
</tablename>

<tablename>
  ...
</tablename>

...

```

If no table name is available, that is, when mapping a query or a cursor, the string `table` is used in the first format, `row` in the second format.

The choice between these formats is up to the user. The first format is a proper XML document, which will be important in many applications. The second format tends to be more useful in the `cursor_to_xml` function if the result values are to be later reassembled into one document. The functions for producing XML content discussed above, in particular `xmlelement`, can be used to alter the results as desired.

The data values are mapped in the same way as described for the function `xmlelement`, above.

The parameter `nulls` determines whether null values should be included in the output. If true, null values in columns are represented as:

```
<columnname xsi:nil="true"/>
```

where `xsi` is the XML namespace prefix for XML schema Instance. An appropriate namespace declaration will be added to the result value. If false, columns containing null values are simply omitted from the output.

The parameter `targetns` specifies the desired XML namespace of the result. If no particular namespace is wanted, an empty string should be passed.

The following functions return XML schema documents describing the mappings performed by the corresponding functions above:

```

able_to_xmlschema(tbl regclass, nulls boolean, tableforest boolean, targetns text)
query_to_xmlschema(query <text>, nulls boolean, tableforest boolean, targetns text)
cursor_to_xmlschema(cursor refcursor, nulls boolean, tableforest boolean, targetns text)

```

It is essential that the same parameters are passed in order to obtain matching XML data mappings and XML schema documents.

The following functions produce XML data mappings and the corresponding XML schema in one document (or `forest`), linked together. They can be useful where self-contained and self-describing results are desired:

```

table_to_xml_and_xmlschema(tbl regclass, nulls boolean, tableforest boolean, targetns text)
query_to_xml_and_xmlschema(query <text>, nulls boolean, tableforest boolean, targetns text)

```

In addition, the following functions are available to produce analogous mappings of entire schemas or the entire current database:

```

schema_to_xml(schema name, nulls boolean, tableforest boolean, targetns text)
schema_to_xmlschema(schema name, nulls boolean, tableforest boolean, targetns text)
schema_to_xml_and_xmlschema(schema name, nulls boolean, tableforest boolean, targetns
text)

database_to_xml(nulls boolean, tableforest boolean, targetns text)
database_to_xmlschema(nulls boolean, tableforest boolean, targetns text)
database_to_xml_and_xmlschema(nulls boolean, tableforest boolean, targetns text)

```

Note that these potentially produce large amounts of data, which needs to be built up in memory. When requesting content mappings of large schemas or databases, consider mapping the tables separately instead, possibly even through a cursor.

The result of a schema content mapping looks like this:

```

<schemaname>

table1-mapping

table2-mapping

...

</schemaname>

```

where the format of a table mapping depends on the `tableforest` parameter, as explained above.

The result of a database content mapping looks like this:

```

<dbname>

<schema1name>
...
</schema1name>

<schema2name>
...
</schema2name>

...

</dbname>

```

where the schema mapping is as above.

The example below demonstrates using the output produced by these functions. The example shows an XSLT stylesheet that converts the output of `table_to_xml_and_xmlschema` to an HTML document containing a tabular rendition of the table data. In a similar manner, the results from these functions can be converted into other XML-based formats.

```

<?xml version="1.0"?>
<xsl:stylesheet version="1.0"
  xmlns:xsl="http://www.w3.org/1999/XSL/Transform"
  xmlns:xsd="http://www.w3.org/2001/XMLSchema"
  xmlns="http://www.w3.org/1999/xhtml"
>

  <xsl:output method="xml"
    doctype-system="http://www.w3.org/TR/xhtml1/DTD/xhtml1-strict.dtd"
    doctype-public="-//W3C/DTD XHTML 1.0 Strict//EN"

```

```

        indent="yes"/>

<xsl:template match="/*">
  <xsl:variable name="schema" select="//xsd:schema"/>
  <xsl:variable name="tabletypename"
    select="$schema/xsd:element[@name=name(current())]/@type"/>
  <xsl:variable name="rowtypename"

      <title><xsl:value-of select="name(current())"/></title>
    </head>
    <body>
      <table>
        <tr>
          <xsl:for-each select="$schema/xsd:complexType[@name=$rowtypename]/xsd:sequ
ence/xsd:element/@name">
            <th><xsl:value-of select="."/></th>
          </xsl:for-each>
        </tr>

        <xsl:for-each select="row">
          <tr>
            <xsl:for-each select="*">
              <td><xsl:value-of select="."/></td>
            </xsl:for-each>
          </tr>
        </xsl:for-each>
      </table>
    </body>
  </html>
</xsl:template>

</xsl:stylesheet>

```

XML Function Reference

The functions described in this section operate on values of type `xml`. The section [XML Predicates](#) also contains information about the `xml` functions and function-like expressions.

Function:

`xmlcomment`

Synopsis:

```
xmlcomment(<text>)
```

The function `xmlcomment` creates an XML value containing an XML comment with the specified text as content. The text cannot contain “–” or end with a “-” so that the resulting construct is a valid XML comment. If the argument is null, the result is null.

Example:

```

SELECT xmlcomment('hello');

  xmlcomment
-----
<!--hello-->

```

Function:

xmlconcat**Synopsis:**

```
xmlconcat(xml[, ...])
```

The function **xmlconcat** concatenates a list of individual XML values to create a single value containing an XML content fragment. Null values are omitted; the result is only null if there are no nonnull arguments.

Example:

```
SELECT xmlconcat('<abc/>', '<bar>foo</bar>');

      xmlconcat
-----
<abc/><bar>foo</bar>
```

XML declarations, if present, are combined as follows:

- If all argument values have the same XML version declaration, that version is used in the result, else no version is used.
- If all argument values have the standalone declaration value “yes”, then that value is used in the result.
- If all argument values have a standalone declaration value and at least one is “no”, then that is used in the result. Otherwise, the result will have no standalone declaration.
- If the result is determined to require a standalone declaration but no version declaration, a version declaration with version 1.0 will be used because XML requires an XML declaration to contain a version declaration.

Encoding declarations are ignored and removed in all cases.

Example:

```
SELECT xmlconcat('<?xml version="1.1"?><foo/>', '<?xml version="1.1" standalone="no"?><bar/>');

      xmlconcat
-----
<?xml version="1.1"?><foo/><bar/>
```

Function:**xmlelement****Synopsis:**

```
xmlelement(name name [, xmlattributes(value [AS attname] [, ... ])] [, content, ...])
```

The **xmlelement** expression produces an XML element with the given name, attributes, and content.

Examples:

```
SELECT xmlelement(name foo);

      xmlelement
-----
<foo/>

SELECT xmlelement(name foo, xmlattributes('xyz' as bar));
```

```

xmlelement
-----
<foo bar="xyz"/>

SELECT xmlelement(name foo, xmlattributes(current_date as bar), 'cont', 'ent');

xmlelement
-----
<foo bar="2017-01-26">content</foo>

```

Element and attribute names that are not valid XML names are escaped by replacing the offending characters by the sequence `_xHHHH_`, where HHHH is the character's Unicode codepoint in hexadecimal notation. For example:

```

SELECT xmlelement(name "foo$bar", xmlattributes('xyz' as "a&b"));

xmlelement
-----
<foo_x0024_bar a_x0026_b="xyz"/>

```

An explicit attribute name need not be specified if the attribute value is a column reference, in which case the column's name will be used as the attribute name by default. In other cases, the attribute must be given an explicit name. So this example is valid:

```

CREATE TABLE test (a xml, b xml);
SELECT xmlelement(name test, xmlattributes(a, b)) FROM test;

```

But these are not:

```

SELECT xmlelement(name test, xmlattributes('constant'), a, b) FROM test;
SELECT xmlelement(name test, xmlattributes(func(a, b))) FROM test;

```

Element content, if specified, will be formatted according to its data type. If the content is itself of type `xml`, complex XML documents can be constructed. For example:

```

SELECT xmlelement(name foo, xmlattributes('xyz' as bar),
                  xmlelement(name abc,
                              xmlcomment('test'),
                              xmlelement(name xyz)));

xmlelement
-----
<foo bar="xyz"><abc/><!--test--><xyz/></foo>

```

Content of other types will be formatted into valid XML character data. This means in particular that the characters `<`, `>`, and `&` will be converted to entities. Binary data (data type `bytea`) will be represented in base64 or hex encoding, depending on the setting of the configuration parameter `xmlbinary`. The particular behavior for individual data types is expected to evolve in order to align the SQL and Greenplum Database data types with the XML schema specification, at which point a more precise description will appear.

Function:

`xmlforest`

Synopsis:

```
xmlforest(<content> [AS <name>] [, ...])
```

The `xmlforest` expression produces an XML forest (sequence) of elements using the given names

and content.

Examples:

```
SELECT xmlforest('abc' AS foo, 123 AS bar);

          xmlforest
-----
<foo>abc</foo><bar>123</bar>

SELECT xmlforest(table_name, column_name)
FROM information_schema.columns
WHERE table_schema = 'pg_catalog';

          xmlforest
-----
<table_name>pg_authid</table_name><column_name>rolname</column_name>
<table_name>pg_authid</table_name><column_name>rolsuper</column_name>
```

As seen in the second example, the element name can be omitted if the content value is a column reference, in which case the column name is used by default. Otherwise, a name must be specified.

Element names that are not valid XML names are escaped as shown for `xmlelement` above. Similarly, content data is escaped to make valid XML content, unless it is already of type `xml`.

Note that XML forests are not valid XML documents if they consist of more than one element, so it might be useful to wrap `xmlforest` expressions in `xmlelement`.

Function:

`xmlpi`

Synopsis:

```
xmlpi(name <target> [, <content>])
```

The `xmlpi` expression creates an XML processing instruction. The content, if present, must not contain the character sequence `?>`.

Example:

```
SELECT xmlpi(name php, 'echo "hello world";');

          xmlpi
-----
<?php echo "hello world";?>
```

Function:

`xmlroot`

Synopsis:

```
xmlroot(<xml>, version <text> | no value [, standalone yes|no|no value])
```

The `xmlroot` expression alters the properties of the root node of an XML value. If a version is specified, it replaces the value in the root node's version declaration; if a standalone setting is specified, it replaces the value in the root node's standalone declaration.

```
SELECT xmlroot(xmlparse(document '<?xml version="1.1"?><content>abc</content>'),
              version '1.0', standalone yes);
```

```

      xmlroot
-----
<?xml version="1.0" standalone="yes"?>
<content>abc</content>

```

Function:`xmlagg`

```
xmlagg (<xml>)
```

The function `xmlagg` is, unlike the other functions described here, an aggregate function. It concatenates the input values to the aggregate function call, much like `xmlconcat` does, except that concatenation occurs across rows rather than across expressions in a single row. See [Using Functions and Operators](#) for additional information about aggregate functions.

Example:

```

CREATE TABLE test (y int, x xml);
INSERT INTO test VALUES (1, '<foo>abc</foo>');
INSERT INTO test VALUES (2, '<bar/>');
SELECT xmlagg(x) FROM test;
      xmlagg
-----
<foo>abc</foo><bar/>

```

To determine the order of the concatenation, an `ORDER BY` clause may be added to the aggregate call. For example:

```

SELECT xmlagg(x ORDER BY y DESC) FROM test;
      xmlagg
-----
<bar/><foo>abc</foo>

```

The following non-standard approach used to be recommended in previous versions, and may still be useful in specific cases:

```

SELECT xmlagg(x) FROM (SELECT * FROM test ORDER BY y DESC) AS tab;
      xmlagg
-----
<bar/><foo>abc</foo>

```

XML Predicates

The expressions described in this section check properties of `xml` values.

Expression:`IS DOCUMENT`**Synopsis:**

```
<xml> IS DOCUMENT
```

The expression `IS DOCUMENT` returns true if the argument XML value is a proper XML document, false if it is not (that is, it is a content fragment), or null if the argument is null.

Expression:`XMLEXISTS`

Synopsis:

```
XML EXISTS (<text> PASSING [BY REF] <xml> [BY REF])
```

The function `xml_exists` returns true if the XPath expression in the first argument returns any nodes, and false otherwise. (If either argument is null, the result is null.)

Example:

```
SELECT xml_exists('//town[<text>() = ''Toronto'']' PASSING BY REF '<towns><town>Toronto
</town><town>Ottawa</town></towns>');

xml_exists
-----
t
(1 row)
```

The `BY REF` clauses have no effect in Greenplum Database, but are allowed for SQL conformance and compatibility with other implementations. Per SQL standard, the first `BY REF` is required, the second is optional. Also note that the SQL standard specifies the `xml_exists` construct to take an XQuery expression as first argument, but Greenplum Database currently only supports XPath, which is a subset of XQuery.

Expression:

`xml_is_well_formed`

Synopsis:

```
xml_is_well_formed(<text>)
xml_is_well_formed_document(<text>)
xml_is_well_formed_content(<text>)
```

These functions check whether a text string is well-formed XML, returning a Boolean result.

`xml_is_well_formed_document` checks for a well-formed document, while `xml_is_well_formed_content` checks for well-formed content. `xml_is_well_formed` does the former if the `xmloption` configuration parameter is set to `DOCUMENT`, or the latter if it is set to `CONTENT`. This means that `xml_is_well_formed` is useful for seeing whether a simple cast to type `xml` will succeed, whereas the other two functions are useful for seeing whether the corresponding variants of `XMLPARSE` will succeed.

Examples:

```
SET xmloption TO DOCUMENT;
SELECT xml_is_well_formed('<>');
xml_is_well_formed
-----
f
(1 row)

SELECT xml_is_well_formed('<abc/>');
xml_is_well_formed
-----
t
(1 row)

SET xmloption TO CONTENT;
SELECT xml_is_well_formed('abc');
xml_is_well_formed
-----
```

```

t
(1 row)

SELECT xml_is_well_formed_document('<pg:foo xmlns:pg="http://postgresql.org/stuff">bar
</pg:foo>');
xml_is_well_formed_document
-----
t
(1 row)

SELECT xml_is_well_formed_document('<pg:foo xmlns:pg="http://postgresql.org/stuff">bar
</my:foo>');
xml_is_well_formed_document
-----
f
(1 row)

```

The last example shows that the checks include whether namespaces are correctly matched.

Using Full Text Search

Greenplum Database provides data types, functions, operators, index types, and configurations for querying natural language documents.

- **About Full Text Search**
This topic provides an overview of Greenplum Database full text search, basic text search expressions, configuring, and customizing text search. Greenplum Database full text search is compared with Tanzu Greenplum Text.
- **Searching Text in Database Tables**
This topic shows how to use text search operators to search database tables and how to create indexes to speed up text searches.
- **Controlling Text Search**
This topic shows how to create search and query vectors, how to rank search results, and how to highlight search terms in the results of text search queries.
- **Additional Text Search Features**
Greenplum Database has additional functions and operators you can use to manipulate search and query vectors, and to rewrite search queries.
- **Text Search Parsers**
This topic describes the types of tokens the Greenplum Database text search parser produces from raw text.
- **Text Search Dictionaries**
Tokens produced by the Greenplum Database full text search parser are passed through a chain of dictionaries to produce a normalized term or “lexeme”. Different kinds of dictionaries are available to filter and transform tokens in different ways and for different languages.
- **Text Search Configuration Example**
This topic shows how to create a customized text search configuration to process document and query text.
- **Testing and Debugging Text Search**
This topic introduces the Greenplum Database functions you can use to test and debug a search configuration or the individual parser and dictionaries specified in a configuration.
- **GiST and GIN Indexes for Text Search**
This topic describes and compares the Greenplum Database index types that are used for full

text searching.

- **psql Support**

The psql command-line utility provides a meta-command to display information about Greenplum Database full text search configurations.

- **Limitations**

This topic lists limitations and maximums for Greenplum Database full text search objects.

Parent topic: [Querying Data](#)

About Full Text Search

This topic provides an overview of Greenplum Database full text search, basic text search expressions, configuring, and customizing text search. Greenplum Database full text search is compared with Tanzu Greenplum Text.

This section contains the following subtopics:

- [What is a Document?](#)
- [Basic Text Matching](#)
- [Configurations](#)
- [Comparing Greenplum Database Text Search with Tanzu Greenplum Text](#)

Full Text Searching (or just “text search”) provides the capability to identify natural-language *documents* that satisfy a *query*, and optionally to rank them by relevance to the query. The most common type of search is to find all documents containing given *query terms* and return them in order of their *similarity* to the query.

Greenplum Database provides a data type `tsvector` to store preprocessed documents, and a data type `tsquery` to store processed queries ([Text Search Data Types](#)). There are many functions and operators available for these data types ([Text Search Functions and Operators](#)), the most important of which is the match operator `@@`, which we introduce in [Basic Text Matching](#). Full text searches can be accelerated using indexes ([GiST and GIN Indexes for Text Search](#)).

Notions of query and similarity are very flexible and depend on the specific application. The simplest search considers query as a set of words and similarity as the frequency of query words in the document.

Greenplum Database supports the standard text matching operators `~`, `~*`, `LIKE`, and `ILIKE` for textual data types, but these operators lack many essential properties required for searching documents:

- There is no linguistic support, even for English. Regular expressions are not sufficient because they cannot easily handle derived words, e.g., `satisfies` and `satisfy`. You might miss documents that contain `satisfies`, although you probably would like to find them when searching for `satisfy`. It is possible to use OR to search for multiple derived forms, but this is tedious and error-prone (some words can have several thousand derivatives).
- They provide no ordering (ranking) of search results, which makes them ineffective when thousands of matching documents are found.
- They tend to be slow because there is no index support, so they must process all documents for every search.

Full text indexing allows documents to be preprocessed and an index saved for later rapid searching. Preprocessing includes:

- **Parsing documents into tokens.** It is useful to identify various classes of tokens, e.g., numbers, words, complex words, email addresses, so that they can be processed differently.

In principle token classes depend on the specific application, but for most purposes it is adequate to use a predefined set of classes. Greenplum Database uses a *parser* to perform this step. A standard parser is provided, and custom parsers can be created for specific needs.

- **Converting tokens into lexemes.** A lexeme is a string, just like a token, but it has been *normalized* so that different forms of the same word are made alike. For example, normalization almost always includes folding upper-case letters to lower-case, and often involves removal of suffixes (such as s or es in English). This allows searches to find variant forms of the same word, without tediously entering all the possible variants. Also, this step typically eliminates *stop words*, which are words that are so common that they are useless for searching. (In short, then, tokens are raw fragments of the document text, while lexemes are words that are believed useful for indexing and searching.) Greenplum Database uses *dictionaries* to perform this step. Various standard dictionaries are provided, and custom ones can be created for specific needs.
- **Storing preprocessed documents optimized for searching.** For example, each document can be represented as a sorted array of normalized lexemes. Along with the lexemes it is often desirable to store positional information to use for *proximity ranking*, so that a document that contains a more “dense” region of query words is assigned a higher rank than one with scattered query words.

Dictionaries allow fine-grained control over how tokens are normalized. With appropriate dictionaries, you can:

- Define stop words that should not be indexed.
- Map synonyms to a single word using Ispell.
- Map phrases to a single word using a thesaurus.
- Map different variations of a word to a canonical form using an Ispell dictionary.
- Map different variations of a word to a canonical form using Snowball stemmer rules.

What is a Document?

A *document* is the unit of searching in a full text search system; for example, a magazine article or email message. The text search engine must be able to parse documents and store associations of lexemes (key words) with their parent document. Later, these associations are used to search for documents that contain query words.

For searches within Greenplum Database, a document is normally a textual field within a row of a database table, or possibly a combination (concatenation) of such fields, perhaps stored in several tables or obtained dynamically. In other words, a document can be constructed from different parts for indexing and it might not be stored anywhere as a whole. For example:

```
SELECT title || ' ' || author || ' ' || abstract || ' ' || body AS document
FROM messages
WHERE mid = 12;

SELECT m.title || ' ' || m.author || ' ' || m.abstract || ' ' || d.body AS document
FROM messages m, docs d
WHERE mid = did AND mid = 12;
```

Note:

In these example queries, `coalesce` should be used to prevent a single `NULL` attribute from causing a `NULL` result for the whole document.

Another possibility is to store the documents as simple text files in the file system. In this case, the

database can be used to store the full text index and to run searches, and some unique identifier can be used to retrieve the document from the file system. However, retrieving files from outside the database requires superuser permissions or special function support, so this is usually less convenient than keeping all the data inside Greenplum Database. Also, keeping everything inside the database allows easy access to document metadata to assist in indexing and display.

For text search purposes, each document must be reduced to the preprocessed `tsvector` format. Searching and ranking are performed entirely on the `tsvector` representation of a document — the original text need only be retrieved when the document has been selected for display to a user. We therefore often speak of the `tsvector` as being the document, but of course it is only a compact representation of the full document.

Basic Text Matching

Full text searching in Greenplum Database is based on the match operator `@@`, which returns `true` if a `tsvector` (document) matches a `tsquery` (query). It does not matter which data type is written first:

```
SELECT 'a fat cat sat on a mat and ate a fat rat'::tsvector @@ 'cat & rat'::tsquery;
?column?
-----
t

SELECT 'fat & cow'::tsquery @@ 'a fat cat sat on a mat and ate a fat rat'::tsvector;
?column?
-----
f
```

As the above example suggests, a `tsquery` is not just raw text, any more than a `tsvector` is. A `tsquery` contains search terms, which must be already-normalized lexemes, and may combine multiple terms using AND, OR, and NOT operators. (For details see.) There are functions `to_tsquery` and `plainto_tsquery` that are helpful in converting user-written text into a proper `tsquery`, for example by normalizing words appearing in the text. Similarly, `to_tsvector` is used to parse and normalize a document string. So in practice a text search match would look more like this:

```
SELECT to_tsvector('fat cats ate fat rats') @@ to_tsquery('fat & rat');
?column?
-----
t
```

Observe that this match would not succeed if written as

```
SELECT 'fat cats ate fat rats'::tsvector @@ to_tsquery('fat & rat');
?column?
-----
f
```

since here no normalization of the word `rats` will occur. The elements of a `tsvector` are lexemes, which are assumed already normalized, so `rats` does not match `rat`.

The `@@` operator also supports `text` input, allowing explicit conversion of a text string to `tsvector` or `tsquery` to be skipped in simple cases. The variants available are:

```
tsvector @@ tsquery
tsquery  @@ tsvector
text     @@ tsquery
text     @@ text
```

The first two of these we saw already. The form `text @@ tsquery` is equivalent to `to_tsvector(x) @@`

y. The form `text @@ text` is equivalent to `to_tsvector(x) @@ plainto_tsquery(y)`.

Configurations

The above are all simple text search examples. As mentioned before, full text search functionality includes the ability to do many more things: skip indexing certain words (stop words), process synonyms, and use sophisticated parsing, e.g., parse based on more than just white space. This functionality is controlled by *text search configurations*. Greenplum Database comes with predefined configurations for many languages, and you can easily create your own configurations. (`psql`'s `\df` command shows all available configurations.)

During installation an appropriate configuration is selected and `default_text_search_config` is set accordingly in `postgresql.conf`. If you are using the same text search configuration for the entire cluster you can use the value in `postgresql.conf`. To use different configurations throughout the cluster but the same configuration within any one database, use `ALTER DATABASE ... SET`. Otherwise, you can set `default_text_search_config` in each session.

Each text search function that depends on a configuration has an optional `regconfig` argument, so that the configuration to use can be specified explicitly. `default_text_search_config` is used only when this argument is omitted.

To make it easier to build custom text search configurations, a configuration is built up from simpler database objects. Greenplum Database's text search facility provides four types of configuration-related database objects:

- *Text search parsers* break documents into tokens and classify each token (for example, as words or numbers).
- *Text search dictionaries* convert tokens to normalized form and reject stop words.
- *Text search templates* provide the functions underlying dictionaries. (A dictionary simply specifies a template and a set of parameters for the template.)
- *Text search configurations* select a parser and a set of dictionaries to use to normalize the tokens produced by the parser.

Text search parsers and templates are built from low-level C functions; therefore it requires C programming ability to develop new ones, and superuser privileges to install one into a database. (There are examples of add-on parsers and templates in the `contrib/` area of the Greenplum Database distribution.) Since dictionaries and configurations just parameterize and connect together some underlying parsers and templates, no special privilege is needed to create a new dictionary or configuration. Examples of creating custom dictionaries and configurations appear later in this chapter.

Comparing Greenplum Database Text Search with Tanzu Greenplum Text

Greenplum Database text search is PostgreSQL text search ported to the Greenplum Database MPP platform. VMware also offers Tanzu Greenplum Text, which integrates Greenplum Database with the Apache Solr text search platform. Tanzu Greenplum Text installs an Apache Solr cluster alongside your Greenplum Database cluster and provides Greenplum Database functions you can use to create Solr indexes, query them, and receive results in the database session.

Both of these systems provide powerful, enterprise-quality document indexing and searching services. Greenplum Database text search is immediately available to you, with no need to install and maintain additional software. If it meets your applications' requirements, you should use it.

Tanzu Greenplum Text, with Solr, has many capabilities that are not available with Greenplum

Database text search. In particular, it is better for advanced text analysis applications. Following are some of the advantages and capabilities available to you when you use Tanzu Greenplum Text for text search applications.

- The Apache Solr cluster can be scaled separately from the database. Solr nodes can be deployed on the Greenplum Database hosts or on separate hosts on the network.
- Indexing and search workloads can be moved out of Greenplum Database to Solr to maintain database query performance.
- Tanzu Greenplum Text creates Solr indexes that are split into *shards*, one per Greenplum Database segment, so the advantages of the Greenplum Database MPP architecture are extended to text search workloads.
- Indexing and searching documents with Solr is very fast and can be scaled by adding more Solr nodes to the cluster.
- Document content can be stored in Greenplum Database tables, in the Solr index, or both.
- Through Tanzu Greenplum Text, Solr can index documents stored as text in Greenplum Database tables, as well as documents in external stores accessible using HTTP, FTP, S3, or HDFS URLs.
- Solr automatically recognizes most rich document formats and indexes document content and metadata separately.
- Solr indexes are highly customizable. You can customize the text analysis chain down to the field level.
- In addition to the large number of languages, tokenizers, and filters available from the Apache project, Tanzu Greenplum Text provides a social media tokenizer, an international text tokenizer, and a universal query parser that understands several common text search syntaxes.
- The Tanzu Greenplum Text API supports advanced text analysis tools, such as faceting, named entity recognition (NER), and parts of speech (POS) recognition.

See the [Tanzu Greenplum Text Documentation web site](#) for more information.

Parent topic: [Using Full Text Search](#)

Searching Text in Database Tables

This topic shows how to use text search operators to search database tables and how to create indexes to speed up text searches.

The examples in the previous section illustrated full text matching using simple constant strings. This section shows how to search table data, optionally using indexes.

This section contains the following subtopics:

- [Searching a Table](#)
- [Creating Indexes](#)

Searching a Table

It is possible to do a full text search without an index. A simple query to print the `title` of each row that contains the word `friend` in its `body` field is:

```
SELECT title
FROM pgweb
```

```
WHERE to_tsvector('english', body) @@ to_tsquery('english', 'friend');
```

This will also find related words such as `friends` and `friendly`, since all these are reduced to the same normalized lexeme.

The query above specifies that the `english` configuration is to be used to parse and normalize the strings. Alternatively we could omit the configuration parameters:

```
SELECT title
FROM pgweb
WHERE to_tsvector(body) @@ to_tsquery('friend');
```

This query will use the configuration set by `default_text_search_config`.

A more complex example is to select the ten most recent documents that contain `create` and `table` in the `title` or `body`:

```
SELECT title
FROM pgweb
WHERE to_tsvector(title || ' ' || body) @@ to_tsquery('create & table')
ORDER BY last_mod_date DESC
LIMIT 10;
```

For clarity we omitted the `coalesce` function calls which would be needed to find rows that contain `NULL` in one of the two fields.

Although these queries will work without an index, most applications will find this approach too slow, except perhaps for occasional ad-hoc searches. Practical use of text searching usually requires creating an index.

Creating Indexes

We can create a GIN index ([GiST and GIN Indexes for Text Search](#)) to speed up text searches:

```
CREATE INDEX pgweb_idx ON pgweb USING gin(to_tsvector('english', body));
```

Notice that the two-argument version of `to_tsvector` is used. Only text search functions that specify a configuration name can be used in expression indexes. This is because the index contents must be unaffected by `default_text_search_config`. If they were affected, the index contents might be inconsistent because different entries could contain `tsvector`s that were created with different text search configurations, and there would be no way to guess which was which. It would be impossible to dump and restore such an index correctly.

Because the two-argument version of `to_tsvector` was used in the index above, only a query reference that uses the two-argument version of `to_tsvector` with the same configuration name will use that index. That is, `WHERE to_tsvector('english', body) @@ 'a & b'` can use the index, but `WHERE to_tsvector(body) @@ 'a & b'` cannot. This ensures that an index will be used only with the same configuration used to create the index entries.

It is possible to set up more complex expression indexes wherein the configuration name is specified by another column, e.g.:

```
CREATE INDEX pgweb_idx ON pgweb USING gin(to_tsvector(config_name, body));
```

where `config_name` is a column in the `pgweb` table. This allows mixed configurations in the same index while recording which configuration was used for each index entry. This would be useful, for example, if the document collection contained documents in different languages. Again, queries that are meant to use the index must be phrased to match, e.g., `WHERE to_tsvector(config_name, body)`

```
@@ 'a & b'.
```

Indexes can even concatenate columns:

```
CREATE INDEX pgweb_idx ON pgweb USING gin(to_tsvector('english', title || ' ' || body)
);
```

Another approach is to create a separate `tsvector` column to hold the output of `to_tsvector`. This example is a concatenation of title and body, using `coalesce` to ensure that one field will still be indexed when the other is NULL:

```
ALTER TABLE pgweb ADD COLUMN textsearchable_index_col tsvector;
UPDATE pgweb SET textsearchable_index_col =
    to_tsvector('english', coalesce(title, '') || ' ' || coalesce(body, ''));
```

Then we create a GIN index to speed up the search:

```
CREATE INDEX textsearch_idx ON pgweb USING gin(textsearchable_index_col);
```

Now we are ready to perform a fast full text search:

```
SELECT title FROM pgweb WHERE textsearchable_index_col @@ to_tsquery('create & table')

ORDER BY last_mod_date DESC LIMIT 10;
```

One advantage of the separate-column approach over an expression index is that it is not necessary to explicitly specify the text search configuration in queries in order to make use of the index. As shown in the example above, the query can depend on `default_text_search_config`. Another advantage is that searches will be faster, since it will not be necessary to redo the `to_tsvector` calls to verify index matches. (This is more important when using a GiST index than a GIN index; see [GiST and GIN Indexes for Text Search](#).) The expression-index approach is simpler to set up, however, and it requires less disk space since the `tsvector` representation is not stored explicitly.

Parent topic: [Using Full Text Search](#)

Controlling Text Search

This topic shows how to create search and query vectors, how to rank search results, and how to highlight search terms in the results of text search queries.

To implement full text searching there must be a function to create a `tsvector` from a document and a `tsquery` from a user query. Also, we need to return results in a useful order, so we need a function that compares documents with respect to their relevance to the query. It's also important to be able to display the results nicely. Greenplum Database provides support for all of these functions.

This topic contains the following subtopics:

- [Parsing Documents](#)
- [Parsing Queries](#)
- [Ranking Search Results](#)
- [Highlighting Results](#)

Parsing Documents

Greenplum Database provides the function `to_tsvector` for converting a document to the `tsvector` data type.

```
to_tsvector([<config> regconfig, ] <document> text) returns tsvector
```

`to_tsvector` parses a textual document into tokens, reduces the tokens to lexemes, and returns a `tsvector` which lists the lexemes together with their positions in the document. The document is processed according to the specified or default text search configuration. Here is a simple example:

```
SELECT to_tsvector('english', 'a fat cat sat on a mat - it ate a fat rats');
           to_tsvector
-----
'ate':9 'cat':3 'fat':2,11 'mat':7 'rat':12 'sat':4
```

In the example above we see that the resulting `tsvector` does not contain the words `a`, `on`, or `it`, the word `rats` became `rat`, and the punctuation sign `-` was ignored.

The `to_tsvector` function internally calls a parser which breaks the document text into tokens and assigns a type to each token. For each token, a list of dictionaries ([Text Search Dictionaries](#)) is consulted, where the list can vary depending on the token type. The first dictionary that *recognizes* the token emits one or more normalized *lexemes* to represent the token. For example, `rats` became `rat` because one of the dictionaries recognized that the word `rats` is a plural form of `rat`. Some words are recognized as *stop words*, which causes them to be ignored since they occur too frequently to be useful in searching. In our example these are `a`, `on`, and `it`. If no dictionary in the list recognizes the token then it is also ignored. In this example that happened to the punctuation sign `-` because there are in fact no dictionaries assigned for its token type (`Space symbols`), meaning space tokens will never be indexed. The choices of parser, dictionaries and which types of tokens to index are determined by the selected text search configuration ([Text Search Configuration Example](#)). It is possible to have many different configurations in the same database, and predefined configurations are available for various languages. In our example we used the default configuration `english` for the English language.

The function `setweight` can be used to label the entries of a `tsvector` with a given *weight*, where a weight is one of the letters `A`, `B`, `C`, or `D`. This is typically used to mark entries coming from different parts of a document, such as `title` versus `body`. Later, this information can be used for ranking of search results.

Because `to_tsvector(NULL)` will return `NULL`, it is recommended to use `coalesce` whenever a field might be null. Here is the recommended method for creating a `tsvector` from a structured document:

```
UPDATE tt SET ti = setweight(to_tsvector(coalesce(title,'')), 'A')
|| setweight(to_tsvector(coalesce(keyword,'')), 'B')
|| setweight(to_tsvector(coalesce(abstract,'')), 'C')
|| setweight(to_tsvector(coalesce(body,'')), 'D');
```

Here we have used `setweight` to label the source of each lexeme in the finished `tsvector`, and then merged the labeled `tsvector` values using the `tsvector` concatenation operator `||`. ([Additional Text Search Features](#) gives details about these operations.)

Parsing Queries

Greenplum Database provides the functions `to_tsquery` and `plainto_tsquery` for converting a query to the `tsquery` data type. `to_tsquery` offers access to more features than `plainto_tsquery`, but is less forgiving about its input.

```
to_tsquery([<config> regconfig, ] <querytext> text) returns tsquery
```

`to_tsquery` creates a `tsquery` value from *querytext*, which must consist of single tokens separated by the Boolean operators `&` (AND), `|` (OR), and `!(NOT)`. These operators can be grouped using parentheses. In other words, the input to `to_tsquery` must already follow the general rules for `tsquery` input, as described in [Text Search Data Types](#). The difference is that while basic `tsquery` input takes the tokens at face value, `to_tsquery` normalizes each token to a lexeme using the specified or default configuration, and discards any tokens that are stop words according to the configuration. For example:

```
SELECT to_tsquery('english', 'The & Fat & Rats');
       to_tsquery
-----
'fat' & 'rat'
```

As in basic `tsquery` input, weight(s) can be attached to each lexeme to restrict it to match only `tsvector` lexemes of those weight(s). For example:

```
SELECT to_tsquery('english', 'Fat | Rats:AB');
       to_tsquery
-----
'fat' | 'rat':AB
```

Also, `*` can be attached to a lexeme to specify prefix matching:

```
SELECT to_tsquery('supern:*A & star:A*B');
       to_tsquery
-----
'supern':*A & 'star':*AB
```

Such a lexeme will match any word in a `tsvector` that begins with the given string.

`to_tsquery` can also accept single-quoted phrases. This is primarily useful when the configuration includes a thesaurus dictionary that may trigger on such phrases. In the example below, a thesaurus contains the rule `supernovae stars : sn:`

```
SELECT to_tsquery('''supernovae stars'' & !crab');
       to_tsquery
-----
'sn' & !'crab'
```

Without quotes, `to_tsquery` will generate a syntax error for tokens that are not separated by an AND or OR operator.

```
plainto_tsquery([ <config> regconfig, ] <querytext> ext) returns tsquery
```

`plainto_tsquery` transforms unformatted text **querytext** to `tsquery`. The text is parsed and normalized much as for `to_tsvector`, then the `&` (AND) Boolean operator is inserted between surviving words.

Example:

```
SELECT plainto_tsquery('english', 'The Fat Rats');
       plainto_tsquery
-----
'fat' & 'rat'
```

Note that `plainto_tsquery` cannot recognize Boolean operators, weight labels, or prefix-match labels in its input:

```
SELECT plainto_tsquery('english', 'The Fat & Rats:C');
      plainto_tsquery
-----
'fat' & 'rat' & 'c'
```

Here, all the input punctuation was discarded as being space symbols.

Ranking Search Results

Ranking attempts to measure how relevant documents are to a particular query, so that when there are many matches the most relevant ones can be shown first. Greenplum Database provides two predefined ranking functions, which take into account lexical, proximity, and structural information; that is, they consider how often the query terms appear in the document, how close together the terms are in the document, and how important is the part of the document where they occur. However, the concept of relevancy is vague and very application-specific. Different applications might require additional information for ranking, e.g., document modification time. The built-in ranking functions are only examples. You can write your own ranking functions and/or combine their results with additional factors to fit your specific needs.

The two ranking functions currently available are:

```
ts_rank([ <weights> float4[], ] <vector> tsvector, <query> tsquery [, <normalization>
integer ]) returns float4
```

Ranks vectors based on the frequency of their matching lexemes.

```
ts_rank_cd([ <weights> float4[], ] <vector> tsvector, <query> tsquery [, <normalization>
integer ]) returns float4
```

This function computes the *cover density* ranking for the given document vector and query, as described in Clarke, Cormack, and Tudhope's "Relevance Ranking for One to Three Term Queries" in the journal "Information Processing and Management", 1999. Cover density is similar to `ts_rank` ranking except that the proximity of matching lexemes to each other is taken into consideration.

This function requires lexeme positional information to perform its calculation. Therefore, it ignores any "stripped" lexemes in the `tsvector`. If there are no unstripped lexemes in the input, the result will be zero. (See [Manipulating Documents](#) for more information about the `strip` function and positional information in `tsvectors`.)

For both these functions, the optional `<weights>` argument offers the ability to weigh word instances more or less heavily depending on how they are labeled. The weight arrays specify how heavily to weigh each category of word, in the order:

```
{D-weight, C-weight, B-weight, A-weight}
```

If no `<weights>` are provided, then these defaults are used:

```
{0.1, 0.2, 0.4, 1.0}
```

Typically weights are used to mark words from special areas of the document, like the title or an initial abstract, so they can be treated with more or less importance than words in the document body.

Since a longer document has a greater chance of containing a query term it is reasonable to take into account document size, e.g., a hundred-word document with five instances of a search word is probably more relevant than a thousand-word document with five instances. Both ranking functions take an integer `<normalization>` option that specifies whether and how a document's length should impact its rank. The integer option controls several behaviors, so it is a bit mask: you can

specify one or more behaviors using `|` (for example, `2|4`).

- 0 (the default) ignores the document length
- 1 divides the rank by 1 + the logarithm of the document length
- 2 divides the rank by the document length
- 4 divides the rank by the mean harmonic distance between extents (this is implemented only by `ts_rank_cd`)
- 8 divides the rank by the number of unique words in document
- 16 divides the rank by 1 + the logarithm of the number of unique words in document
- 32 divides the rank by itself + 1

If more than one flag bit is specified, the transformations are applied in the order listed.

It is important to note that the ranking functions do not use any global information, so it is impossible to produce a fair normalization to 1% or 100% as sometimes desired. Normalization option `32` (`rank/(rank+1)`) can be applied to scale all ranks into the range zero to one, but of course this is just a cosmetic change; it will not affect the ordering of the search results.

Here is an example that selects only the ten highest-ranked matches:

```
SELECT title, ts_rank_cd(textsearch, query) AS rank
FROM apod, to_tsquery('neutrino|(dark & matter)') query
WHERE query @@ textsearch
ORDER BY rank DESC
LIMIT 10;
```

title	rank
Neutrinos in the Sun	3.1
The Sudbury Neutrino Detector	2.4
A MACHO View of Galactic Dark Matter	2.01317
Hot Gas and Dark Matter	1.91171
The Virgo Cluster: Hot Plasma and Dark Matter	1.90953
Rafting for Solar Neutrinos	1.9
NGC 4650A: Strange Galaxy and Dark Matter	1.85774
Hot Gas and Dark Matter	1.6123
Ice Fishing for Cosmic Neutrinos	1.6
Weak Lensing Distorts the Universe	0.818218

This is the same example using normalized ranking:

```
SELECT title, ts_rank_cd(textsearch, query, 32 /* rank/(rank+1) */ ) AS rank
FROM apod, to_tsquery('neutrino|(dark & matter)') query
WHERE query @@ textsearch
ORDER BY rank DESC
LIMIT 10;
```

title	rank
Neutrinos in the Sun	0.756097569485493
The Sudbury Neutrino Detector	0.705882361190954
A MACHO View of Galactic Dark Matter	0.668123210574724
Hot Gas and Dark Matter	0.65655958650282
The Virgo Cluster: Hot Plasma and Dark Matter	0.656301290640973
Rafting for Solar Neutrinos	0.655172410958162
NGC 4650A: Strange Galaxy and Dark Matter	0.650072921219637
Hot Gas and Dark Matter	0.617195790024749
Ice Fishing for Cosmic Neutrinos	0.615384618911517
Weak Lensing Distorts the Universe	0.450010798361481

Ranking can be expensive since it requires consulting the tsvector of each matching document,

which can be I/O bound and therefore slow. Unfortunately, it is almost impossible to avoid since practical queries often result in large numbers of matches.

Highlighting Results

To present search results it is ideal to show a part of each document and how it is related to the query. Usually, search engines show fragments of the document with marked search terms.

Greenplum Database provides a function `ts_headline` that implements this functionality.

```
ts_headline([<config> regconfig, ] <document> text, <query> tsquery [, <options> text
]) returns text
```

`ts_headline` accepts a document along with a query, and returns an excerpt from the document in which terms from the query are highlighted. The configuration to be used to parse the document can be specified by `*config*`; if `*config*` is omitted, the `default_text_search_config` configuration is used.

If an `*options*` string is specified it must consist of a comma-separated list of one or more `*option=value*` pairs. The available options are:

- `StartSel`, `StopSel`: the strings with which to delimit query words appearing in the document, to distinguish them from other excerpted words. You must double-quote these strings if they contain spaces or commas.
- `MaxWords`, `MinWords`: these numbers determine the longest and shortest headlines to output.
- `ShortWord`: words of this length or less will be dropped at the start and end of a headline. The default value of three eliminates common English articles.
- `HighlightAll`: Boolean flag; if `true` the whole document will be used as the headline, ignoring the preceding three parameters.
- `MaxFragments`: maximum number of text excerpts or fragments to display. The default value of zero selects a non-fragment-oriented headline generation method. A value greater than zero selects fragment-based headline generation. This method finds text fragments with as many query words as possible and stretches those fragments around the query words. As a result query words are close to the middle of each fragment and have words on each side. Each fragment will be of at most `MaxWords` and words of length `ShortWord` or less are dropped at the start and end of each fragment. If not all query words are found in the document, then a single fragment of the first `MinWords` in the document will be displayed.
- `FragmentDelimiter`: When more than one fragment is displayed, the fragments will be separated by this string.

Any unspecified options receive these defaults:

```
StartSel=<b>, StopSel=</b>,
MaxWords=35, MinWords=15, ShortWord=3, HighlightAll=FALSE,
MaxFragments=0, FragmentDelimiter=" ... "
```

For example:

```
SELECT ts_headline('english',
  'The most common type of search
is to find all documents containing given query terms
and return them in order of their similarity to the
query.',
  to_tsquery('query & similarity'));
      ts_headline
-----
```

```

containing given <b>query</b> terms
and return them in order of their <b>similarity</b> to the
<b>query</b>.

SELECT ts_headline('english',
  'The most common type of search
is to find all documents containing given query terms
and return them in order of their similarity to the
query.',
  to_tsquery('query & similarity'),
  'StartSel = <, StopSel = >');
          ts_headline
-----
containing given <query> terms
and return them in order of their <similarity> to the
<query>.

```

`ts_headline` uses the original document, not a `tsvector` summary, so it can be slow and should be used with care. A typical mistake is to call `ts_headline` for every matching document when only ten documents are to be shown. SQL subqueries can help; here is an example:

```

SELECT id, ts_headline(body, q), rank
FROM (SELECT id, body, q, ts_rank_cd(ti, q) AS rank
      FROM apod, to_tsquery('stars') q
      WHERE ti @@ q
      ORDER BY rank DESC
      LIMIT 10) AS foo;

```

Parent topic: [Using Full Text Search](#)

Additional Text Search Features

Greenplum Database has additional functions and operators you can use to manipulate search and query vectors, and to rewrite search queries.

This section contains the following subtopics:

- [Manipulating Documents](#)
- [Manipulating Queries](#)
- [Rewriting Queries](#)
- [Gathering Document Statistics](#)

Manipulating Documents

[Parsing Documents](#) showed how raw textual documents can be converted into `tsvector` values. Greenplum Database also provides functions and operators that can be used to manipulate documents that are already in `tsvector` form.

`tsvector || tsvector`

The `tsvector` concatenation operator returns a vector which combines the lexemes and positional information of the two vectors given as arguments. Positions and weight labels are retained during the concatenation. Positions appearing in the right-hand vector are offset by the largest position mentioned in the left-hand vector, so that the result is nearly equivalent to the result of performing `to_tsvector` on the concatenation of the two original document strings. (The equivalence is not exact, because any stop-words removed from the end of the left-hand argument will not affect the result, whereas they would have affected the positions of the lexemes in the right-hand argument if textual concatenation were used.)

One advantage of using concatenation in the vector form, rather than concatenating text before applying `to_tsvector`, is that you can use different configurations to parse different sections of the document. Also, because the `setweight` function marks all lexemes of the given vector the same way, it is necessary to parse the text and do `setweight` before concatenating if you want to label different parts of the document with different weights.

`setweight(<vector> tsvector, <weight> "char")` returns `tsvector`

`setweight` returns a copy of the input vector in which every position has been labeled with the given `<weight>`, either A, B, C, or D. (D is the default for new vectors and as such is not displayed on output.) These labels are retained when vectors are concatenated, allowing words from different parts of a document to be weighted differently by ranking functions.

Note that weight labels apply to **positions**, not **lexemes**. If the input vector has been stripped of positions then `setweight` does nothing.

`length(<vector> tsvector)` returns `integer`

Returns the number of lexemes stored in the vector.

`strip(vector tsvector)` returns `tsvector`

Returns a vector which lists the same lexemes as the given vector, but which lacks any position or weight information. While the returned vector is much less useful than an unstripped vector for relevance ranking, it will usually be much smaller.

Manipulating Queries

[Parsing Queries](#) showed how raw textual queries can be converted into `tsquery` values. Greenplum Database also provides functions and operators that can be used to manipulate queries that are already in `tsquery` form.

`tsquery && tsquery`

Returns the AND-combination of the two given queries.

`tsquery || tsquery`

Returns the OR-combination of the two given queries.

`!! tsquery`

Returns the negation (NOT) of the given query.

`numnode(<query> tsquery)` returns `integer`

Returns the number of nodes (lexemes plus operators) in a `tsquery`. This function is useful to determine if the **query** is meaningful (returns > 0), or contains only stop words (returns 0).

Examples:

```
SELECT numnode(plainto_tsquery('the any'));
NOTICE:  query contains only stopword(s) or doesn't contain lexeme(s), ignored
 numnode
-----
      0

SELECT numnode('foo & bar'::tsquery);
 numnode
-----
      3
```

`querytree(<query> tsquery)` returns `text`

Returns the portion of a `tsquery` that can be used for searching an index. This function is useful for detecting unindexable queries, for example those containing only stop words or only negated terms. For example:

```
SELECT querytree(to_tsquery('!defined'));
querytree
-----
```

Rewriting Queries

The `ts_rewrite` family of functions search a given `tsquery` for occurrences of a target subquery, and replace each occurrence with a substitute subquery. In essence this operation is a `tsquery`-specific version of substring replacement. A target and substitute combination can be thought of as a *query rewrite rule*. A collection of such rewrite rules can be a powerful search aid. For example, you can expand the search using synonyms (e.g., `new york`, `big apple`, `nyc`, `gotham`) or narrow the search to direct the user to some hot topic. There is some overlap in functionality between this feature and thesaurus dictionaries ([Thesaurus Dictionary](#)). However, you can modify a set of rewrite rules on-the-fly without reindexing, whereas updating a thesaurus requires reindexing to be effective.

`ts_rewrite(<query> tsquery, <target> tsquery, <substitute> tsquery)` returns `tsquery`

This form of `ts_rewrite` simply applies a single rewrite rule: `<target>` is replaced by `<substitute>` wherever it appears in `<query>`. For example:

```
SELECT ts_rewrite('a & b'::tsquery, 'a'::tsquery, 'c'::tsquery);
ts_rewrite
-----
'b' & 'c'
```

`ts_rewrite(<query> tsquery, <select> text)` returns `tsquery`

This form of `ts_rewrite` accepts a starting `<query>` and a SQL `<select>` command, which is given as a text string. The `<select>` must yield two columns of `tsquery` type. For each row of the `<select>` result, occurrences of the first column value (the target) are replaced by the second column value (the substitute) within the current `<query>` value. For example:

```
CREATE TABLE aliases (id int, t tsquery, s tsquery);
INSERT INTO aliases VALUES(1, 'a', 'c');

SELECT ts_rewrite('a & b'::tsquery, 'SELECT t,s FROM aliases');
ts_rewrite
-----
'b' & 'c'
```

Note that when multiple rewrite rules are applied in this way, the order of application can be important; so in practice you will want the source query to `ORDER BY` some ordering key.

Let's consider a real-life astronomical example. We'll expand query `supernovae` using table-driven rewriting rules:

```
CREATE TABLE aliases (id int, t tsquery primary key, s tsquery);
INSERT INTO aliases VALUES(1, to_tsquery('supernovae'), to_tsquery('supernovae|sn'));

SELECT ts_rewrite(to_tsquery('supernovae & crab'), 'SELECT t, s FROM aliases');
ts_rewrite
-----
'crab' & ( 'supernova' | 'sn' )
```

We can change the rewriting rules just by updating the table:

```
UPDATE aliases
SET s = to_tsquery('supernovae|sn & !nebulae')
```

```
WHERE t = to_tsquery('supernovae');

SELECT ts_rewrite(to_tsquery('supernovae & crab'), 'SELECT t, s FROM aliases');
       ts_rewrite
-----
'crab' & ( 'supernova' | 'sn' & !'nebula' )
```

Rewriting can be slow when there are many rewriting rules, since it checks every rule for a possible match. To filter out obvious non-candidate rules we can use the containment operators for the `tsquery` type. In the example below, we select only those rules which might match the original query:

```
SELECT ts_rewrite('a & b'::tsquery,
                  'SELECT t,s FROM aliases WHERE 'a & b'::tsquery @> t');
       ts_rewrite
-----
'b' & 'c'
```

Gathering Document Statistics

The function `ts_stat` is useful for checking your configuration and for finding stop-word candidates.

```
ts_stat(<sqlquery> text, [ <weights> text, ]
       OUT <word> text, OUT <ndoc> integer,
       OUT <nentry> integer) returns setof record
```

`<sqlquery>` is a text value containing an SQL query which must return a single `tsvector` column. `ts_stat` runs the query and returns statistics about each distinct lexeme (word) contained in the `tsvector` data. The columns returned are

- `<word> text` — the value of a lexeme
- `<ndoc> integer` — number of documents (`tsvector`s) the word occurred in
- `<nentry> integer` — total number of occurrences of the word

If `weights` is supplied, only occurrences having one of those weights are counted.

For example, to find the ten most frequent words in a document collection:

```
SELECT * FROM ts_stat('SELECT vector FROM apod')
ORDER BY nentry DESC, ndoc DESC, word
LIMIT 10;
```

The same, but counting only word occurrences with weight `A` or `B`:

```
SELECT * FROM ts_stat('SELECT vector FROM apod', 'ab')
ORDER BY nentry DESC, ndoc DESC, word
LIMIT 10;
```

Parent topic: [Using Full Text Search](#)

Text Search Parsers

This topic describes the types of tokens the Greenplum Database text search parser produces from raw text.

Text search parsers are responsible for splitting raw document text into *tokens* and identifying each token's type, where the set of possible types is defined by the parser itself. Note that a parser does not modify the text at all — it simply identifies plausible word boundaries. Because of this limited

scope, there is less need for application-specific custom parsers than there is for custom dictionaries. At present Greenplum Database provides just one built-in parser, which has been found to be useful for a wide range of applications.

The built-in parser is named `pg_catalog.default`. It recognizes 23 token types, shown in the following table.

Alias	Description	Example
<code>asciiword</code>	Word, all ASCII letters	elephant
<code>word</code>	Word, all letters	mañana
<code>numword</code>	Word, letters and digits	beta1
<code>asciihword</code>	Hyphenated word, all ASCII	up-to-date
<code>hword</code>	Hyphenated word, all letters	lógico-matemática
<code>numhword</code>	Hyphenated word, letters and digits	postgresql-beta1
<code>hword_asciipart</code>	Hyphenated word part, all ASCII	postgresql in the context postgresql-beta1
<code>hword_part</code>	Hyphenated word part, all letters	lógico or matemática in the context lógico-matemática
<code>hword_numpart</code>	Hyphenated word part, letters and digits	beta1 in the context postgresql-beta1
<code>email</code>	Email address	foo@example.com
<code>protocol</code>	Protocol head	http://
<code>url</code>	URL	example.com/stuff/index.html
<code>host</code>	Host	example.com
<code>url_path</code>	URL path	/stuff/index.html, in the context of a URL
<code>file</code>	File or path name	/usr/local/foo.txt, if not within a URL
<code>sfloat</code>	Scientific notation	-1.234e56
<code>float</code>	Decimal notation	-1.234
<code>int</code>	Signed integer	-1234
<code>uint</code>	Unsigned integer	1234
<code>version</code>	Version number	8.3.0
<code>tag</code>	XML tag	
<code>entity</code>	XML entity	&
<code>blank</code>	Space symbols	(any whitespace or punctuation not otherwise recognized)

Note:

The parser's notion of a "letter" is determined by the database's locale setting, specifically `lc_ctype`. Words containing only the basic ASCII letters are reported as a separate token type, since it is sometimes useful to distinguish them. In most European languages, token types `word` and `asciiword` should be treated alike.

`email` does not support all valid email characters as defined by RFC 5322. Specifically, the only non-alphanumeric characters supported for email user names are period, dash, and underscore.

It is possible for the parser to produce overlapping tokens from the same piece of text. As an

example, a hyphenated word will be reported both as the entire word and as each component:

```
SELECT alias, description, token FROM ts_debug('foo-bar-betal');
```

alias	description	token
numhword	Hyphenated word, letters and digits	foo-bar-betal
hword_asciipart	Hyphenated word part, all ASCII	foo
blank	Space symbols	-
hword_asciipart	Hyphenated word part, all ASCII	bar
blank	Space symbols	-
hword_numpart	Hyphenated word part, letters and digits	betal

This behavior is desirable since it allows searches to work for both the whole compound word and for components. Here is another instructive example:

```
SELECT alias, description, token FROM ts_debug('http://example.com/stuff/index.html');
```

alias	description	token
protocol	Protocol head	http://
url	URL	example.com/stuff/index.html
host	Host	example.com
url_path	URL path	/stuff/index.html

Parent topic: [Using Full Text Search](#)

Text Search Dictionaries

Tokens produced by the Greenplum Database full text search parser are passed through a chain of dictionaries to produce a normalized term or “lexeme”. Different kinds of dictionaries are available to filter and transform tokens in different ways and for different languages.

This section contains the following subtopics:

- [About Text Search Dictionaries](#)
- [Stop Words](#)
- [Simple Dictionary](#)
- [Synonym Dictionary](#)
- [Thesaurus Dictionary](#)
- [IsPELL Dictionary](#)
- [SnowBall Dictionary](#)

About Text Search Dictionaries

Dictionaries are used to eliminate words that should not be considered in a search (*stop words*), and to *normalize* words so that different derived forms of the same word will match. A successfully normalized word is called a *lexeme*. Aside from improving search quality, normalization and removal of stop words reduces the size of the `tsvector` representation of a document, thereby improving performance. Normalization does not always have linguistic meaning and usually depends on application semantics.

Some examples of normalization:

- Linguistic - IsPELL dictionaries try to reduce input words to a normalized form; stemmer dictionaries remove word endings
- URL locations can be canonicalized to make equivalent URLs match:

- ♦ `http://www.pgsql.ru/db/mw/index.html`
- ♦ `http://www.pgsql.ru/db/mw/`
- ♦ `http://www.pgsql.ru/db/./db/mw/index.html`
- Color names can be replaced by their hexadecimal values, e.g., `red`, `green`, `blue`, `magenta` -> `FF0000`, `00FF00`, `0000FF`, `FF00FF`
- If indexing numbers, we can remove some fractional digits to reduce the range of possible numbers, so for example 3.14159265359, 3.1415926, 3.14 will be the same after normalization if only two digits are kept after the decimal point.

A dictionary is a program that accepts a token as input and returns:

- an array of lexemes if the input token is known to the dictionary (notice that one token can produce more than one lexeme)
- a single lexeme with the `TSL_FILTER` flag set, to replace the original token with a new token to be passed to subsequent dictionaries (a dictionary that does this is called a *filtering dictionary*)
- an empty array if the dictionary knows the token, but it is a stop word
- `NULL` if the dictionary does not recognize the input token

Greenplum Database provides predefined dictionaries for many languages. There are also several predefined templates that can be used to create new dictionaries with custom parameters. Each predefined dictionary template is described below. If no existing template is suitable, it is possible to create new ones; see the `contrib/` area of the Greenplum Database distribution for examples.

A text search configuration binds a parser together with a set of dictionaries to process the parser's output tokens. For each token type that the parser can return, a separate list of dictionaries is specified by the configuration. When a token of that type is found by the parser, each dictionary in the list is consulted in turn, until some dictionary recognizes it as a known word. If it is identified as a stop word, or if no dictionary recognizes the token, it will be discarded and not indexed or searched for. Normally, the first dictionary that returns a `non-NULL` output determines the result, and any remaining dictionaries are not consulted; but a filtering dictionary can replace the given word with a modified word, which is then passed to subsequent dictionaries.

The general rule for configuring a list of dictionaries is to place first the most narrow, most specific dictionary, then the more general dictionaries, finishing with a very general dictionary, like a Snowball stemmer or `simple`, which recognizes everything. For example, for an astronomy-specific search (`astro_en` configuration) one could bind token type `asciiword` (ASCII word) to a synonym dictionary of astronomical terms, a general English dictionary and a Snowball English stemmer:

```
ALTER TEXT SEARCH CONFIGURATION astro_en
ADD MAPPING FOR asciiword WITH astrosyn, english_ispell, english_stem;
```

A filtering dictionary can be placed anywhere in the list, except at the end where it'd be useless. Filtering dictionaries are useful to partially normalize words to simplify the task of later dictionaries. For example, a filtering dictionary could be used to remove accents from accented letters, as is done by the `unaccent` module.

Stop Words

Stop words are words that are very common, appear in almost every document, and have no discrimination value. Therefore, they can be ignored in the context of full text searching. For example, every English text contains words like `a` and `the`, so it is useless to store them in an index. However, stop words do affect the positions in `tsvector`, which in turn affect ranking:

```
SELECT to_tsvector('english','in the list of stop words');
       to_tsvector
-----
 'list':3 'stop':5 'word':6
```

The missing positions 1,2,4 are because of stop words. Ranks calculated for documents with and without stop words are quite different:

```
SELECT ts_rank_cd (to_tsvector('english','in the list of stop words'), to_tsquery('list & stop'));
       ts_rank_cd
-----
           0.05

SELECT ts_rank_cd (to_tsvector('english','list stop words'), to_tsquery('list & stop'));
       ts_rank_cd
-----
           0.1
```

It is up to the specific dictionary how it treats stop words. For example, `ispell` dictionaries first normalize words and then look at the list of stop words, while `Snowball` stemmers first check the list of stop words. The reason for the different behavior is an attempt to decrease noise.

Simple Dictionary

The simple dictionary template operates by converting the input token to lower case and checking it against a file of stop words. If it is found in the file then an empty array is returned, causing the token to be discarded. If not, the lower-cased form of the word is returned as the normalized lexeme. Alternatively, the dictionary can be configured to report non-stop-words as unrecognized, allowing them to be passed on to the next dictionary in the list.

Here is an example of a dictionary definition using the simple template:

```
CREATE TEXT SEARCH DICTIONARY public.simple_dict (
    TEMPLATE = pg_catalog.simple,
    STOPWORDS = english
);
```

Here, `english` is the base name of a file of stop words. The file's full name will be `$SHAREDIR/tsearch_data/english.stop`, where `$SHAREDIR` means the Greenplum Database installation's shared-data directory, often `/usr/local/greenplum-db-<version>/share/postgresql` (use `pg_config --sharedir` to determine it if you're not sure). The file format is simply a list of words, one per line. Blank lines and trailing spaces are ignored, and upper case is folded to lower case, but no other processing is done on the file contents.

Now we can test our dictionary:

```
SELECT ts_lexize('public.simple_dict','YeS');
       ts_lexize
-----
 {yes}

SELECT ts_lexize('public.simple_dict','The');
       ts_lexize
-----
 {}
```

We can also choose to return `NULL`, instead of the lower-cased word, if it is not found in the stop words file. This behavior is selected by setting the dictionary's `Accept` parameter to false. Continuing the example:

```
ALTER TEXT SEARCH DICTIONARY public.simple_dict ( Accept = false );

SELECT ts_lexize('public.simple_dict','YeS');
ts_lexize
-----
{yes}

SELECT ts_lexize('public.simple_dict','The');
ts_lexize
-----
{}
```

With the default setting of `Accept = true`, it is only useful to place a simple dictionary at the end of a list of dictionaries, since it will never pass on any token to a following dictionary. Conversely, `Accept = false` is only useful when there is at least one following dictionary.

CAUTION:

Most types of dictionaries rely on configuration files, such as files of stop words. These files must be stored in UTF-8 encoding. They will be translated to the actual database encoding, if that is different, when they are read into the server.

CAUTION:

Normally, a database session will read a dictionary configuration file only once, when it is first used within the session. If you modify a configuration file and want to force existing sessions to pick up the new contents, issue an `ALTER TEXT SEARCH DICTIONARY` command on the dictionary. This can be a “dummy” update that doesn't actually change any parameter values.

Synonym Dictionary

This dictionary template is used to create dictionaries that replace a word with a synonym. Phrases are not supported—use the thesaurus template ([Thesaurus Dictionary](#)) for that. A synonym dictionary can be used to overcome linguistic problems, for example, to prevent an English stemmer dictionary from reducing the word “Paris” to “pari”. It is enough to have a `Paris paris` line in the synonym dictionary and put it before the `english_stem` dictionary. For example:

```
SELECT * FROM ts_debug('english', 'Paris');
  alias | description | token | dictionaries | dictionary | lexemes
-----+-----+-----+-----+-----+-----
asciiword | Word, all ASCII | Paris | {english_stem} | english_stem | {pari}

CREATE TEXT SEARCH DICTIONARY my_synonym (
  TEMPLATE = synonym,
  SYNONYMS = my_synonyms
);

ALTER TEXT SEARCH CONFIGURATION english
  ALTER MAPPING FOR asciiword
  WITH my_synonym, english_stem;

SELECT * FROM ts_debug('english', 'Paris');
  alias | description | token | dictionaries | dictionary | lexeme
-----+-----+-----+-----+-----+-----
s
--
asciiword | Word, all ASCII | Paris | {my_synonym,english_stem} | my_synonym | {paris}
```

```
}
```

The only parameter required by the synonym template is `SYNONYMS`, which is the base name of its configuration file — `my_synonyms` in the above example. The file's full name will be `$SHAREDIR/tsearch_data/my_synonyms.syn` (where `$SHAREDIR` means the Greenplum Database installation's shared-data directory). The file format is just one line per word to be substituted, with the word followed by its synonym, separated by white space. Blank lines and trailing spaces are ignored.

The synonym template also has an optional parameter `CaseSensitive`, which defaults to `false`. When `CaseSensitive` is `false`, words in the synonym file are folded to lower case, as are input tokens. When it is `true`, words and tokens are not folded to lower case, but are compared as-is.

An asterisk (*) can be placed at the end of a synonym in the configuration file. This indicates that the synonym is a prefix. The asterisk is ignored when the entry is used in `to_tsvector()`, but when it is used in `to_tsquery()`, the result will be a query item with the prefix match marker (see [Parsing Queries](#)). For example, suppose we have these entries in

`$SHAREDIR/tsearch_data/synonym_sample.syn`:

```
postgres pgsq postgresql pgsq postgre pgsq
gogle googl
indices index*
```

Then we will get these results:

```
mydb=# CREATE TEXT SEARCH DICTIONARY syn (template=synonym, synonyms='synonym_sample')
;
mydb=# SELECT ts_lexize('syn','indices');
 ts_lexize
-----
 {index}
(1 row)

mydb=# CREATE TEXT SEARCH CONFIGURATION tst (copy=simple);
mydb=# ALTER TEXT SEARCH CONFIGURATION tst ALTER MAPPING FOR asciiword WITH syn;
mydb=# SELECT to_tsvector('tst','indices');
 to_tsvector
-----
 'index':1
(1 row)

mydb=# SELECT to_tsquery('tst','indices');
 to_tsquery
-----
 'index':*
(1 row)

mydb=# SELECT 'indexes are very useful'::tsvector;
          tsvector
-----
 'are' 'indexes' 'useful' 'very'
(1 row)

mydb=# SELECT 'indexes are very useful'::tsvector @@ to_tsquery('tst','indices');
 ?column?
-----
 t
(1 row)
```

Thesaurus Dictionary

A thesaurus dictionary (sometimes abbreviated as TZ) is a collection of words that includes information about the relationships of words and phrases, i.e., broader terms (BT), narrower terms (NT), preferred terms, non-preferred terms, related terms, etc.

Basically a thesaurus dictionary replaces all non-preferred terms by one preferred term and, optionally, preserves the original terms for indexing as well. Greenplum Database's current implementation of the thesaurus dictionary is an extension of the synonym dictionary with added *phrase* support. A thesaurus dictionary requires a configuration file of the following format:

```
# this is a comment
sample word(s) : indexed word(s)
more sample word(s) : more indexed word(s)
...
```

where the colon (:) symbol acts as a delimiter between a phrase and its replacement.

A thesaurus dictionary uses a *subdictionary* (which is specified in the dictionary's configuration) to normalize the input text before checking for phrase matches. It is only possible to select one subdictionary. An error is reported if the subdictionary fails to recognize a word. In that case, you should remove the use of the word or teach the subdictionary about it. You can place an asterisk (*) at the beginning of an indexed word to skip applying the subdictionary to it, but all sample words **must** be known to the subdictionary.

The thesaurus dictionary chooses the longest match if there are multiple phrases matching the input, and ties are broken by using the last definition.

Specific stop words recognized by the subdictionary cannot be specified; instead use ? to mark the location where any stop word can appear. For example, assuming that **a** and **the** are stop words according to the subdictionary:

```
? one ? two : swsw
```

matches **a one the two** and **the one a two**; both would be replaced by **swsw**.

Since a thesaurus dictionary has the capability to recognize phrases it must remember its state and interact with the parser. A thesaurus dictionary uses these assignments to check if it should handle the next word or stop accumulation. The thesaurus dictionary must be configured carefully. For example, if the thesaurus dictionary is assigned to handle only the `asciiword` token, then a thesaurus dictionary definition like `one 7` will not work since token type `uint` is not assigned to the thesaurus dictionary.

CAUTION:

Thesauruses are used during indexing so any change in the thesaurus dictionary's parameters requires reindexing. For most other dictionary types, small changes such as adding or removing stopwords does not force reindexing.

Thesaurus Configuration

To define a new thesaurus dictionary, use the `thesaurus` template. For example:

```
CREATE TEXT SEARCH DICTIONARY thesaurus_simple (
  TEMPLATE = thesaurus,
  DictFile = mythesaurus,
  Dictionary = pg_catalog.english_stem
);
```

Here:

- `thesaurus_simple` is the new dictionary's name

- `mythesaurus` is the base name of the thesaurus configuration file. (Its full name will be `$SHAREDIR/tsearch_data/mythesaurus.ths`, where `$SHAREDIR` means the installation shared-data directory.)
- `pg_catalog.english_stem` is the subdictionary (here, a Snowball English stemmer) to use for thesaurus normalization. Notice that the subdictionary will have its own configuration (for example, stop words), which is not shown here.

Now it is possible to bind the thesaurus dictionary `thesaurus_simple` to the desired token types in a configuration, for example:

```
ALTER TEXT SEARCH CONFIGURATION russian
  ALTER MAPPING FOR asciiword, asciihword, hword_asciipart
  WITH thesaurus_simple;
```

Thesaurus Example

Consider a simple astronomical thesaurus `thesaurus_astro`, which contains some astronomical word combinations:

```
supernovae stars : sn
crab nebulae : crab
```

Below we create a dictionary and bind some token types to an astronomical thesaurus and English stemmer:

```
CREATE TEXT SEARCH DICTIONARY thesaurus_astro (
  TEMPLATE = thesaurus,
  DictFile = thesaurus_astro,
  Dictionary = english_stem
);

ALTER TEXT SEARCH CONFIGURATION russian
  ALTER MAPPING FOR asciiword, asciihword, hword_asciipart
  WITH thesaurus_astro, english_stem;
```

Now we can see how it works. `ts_lexize` is not very useful for testing a thesaurus, because it treats its input as a single token. Instead we can use `plainto_tsquery` and `to_tsvector`, which will break their input strings into multiple tokens:

```
SELECT plainto_tsquery('supernova star');
plainto_tsquery
-----
'supernova' & 'star'

SELECT to_tsvector('supernova star');
to_tsvector
-----
'star':2 'supernova':1
```

In principle, one can use `to_tsquery` if you quote the argument:

```
SELECT to_tsquery(''supernova star'');
to_tsquery
-----
'supernova' & 'star'
```

Notice that `supernova star` matches `supernovae stars` in `thesaurus_astro` because we specified the `english_stem` stemmer in the `thesaurus` definition. The stemmer removed the `e` and `s`.

To index the original phrase as well as the substitute, just include it in the right-hand part of the

definition:

```
supernovae stars : sn supernovae stars

SELECT plainto_tsquery('supernova star');
       plainto_tsquery
-----
'supernova' & 'star'
```

Ispell Dictionary

The Ispell dictionary template supports *morphological dictionaries*, which can normalize many different linguistic forms of a word into the same lexeme. For example, an English Ispell dictionary can match all declensions and conjugations of the search term `bank`, e.g., `banking`, `banked`, `banks`, `banks'`, and `bank's`.

The standard Greenplum Database distribution does not include any Ispell configuration files. Dictionaries for a large number of languages are available from [Ispell](#). Also, some more modern dictionary file formats are supported — [MySpell](#) (OO < 2.0.1) and [Hunspell](#) (OO >= 2.0.2). A large list of dictionaries is available on the [OpenOffice Wiki](#).

To create an Ispell dictionary, use the built-in `ispell` template and specify several parameters:

```
CREATE TEXT SEARCH DICTIONARY english_ispell (
    TEMPLATE = ispell,
    DictFile = english,
    AffFile = english,
    StopWords = english
);
```

Here, `DictFile`, `AffFile`, and `StopWords` specify the base names of the dictionary, affixes, and stop-words files. The stop-words file has the same format explained above for the `simple` dictionary type. The format of the other files is not specified here but is available from the above-mentioned web sites.

Ispell dictionaries usually recognize a limited set of words, so they should be followed by another broader dictionary; for example, a Snowball dictionary, which recognizes everything.

Ispell dictionaries support splitting compound words; a useful feature. Notice that the affix file should specify a special flag using the `compoundwords controlled` statement that marks dictionary words that can participate in compound formation:

```
compoundwords controlled z
```

Here are some examples for the Norwegian language:

```
SELECT ts_lexize('norwegian_ispell', 'overbuljongterningpakkmasterassistent');
      {over,buljong,terning,pakk,mester,assistent}
SELECT ts_lexize('norwegian_ispell', 'sjokoladefabrikk');
      {sjokoladefabrikk,sjokolade,fabrikk}
```

Note:

MySpell does not support compound words. Hunspell has sophisticated support for compound words. At present, Greenplum Database implements only the basic compound word operations of Hunspell.

SnowBall Dictionary

The Snowball dictionary template is based on a project by Martin Porter, inventor of the popular Porter's stemming algorithm for the English language. Snowball now provides stemming algorithms for many languages (see the [Snowball site](#) for more information). Each algorithm understands how to reduce common variant forms of words to a base, or stem, spelling within its language. A Snowball dictionary requires a language parameter to identify which stemmer to use, and optionally can specify a stopwords file name that gives a list of words to eliminate. (Greenplum Database's standard stopwords lists are also provided by the Snowball project.) For example, there is a built-in definition equivalent to

```
CREATE TEXT SEARCH DICTIONARY english_stem (
    TEMPLATE = snowball,
    Language = english,
    StopWords = english
);
```

The stopwords file format is the same as already explained.

A Snowball dictionary recognizes everything, whether or not it is able to simplify the word, so it should be placed at the end of the dictionary list. It is useless to have it before any other dictionary because a token will never pass through it to the next dictionary.

Parent topic: [Using Full Text Search](#)

Text Search Configuration Example

This topic shows how to create a customized text search configuration to process document and query text.

A text search configuration specifies all options necessary to transform a document into a `tsvector`: the parser to use to break text into tokens, and the dictionaries to use to transform each token into a lexeme. Every call of `to_tsvector` or `to_tsquery` needs a text search configuration to perform its processing. The configuration parameter `default_text_search_config` specifies the name of the default configuration, which is the one used by text search functions if an explicit configuration parameter is omitted. It can be set in `postgresql.conf` using the `gpconfig` command-line utility, or set for an individual session using the `SET` command.

Several predefined text search configurations are available, and you can create custom configurations easily. To facilitate management of text search objects, a set of SQL commands is available, and there are several `psql` commands that display information about text search objects ([psql Support](#)).

As an example we will create a configuration `pg`, starting by duplicating the built-in `english` configuration:

```
CREATE TEXT SEARCH CONFIGURATION public.pg ( COPY = pg_catalog.english );
```

We will use a PostgreSQL-specific synonym list and store it in `$SHAREDIR/tsearch_data/pg_dict.syn`. The file contents look like:

```
postgres    pg
pgsql       pg
postgresql  pg
```

We define the synonym dictionary like this:

```
CREATE TEXT SEARCH DICTIONARY pg_dict (
    TEMPLATE = synonym,
    SYNONYMS = pg_dict
```

```
);
```

Next we register the Ispell dictionary `english_ispell`, which has its own configuration files:

```
CREATE TEXT SEARCH DICTIONARY english_ispell (
    TEMPLATE = ispell,
    DictFile = english,
    AffFile = english,
    StopWords = english
);
```

Now we can set up the mappings for words in configuration `pg`:

```
ALTER TEXT SEARCH CONFIGURATION pg
    ALTER MAPPING FOR asciiword, asciihword, hword_asciipart,
                    word, hword, hword_part
    WITH pg_dict, english_ispell, english_stem;
```

We choose not to index or search some token types that the built-in configuration does handle:

```
ALTER TEXT SEARCH CONFIGURATION pg
    DROP MAPPING FOR email, url, url_path, sfloat, float;
```

Now we can test our configuration:

```
SELECT * FROM ts_debug('public.pg', '
PostgreSQL, the highly scalable, SQL compliant, open source object-relational
database management system, is now undergoing beta testing of the next
version of our software.
');
```

The next step is to set the session to use the new configuration, which was created in the `public` schema:

```
=> \dF
    List of text search configurations
 Schema | Name | Description
-----+-----+-----
 public | pg   |

SET default_text_search_config = 'public.pg';
SET

SHOW default_text_search_config;
 default_text_search_config
-----
 public.pg
```

Parent topic: [Using Full Text Search](#)

Testing and Debugging Text Search

This topic introduces the Greenplum Database functions you can use to test and debug a search configuration or the individual parser and dictionaries specified in a configuration.

The behavior of a custom text search configuration can easily become confusing. The functions described in this section are useful for testing text search objects. You can test a complete configuration, or test parsers and dictionaries separately.

This section contains the following subtopics:

- [Configuration Testing](#)
- [Parser Testing](#)
- [Dictionary Testing](#)

Configuration Testing

The function `ts_debug` allows easy testing of a text search configuration.

```
ts_debug([<config> regconfig, ] <document> text,
        OUT <alias> text,
        OUT <description> text,
        OUT <token> text,
        OUT <dictionaries> regdictionary[],
        OUT <dictionary> regdictionary,
        OUT <lexemes> text[])
returns setof record
```

`ts_debug` displays information about every token of **document** as produced by the parser and processed by the configured dictionaries. It uses the configuration specified by **config**, or `default_text_search_config` if that argument is omitted.

`ts_debug` returns one row for each token identified in the text by the parser. The columns returned are

- **alias** `text` — short name of the token type
- **description** `text` — description of the token type
- **token** `text` — text of the token
- **dictionaries** `regdictionary[]` — the dictionaries selected by the configuration for this token type
- **dictionary** `regdictionary` — the dictionary that recognized the token, or `NULL` if none did
- **lexemes** `text[]` — the lexeme(s) produced by the dictionary that recognized the token, or `NULL` if none did; an empty array (`{}`) means it was recognized as a stop word

Here is a simple example:

```
SELECT * FROM ts_debug('english','a fat  cat sat on a mat - it ate a fat rats');
  alias | description | token | dictionaries | dictionary | lexemes
-----+-----+-----+-----+-----+-----
asciiword | Word, all ASCII | a | {english_stem} | english_stem | {}
blank | Space symbols | | {} | | 
asciiword | Word, all ASCII | fat | {english_stem} | english_stem | {fat}
blank | Space symbols | | {} | | 
asciiword | Word, all ASCII | cat | {english_stem} | english_stem | {cat}
blank | Space symbols | | {} | | 
asciiword | Word, all ASCII | sat | {english_stem} | english_stem | {sat}
blank | Space symbols | | {} | | 
asciiword | Word, all ASCII | on | {english_stem} | english_stem | {}
blank | Space symbols | | {} | | 
asciiword | Word, all ASCII | a | {english_stem} | english_stem | {}
blank | Space symbols | | {} | | 
asciiword | Word, all ASCII | mat | {english_stem} | english_stem | {mat}
blank | Space symbols | | {} | | 
blank | Space symbols | - | {} | | 
asciiword | Word, all ASCII | it | {english_stem} | english_stem | {}
blank | Space symbols | | {} | | 
asciiword | Word, all ASCII | ate | {english_stem} | english_stem | {ate}
blank | Space symbols | | {} | | 
```

```

asciiword | Word, all ASCII | a      | {english_stem} | english_stem | {}
blank     | Space symbols   |      | {}              |              |
asciiword | Word, all ASCII | fat   | {english_stem} | english_stem | {fat}
blank     | Space symbols   |      | {}              |              |
asciiword | Word, all ASCII | rats  | {english_stem} | english_stem | {rat}

```

For a more extensive demonstration, we first create a `public.english` configuration and Ispell dictionary for the English language:

```

CREATE TEXT SEARCH CONFIGURATION public.english ( COPY = pg_catalog.english );

CREATE TEXT SEARCH DICTIONARY english_ispell (
    TEMPLATE = ispell,
    DictFile = english,
    AffFile = english,
    StopWords = english
);

ALTER TEXT SEARCH CONFIGURATION public.english
    ALTER MAPPING FOR asciiword WITH english_ispell, english_stem;

```

```

SELECT * FROM ts_debug('public.english','The Brightest supernovaes');

```

alias	description	token	dictionaries	dictionary	lexemes
asciiword	Word, all ASCII	The	{english_ispell,english_stem}	english_ispell	{}
blank	Space symbols		{}		
asciiword	Word, all ASCII	Brightest	{english_ispell,english_stem}	english_ispell	{bright}
blank	Space symbols		{}		
asciiword	Word, all ASCII	supernovaes	{english_ispell,english_stem}	english_stem	{supernova}

In this example, the word `Brightest` was recognized by the parser as an `ASCII` word (alias `asciiword`). For this token type the dictionary list is `english_ispell` and `english_stem`. The word was recognized by `english_ispell`, which reduced it to the noun `bright`. The word `supernovaes` is unknown to the `english_ispell` dictionary so it was passed to the next dictionary, and, fortunately, was recognized (in fact, `english_stem` is a Snowball dictionary which recognizes everything; that is why it was placed at the end of the dictionary list).

The word `The` was recognized by the `english_ispell` dictionary as a stop word (**Stop Words**) and will not be indexed. The spaces are discarded too, since the configuration provides no dictionaries at all for them.

You can reduce the width of the output by explicitly specifying which columns you want to see:

```

SELECT alias, token, dictionary, lexemes FROM ts_debug('public.english','The Brightest supernovaes');

```

alias	token	dictionary	lexemes
asciiword	The	english_ispell	{}
blank			
asciiword	Brightest	english_ispell	{bright}
blank			
asciiword	supernovaes	english_stem	{supernova}

Parser Testing

The following functions allow direct testing of a text search parser.

```
ts_parse(<parser_name> text, <document> text,
        OUT <tokid> integer, OUT <token> text) returns setof record
ts_parse(<parser_oid> oid, <document> text,
        OUT <tokid> integer, OUT <token> text) returns setof record
```

`ts_parse` parses the given document and returns a series of records, one for each token produced by parsing. Each record includes a `tokid` showing the assigned token type and a `token`, which is the text of the token. For example:

```
SELECT * FROM ts_parse('default', '123 - a number');
 tokid | token
-----+-----
      22 | 123
      12 | 
      12 | -
       1 | a
      12 | 
       1 | number
```

```
ts_token_type(<parser_name> text, OUT <tokid> integer,
             OUT <alias> text, OUT <description> text) returns setof record
ts_token_type(<parser_oid> oid, OUT <tokid> integer,
             OUT <alias> text, OUT <description> text) returns setof record
```

`ts_token_type` returns a table which describes each type of token the specified parser can recognize. For each token type, the table gives the integer `tokid` that the parser uses to label a token of that type, the `alias` that names the token type in configuration commands, and a short `description`. For example:

```
SELECT * FROM ts_token_type('default');
 tokid |      alias      | description
-----+-----+-----
      1 | asciiword       | Word, all ASCII
      2 | word            | Word, all letters
      3 | numword         | Word, letters and digits
      4 | email           | Email address
      5 | url             | URL
      6 | host            | Host
      7 | sfloat          | Scientific notation
      8 | version         | Version number
      9 | hword_numpart   | Hyphenated word part, letters and digits
     10 | hword_part      | Hyphenated word part, all letters
     11 | hword_asciipart | Hyphenated word part, all ASCII
     12 | blank           | Space symbols
     13 | tag             | XML tag
     14 | protocol        | Protocol head
     15 | numhword        | Hyphenated word, letters and digits
     16 | asciihword      | Hyphenated word, all ASCII
     17 | hword           | Hyphenated word, all letters
     18 | url_path        | URL path
     19 | file            | File or path name
     20 | float           | Decimal notation
     21 | int             | Signed integer
     22 | uint            | Unsigned integer
     23 | entity          | XML entity
```

Dictionary Testing

The `ts_lexize` function facilitates dictionary testing.

```
ts_lexize(*dictreg* dictionary, *token* text) returns text[]
```

`ts_lexize` returns an array of lexemes if the input `*token*` is known to the dictionary, or an empty array if the token is known to the dictionary but it is a stop word, or `NULL` if it is an unknown word.

Examples:

```
SELECT ts_lexize('english_stem', 'stars');
ts_lexize
-----
{star}

SELECT ts_lexize('english_stem', 'a');
ts_lexize
-----
{}
```

Note: The `ts_lexize` function expects a single token, not text. Here is a case where this can be confusing:

```
SELECT ts_lexize('thesaurus_astro','supernovae stars') is null;
?column?
-----
t
```

The thesaurus dictionary `thesaurus_astro` does know the phrase `supernovae stars`, but `ts_lexize` fails since it does not parse the input text but treats it as a single token. Use `plainto_tsquery` or `to_tsvector` to test thesaurus dictionaries, for example:

```
SELECT plainto_tsquery('supernovae stars');
plainto_tsquery
-----
'sn'
```

GiST and GIN Indexes for Text Search

This topic describes and compares the Greenplum Database index types that are used for full text searching.

There are two kinds of indexes that can be used to speed up full text searches. Indexes are not mandatory for full text searching, but in cases where a column is searched on a regular basis, an index is usually desirable.

```
CREATE INDEX <name> ON <table> USING gist(<column>);
```

Creates a GiST (Generalized Search Tree)-based index. The `<column>` can be of `tsvector` or `tsquery` type.

```
CREATE INDEX <name> ON <table> USING gin(<column>);
```

Creates a GIN (Generalized Inverted Index)-based index. The `<column>` must be of `tsvector` type.

There are substantial performance differences between the two index types, so it is important to understand their characteristics.

A GiST index is *lossy*, meaning that the index may produce false matches, and it is necessary to check the actual table row to eliminate such false matches. (Greenplum Database does this automatically when needed.) GiST indexes are lossy because each document is represented in the index by a fixed-length signature. The signature is generated by hashing each word into a single bit in an n-bit string, with all these bits OR-ed together to produce an n-bit document signature. When two words hash to the same bit position there will be a false match. If all words in the query have matches (real or false) then the table row must be retrieved to see if the match is correct.

Lossiness causes performance degradation due to unnecessary fetches of table records that turn out to be false matches. Since random access to table records is slow, this limits the usefulness of GiST indexes. The likelihood of false matches depends on several factors, in particular the number of unique words, so using dictionaries to reduce this number is recommended.

GIN indexes are not lossy for standard queries, but their performance depends logarithmically on the number of unique words. (However, GIN indexes store only the words (lexemes) of `tsvector` values, and not their weight labels. Thus a table row recheck is needed when using a query that involves weights.)

In choosing which index type to use, GiST or GIN, consider these performance differences:

- GIN index lookups are about three times faster than GiST
- GIN indexes take about three times longer to build than GiST
- GIN indexes are moderately slower to update than GiST indexes, but about 10 times slower if fast-update support was disabled (see [GIN Fast Update Technique](#) in the PostgreSQL documentation for details)
- GIN indexes are two-to-three times larger than GiST indexes

As a general rule, GIN indexes are best for static data because lookups are faster. For dynamic data, GiST indexes are faster to update. Specifically, GiST indexes are very good for dynamic data and fast if the number of unique words (lexemes) is under 100,000, while GIN indexes will handle 100,000+ lexemes better but are slower to update.

Note that GIN index build time can often be improved by increasing `maintenance_work_mem`, while GiST index build time is not sensitive to that parameter.

Partitioning of big collections and the proper use of GiST and GIN indexes allows the implementation of very fast searches with online update. Partitioning can be done at the database level using table inheritance, or by distributing documents over servers and collecting search results using [dblink](#). The latter is possible because ranking functions use only local information.

Parent topic: [Using Full Text Search](#)

psql Support

The `psql` command-line utility provides a meta-command to display information about Greenplum Database full text search configurations.

Information about text search configuration objects can be obtained in `psql` using a set of commands:

```
\dF{d,p,t}[+] [PATTERN]
```

An optional `+` produces more details.

The optional parameter `PATTERN` can be the name of a text search object, optionally schema-qualified. If `PATTERN` is omitted then information about all visible objects will be displayed. `PATTERN` can be a regular expression and can provide **separate** patterns for the schema and object names. The following examples illustrate this:

```
=> \dF *fulltext*
      List of text search configurations
Schema | Name          | Description
-----+-----+-----
public | fulltext_cfg |
```

```
=> \dF *.fulltext*
      List of text search configurations
Schema | Name          | Description
-----+-----+-----
fulltext | fulltext_cfg |
public   | fulltext_cfg |
```

The available commands are:

`\dF[+] [PATTERN]`

List text search configurations (add + for more detail).

```
=> \dF russian
      List of text search configurations
Schema | Name          | Description

Limitations

This topic lists limitations and maximums for Greenplum Database full text search objects.

The current limitations of Greenplum Database's text search features are:

- The `tsvector` and `tsquery` types are not supported in the distribution key for a Greenplum Database table
- The length of each lexeme must be less than 2K bytes
- The length of a `tsvector` (lexemes + positions) must be less than 1 megabyte
- The number of lexemes must be less than 264
- Position values in `tsvector` must be greater than 0 and no more than 16,383
- No more than 256 positions per lexeme
- The number of nodes (lexemes + operators) in a `tsquery` must be less than 32,768

For comparison, the PostgreSQL 8.1 documentation contained 10,441 unique words, a total of 335,420 words, and the most frequent word “postgresql” was mentioned 6,127 times in 655 documents.

Another example — the PostgreSQL mailing list archives contained 910,989 unique words with 57,491,343 lexemes in 461,020 messages.

Using Greenplum MapReduce

MapReduce is a programming model developed by Google for processing and generating large data sets on an array of commodity servers. Greenplum MapReduce allows programmers who are familiar with the MapReduce model to write map and reduce functions and submit them to the Greenplum Database parallel engine for processing.

You configure a Greenplum MapReduce job via a YAML-formatted configuration file, then pass the file to the Greenplum MapReduce program, `gmapreduce`, for execution by the Greenplum Database parallel engine. The Greenplum Database system distributes the input data, runs the program across a set of machines, handles machine failures, and manages the required inter-machine communication.

Refer to [gmapreduce](#) for details about running the Greenplum MapReduce program.

Parent topic: [Querying Data](#)

About the Greenplum MapReduce Configuration File

This section explains some basics of the Greenplum MapReduce configuration file format to help you get started creating your own Greenplum MapReduce configuration files. Greenplum uses the [YAML](#)

1.1 document format and then implements its own schema for defining the various steps of a MapReduce job.

All Greenplum MapReduce configuration files must first declare the version of the YAML specification they are using. After that, three dashes (`---`) denote the start of a document, and three dots (`...`) indicate the end of a document without starting a new one. (A document in this context is equivalent to a MapReduce job.) Comment lines are prefixed with a pound symbol (`#`). You can declare multiple Greenplum MapReduce documents/jobs in the same file:

```
%YAML 1.1
---
# Begin Document 1
# ...
---
# Begin Document 2
# ...
```

Within a Greenplum MapReduce document, there are three basic types of data structures or *nodes*: *scalars*, *sequences* and *mappings*.

A *scalar* is a basic string of text indented by a space. If you have a scalar input that spans multiple lines, a preceding pipe (`|`) denotes a *literal* style, where all line breaks are significant. Alternatively, a preceding angle bracket (`>`) folds a single line break to a space for subsequent lines that have the same indentation level. If a string contains characters that have reserved meaning, the string must be quoted or the special character must be escaped with a backslash (`\`).

```
# Read each new line literally
somekey: |  this value contains two lines
           and each line is read literally
# Treat each new line as a space
anotherkey: >
           this value contains two lines
           but is treated as one continuous line
# This quoted string contains a special character
ThirdKey: "This is a string: not a mapping"
```

A *sequence* is a list with each entry in the list on its own line denoted by a dash and a space (`-`). Alternatively, you can specify an inline sequence as a comma-separated list within square brackets. A sequence provides a set of data and gives it an order. When you load a list into the Greenplum MapReduce program, the order is kept.

```
# list sequence
- this
- is
- a list
- with
- five scalar values
# inline sequence
[this, is, a list, with, five scalar values]
```

A *mapping* is used to pair up data values with identifiers called *keys*. Mappings use a colon and space (`:`) for each *key: value* pair, or can also be specified inline as a comma-separated list within curly braces. The *key* is used as an index for retrieving data from a mapping.

```
# a mapping of items
title: War and Peace
author: Leo Tolstoy
date: 1865
# same mapping written inline
```

```
{title: War and Peace, author: Leo Tolstoy, date: 1865}
```

Keys are used to associate meta information with each node and specify the expected node type (*scalar*, *sequence* or *mapping*).

The Greenplum MapReduce program processes the nodes of a document in order and uses indentation (spaces) to determine the document hierarchy and the relationships of the nodes to one another. The use of white space is significant. White space should not be used simply for formatting purposes, and tabs should not be used at all.

Refer to [gpmmapreduce.yaml](#) for detailed information about the Greenplum MapReduce configuration file format and the keys and values supported.

Example Greenplum MapReduce Job

In this example, you create a MapReduce job that processes text documents and reports on the number of occurrences of certain keywords in each document. The documents and keywords are stored in separate Greenplum Database tables that you create as part of the exercise.

This example MapReduce job utilizes the untrusted `plpythonu` language; as such, you must run the job as a user with Greenplum Database administrative privileges.

1. Log in to the Greenplum Database master host as the `gpadmin` administrative user and set up your environment. For example:

```
$ ssh gpadmin@gpmaster>
gpadmin@gpmaster$ . /usr/local/greenplum-db/greenplum_path.sh
```

2. Create a new database for the MapReduce example: For example:

```
gpadmin@gpmaster$ createdb mapredex_db
```

3. Start the `psql` subsystem, connecting to the new database:

```
gpadmin@gpmaster$ psql -d mapredex_db
```

4. Register the PL/Python language in the database. For example:

```
mapredex_db=> CREATE EXTENSION plpythonu;
```

5. Create the `documents` table and add some data to the table. For example:

```
CREATE TABLE documents (doc_id int, url text, data text);
INSERT INTO documents VALUES (1, 'http://url/1', 'this is one document in the co
rpus');
INSERT INTO documents VALUES (2, 'http://url/2', 'i am the second document in th
e corpus');
INSERT INTO documents VALUES (3, 'http://url/3', 'being third never really bothe
red me until now');
INSERT INTO documents VALUES (4, 'http://url/4', 'the document before me is the
third document');
```

6. Create the `keywords` table and add some data to the table. For example:

```
CREATE TABLE keywords (keyword_id int, keyword text);
INSERT INTO keywords VALUES (1, 'the');
INSERT INTO keywords VALUES (2, 'document');
INSERT INTO keywords VALUES (3, 'me');
INSERT INTO keywords VALUES (4, 'being');
INSERT INTO keywords VALUES (5, 'now');
```

```
INSERT INTO keywords VALUES (6, 'corpus');
INSERT INTO keywords VALUES (7, 'is');
INSERT INTO keywords VALUES (8, 'third');
```

7. Construct the MapReduce YAML configuration file. For example, open a file named `mymrjob.yaml` in the editor of your choice and copy/paste the following large text block:

```
# This example MapReduce job processes documents and looks for keywords in them
.
# It takes two database tables as input:
# - documents (doc_id integer, url text, data text)
# - keywords (keyword_id integer, keyword text)#
# The documents data is searched for occurrences of keywords and returns result
s of
# url, data and keyword (a keyword can be multiple words, such as "high perform
ance # computing")
%YAML 1.1
---
VERSION: 1.0.0.2

# Connect to Greenplum Database using this database and role
DATABASE: mapredex_db
USER: gpadmin

# Begin definition section
DEFINE:

# Declare the input, which selects all columns and rows from the
# 'documents' and 'keywords' tables.

```

    for kw_p in kw_positions.split(','):
        kw_split[int(kw_p)-1] = doc_positions

    # This section takes each element in the 'kw_split' array and strings
    # them together placing a ':' in between each element from the array.
    # For example: for the keyword "computer software computer hardware",
    # the 'kw_split' array matched up to the document data of
    # "in the business of computer software software engineers"
    # would look like: ['5', '6,7', '5', '']
    # and the outstate would look like: 5:6,7:5:
    outstate = kw_split[0]
    for s in kw_split[1:]:
        outstate = outstate + ':' + s
    return outstate

- FINALIZE:
    NAME: term_finalizer
    LANGUAGE: python
    RETURNS:
        - count integer
    MODE: MULTI
    FUNCTION: |
        if not state:
            yield 0
        kw_split = state.split(':')

        # This function does the following:
        # 1) Splits 'kw_split' on ':'
        #    for example, 1,5,7:2,8 creates '1,5,7' and '2,8'
        # 2) For each group of positions in 'kw_split', splits the set on ','
        #    to create ['1','5','7'] from Set 0: 1,5,7 and
        #    eventually ['2', '8'] from Set 1: 2,8
        # 3) Checks for empty strings
        # 4) Adjusts the split sets by subtracting the position of the set
        #    in the 'kw_split' array
        #    ['1','5','7'] - 0 from each element = ['1','5','7']
        #    ['2', '8'] - 1 from each element = ['1', '7']
        # 5) Resulting arrays after subtracting the offset in step 4 are
        #    intersected and their overlapping values kept:
        #    ['1','5','7'].intersect(['1', '7']) = [1,7]
        # 6) Determines the length of the intersection, which is the number of
        #    times that an entire keyword (with all its pieces) matches in the
        #    document data.
        previous = None
        for i in range(0,len(kw_split)):
            isplit = kw_split[i].split(',')
            if any(map(lambda(x): x == '', isplit)):
                yield 0
            adjusted = set(map(lambda(x): int(x)-i, isplit))
            if (previous):
                previous = adjusted.intersection(previous)
            else:
                previous = adjusted

        # return the final count
        if previous:
            yield len(previous)

# Define the 'term_match' task which is then run as part
# of the 'final_output' query. It takes the INPUT 'term_join' defined
# earlier and uses the REDUCE function 'term_reducer' defined earlier
- TASK:
    NAME: term_match
    SOURCE: term_join
    REDUCE: term_reducer

```

```

- INPUT:
  NAME: final_output
  QUERY: |
    SELECT doc.*, kw.*, tm.count
    FROM documents doc, keywords kw, term_match tm
    WHERE doc.doc_id = tm.doc_id
      AND kw.keyword_id = tm.keyword_id
      AND tm.count > 0

# Execute this MapReduce job and send output to STDOUT
EXECUTE:
- RUN:
  SOURCE: final_output
  TARGET: STDOUT

```

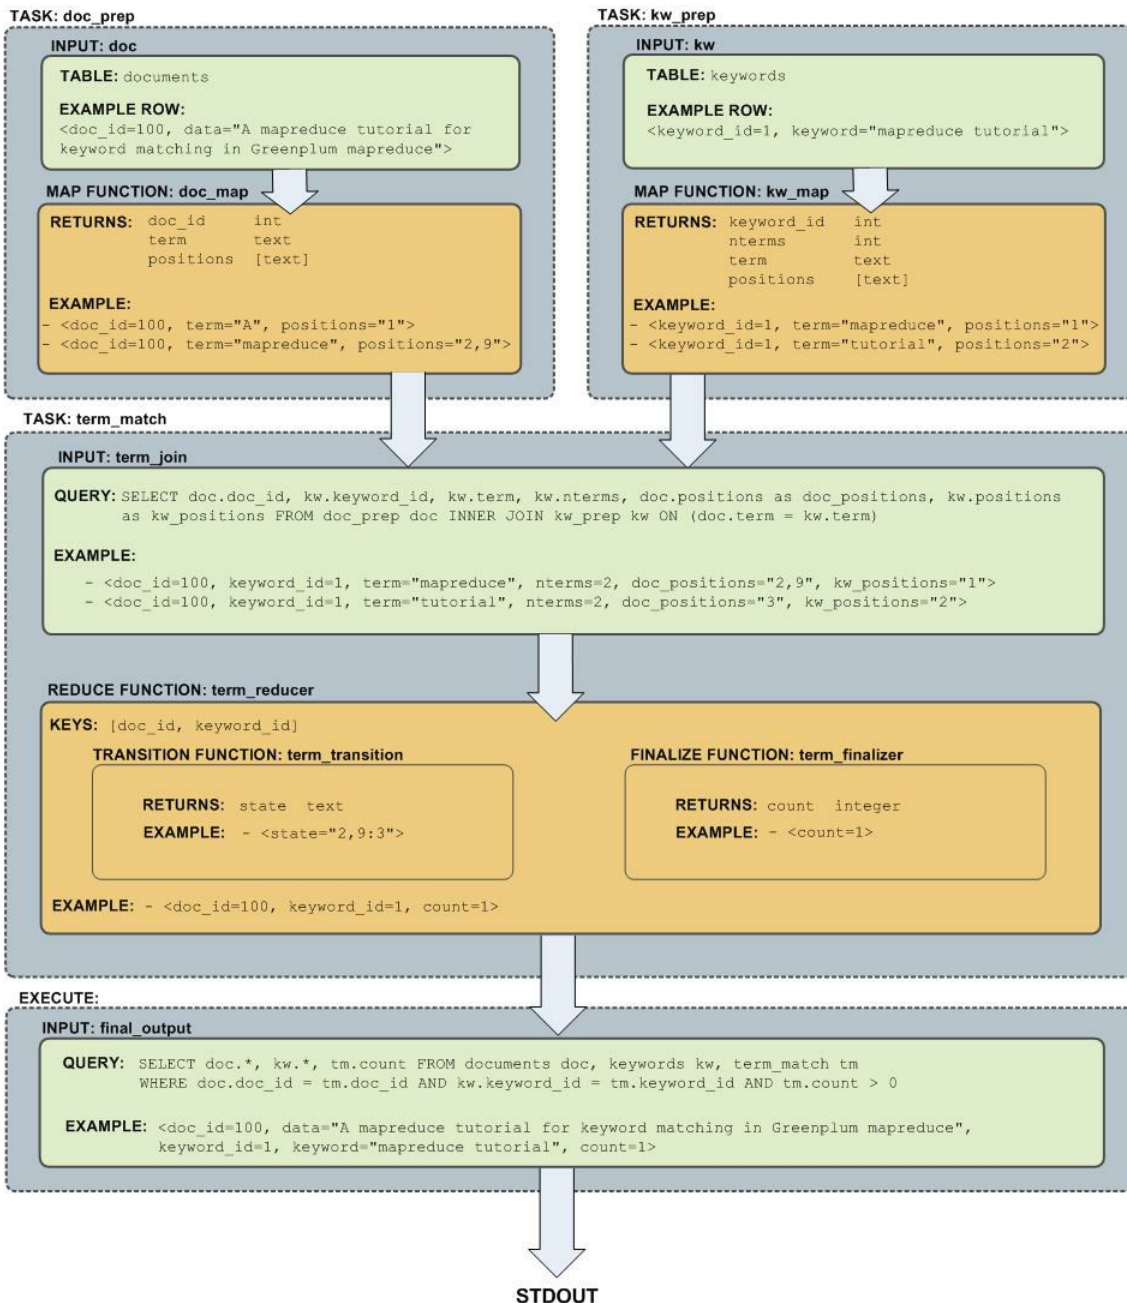

8. Save the file and exit the editor.
9. Run the MapReduce job. For example:

```
gpadmin@gpmaster$ gpmapreduce -f mymrjob.yaml
```

The job displays the number of occurrences of each keyword in each document to `stdout`.

Flow Diagram for MapReduce Example

The following diagram shows the job flow of the MapReduce job defined in the example:

Query Performance

Greenplum Database dynamically eliminates irrelevant partitions in a table and optimally allocates memory for different operators in a query. These enhancements scan less data for a query, accelerate query processing, and support more concurrency.

- Dynamic Partition Elimination

In Greenplum Database, values available only when a query runs are used to dynamically prune partitions, which improves query processing speed. Enable or disable dynamic partition elimination by setting the server configuration parameter `gp_dynamic_partition_pruning` to `ON` or `OFF`; it is `ON` by default.

- Memory Optimizations

Greenplum Database allocates memory optimally for different operators in a query and frees and re-allocates memory during the stages of processing a query.

Note: Greenplum Database uses GPORCA, the Greenplum next generation query optimizer, by default. GPORCA extends the planning and optimization capabilities of the Postgres optimizer. For information about the features and limitations of GPORCA, see [Overview of GPORCA](#).

Parent topic: [Querying Data](#)

Managing Spill Files Generated by Queries

Greenplum Database creates spill files, also known as workfiles, on disk if it does not have sufficient memory to run an SQL query in memory.

The maximum number of spill files for a given query is governed by the `gp_workfile_limit_files_per_query` server configuration parameter setting. The default value of 100,000 spill files is sufficient for the majority of queries.

If a query creates more than the configured number of spill files, Greenplum Database returns this error:

```
ERROR: number of workfiles per query limit exceeded
```

Greenplum Database may generate a large number of spill files when:

- Data skew is present in the queried data. To check for data skew, see [Checking for Data Distribution Skew](#).
- The amount of memory allocated for the query is too low. You control the maximum amount of memory that can be used by a query with the Greenplum Database server configuration parameters `max_statement_mem` and `statement_mem`, or through resource group or resource queue configuration.

You might be able to run the query successfully by changing the query, changing the data distribution, or changing the system memory configuration. The `gp_toolkit gp_workfile_*` views display spill file usage information. You can use this information to troubleshoot and tune queries. The `gp_workfile_*` views are described in [Checking Query Disk Spill Space Usage](#).

Additional documentation resources:

- [Memory Consumption Parameters](#) identifies the memory-related spill file server configuration parameters.
- [Using Resource Groups](#) describes memory and spill considerations when resource group-based resource management is active.
- [Using Resource Queues](#) describes memory and spill considerations when resource queue-based resource management is active.

Parent topic: [Querying Data](#)

Query Profiling

Examine the query plans of poorly performing queries to identify possible performance tuning opportunities.

Greenplum Database devises a *query plan* for each query. Choosing the right query plan to match the query and data structure is necessary for good performance. A query plan defines how Greenplum Database will run the query in the parallel execution environment.

The query optimizer uses data statistics maintained by the database to choose a query plan with the lowest possible cost. Cost is measured in disk I/O, shown as units of disk page fetches. The goal is to minimize the total execution cost for the plan.

View the plan for a given query with the `EXPLAIN` command. `EXPLAIN` shows the query optimizer's estimated cost for the query plan. For example:

```
EXPLAIN SELECT * FROM names WHERE id=22;
```

`EXPLAIN ANALYZE` runs the statement in addition to displaying its plan. This is useful for determining how close the optimizer's estimates are to reality. For example:

```
EXPLAIN ANALYZE SELECT * FROM names WHERE id=22;
```

Note: In Greenplum Database, the default GPORCA optimizer co-exists with the Postgres Planner. The `EXPLAIN` output generated by GPORCA is different than the output generated by the Postgres Planner.

By default, Greenplum Database uses GPORCA to generate an execution plan for a query when possible.

When the `EXPLAIN ANALYZE` command uses GPORCA, the `EXPLAIN` plan shows only the number of partitions that are being eliminated. The scanned partitions are not shown. To show name of the scanned partitions in the segment logs set the server configuration parameter `gp_log_dynamic_partition_pruning` to `on`. This example `SET` command enables the parameter.

```
SET gp_log_dynamic_partition_pruning = on;
```

For information about GPORCA, see [Querying Data](#).

Parent topic: [Querying Data](#)

Reading EXPLAIN Output

A query plan is a tree of nodes. Each node in the plan represents a single operation, such as a table scan, join, aggregation, or sort.

Read plans from the bottom to the top: each node feeds rows into the node directly above it. The bottom nodes of a plan are usually table scan operations: sequential, index, or bitmap index scans. If the query requires joins, aggregations, sorts, or other operations on the rows, there are additional nodes above the scan nodes to perform these operations. The topmost plan nodes are usually Greenplum Database motion nodes: redistribute, explicit redistribute, broadcast, or gather motions. These operations move rows between segment instances during query processing.

The output of `EXPLAIN` has one line for each node in the plan tree and shows the basic node type and the following execution cost estimates for that plan node:

- **cost** — Measured in units of disk page fetches. 1.0 equals one sequential disk page read. The first estimate is the start-up cost of getting the first row and the second is the total cost of cost of getting all rows. The total cost assumes all rows will be retrieved, which is not always true; for example, if the query uses `LIMIT`, not all rows are retrieved.

Note: The cost values generated by GPORCA and the Postgres Planner are not directly comparable. The two optimizers use different cost models, as well as different algorithms, to determine the cost of an execution plan. Nothing can or should be inferred by comparing cost values between the two optimizers.

In addition, the cost generated for any given optimizer is valid only for comparing plan alternatives for a given single query and set of statistics. Different queries can generate plans with different costs, even when keeping the optimizer a constant.

To summarize, the cost is essentially an internal number used by a given optimizer, and nothing should be inferred by examining only the cost value displayed in the `EXPLAIN` plans.

- **rows** —The total number of rows output by this plan node. This number is usually less than the number of rows processed or scanned by the plan node, reflecting the estimated selectivity of any `WHERE` clause conditions. Ideally, the estimate for the topmost node approximates the number of rows that the query actually returns, updates, or deletes.
- **width** —The total bytes of all the rows that this plan node outputs.

Note the following:

- The cost of a node includes the cost of its child nodes. The topmost plan node has the estimated total execution cost for the plan. This is the number the optimizer intends to minimize.
- The cost reflects only the aspects of plan execution that the query optimizer takes into consideration. For example, the cost does not reflect time spent transmitting result rows to the client.

EXPLAIN Example

The following example describes how to read an `EXPLAIN` query plan for a query:

```
EXPLAIN SELECT * FROM names WHERE name = 'Joelle';
               QUERY PLAN
-----
Gather Motion 2:1 (slice1) (cost=0.00..20.88 rows=1 width=13)

  -> Seq Scan on 'names' (cost=0.00..20.88 rows=1 width=13)
       Filter: name::text ~~ 'Joelle'::text
```

Read the plan from the bottom to the top. To start, the query optimizer sequentially scans the `names` table. Notice the `WHERE` clause is applied as a *filter* condition. This means the scan operation checks the condition for each row it scans and outputs only the rows that satisfy the condition.

The results of the scan operation are passed to a *gather motion* operation. In Greenplum Database, a gather motion is when segments send rows to the master. In this example, we have two segment instances that send to one master instance. This operation is working on `slice1` of the parallel query execution plan. A query plan is divided into *slices* so the segments can work on portions of the query plan in parallel.

The estimated startup cost for this plan is `00.00` (no cost) and a total cost of `20.88` disk page fetches. The optimizer estimates this query will return one row.

Reading EXPLAIN ANALYZE Output

`EXPLAIN ANALYZE` plans and runs the statement. The `EXPLAIN ANALYZE` plan shows the actual execution cost along with the optimizer's estimates. This allows you to see if the optimizer's estimates are close to reality. `EXPLAIN ANALYZE` also shows the following:

- The total runtime (in milliseconds) in which the query ran.
- The memory used by each slice of the query plan, as well as the memory reserved for the whole query statement.
- The number of *workers* (segments) involved in a plan node operation. Only segments that return rows are counted.
- The maximum number of rows returned by the segment that produced the most rows for the

operation. If multiple segments produce an equal number of rows, **EXPLAIN ANALYZE** shows the segment with the longest *<time> to end*.

- The segment id of the segment that produced the most rows for an operation.
- For relevant operations, the amount of memory (**work_mem**) used by the operation. If the **work_mem** was insufficient to perform the operation in memory, the plan shows the amount of data spilled to disk for the lowest-performing segment. For example:

```
Work_mem used: 64K bytes avg, 64K bytes max (seg0).
Work_mem wanted: 90K bytes avg, 90K bytes max (seg0) to lessen
workfile I/O affecting 2 workers.
```

- The time (in milliseconds) in which the segment that produced the most rows retrieved the first row, and the time taken for that segment to retrieve all rows. The result may omit *<time> to first row* if it is the same as the *<time> to end*.

EXPLAIN ANALYZE Examples

This example describes how to read an **EXPLAIN ANALYZE** query plan using the same query. The **bold** parts of the plan show actual timing and rows returned for each plan node, as well as memory and time statistics for the whole query.

```
EXPLAIN ANALYZE SELECT * FROM names WHERE name = 'Joelle';
               QUERY PLAN
-----
Gather Motion 2:1 (slice1; segments: 2) (cost=0.00..20.88 rows=1 width=13)
  Rows out: 1 rows at destination with 0.305 ms to first row, 0.537 ms to end, start
  offset by 0.289 ms.
    -> Seq Scan on names (cost=0.00..20.88 rows=1 width=13)
      Rows out: Avg 1 rows x 2 workers. Max 1 rows (seg0) with 0.255 ms to first
      row, 0.486 ms to end, start offset by 0.968 ms.
        Filter: name = 'Joelle'::text
      Slice statistics:

        (slice0) Executor memory: 135K bytes.

        (slice1) Executor memory: 151K bytes avg x 2 workers, 151K bytes max (seg0).

Statement statistics:
Memory used: 128000K bytes
Total runtime: 22.548 ms
```

Read the plan from the bottom to the top. The total elapsed time to run this query was **22.548** milliseconds.

The *sequential scan* operation had only one segment (*seg0*) that returned rows, and it returned just **1 row**. It took **0.255** milliseconds to find the first row and **0.486** to scan all rows. This result is close to the optimizer's estimate: the query optimizer estimated it would return one row for this query. The *gather motion* (segments sending data to the master) received 1 row. The total elapsed time for this operation was **0.537** milliseconds.

Determining the Query Optimizer

You can view EXPLAIN output to determine if GPORCA is enabled for the query plan and whether GPORCA or the Postgres Planner generated the explain plan. The information appears at the end of the EXPLAIN output. The **Settings** line displays the setting of the server configuration parameter **OPTIMIZER**. The **Optimizer status** line displays whether GPORCA or the Postgres Planner generated

the explain plan.

For these two example query plans, GPORCA is enabled, the server configuration parameter `OPTIMIZER` is `on`. For the first plan, GPORCA generated the EXPLAIN plan. For the second plan, Greenplum Database fell back to the Postgres Planner to generate the query plan.

```

QUERY PLAN
-----
Aggregate  (cost=0.00..296.14 rows=1 width=8)
->  Gather Motion 2:1  (slicel1; segments: 2)  (cost=0.00..295.10 rows=1 width=8)
    ->  Aggregate  (cost=0.00..294.10 rows=1 width=8)
        ->  Seq Scan on part  (cost=0.00..97.69 rows=100040 width=1)
Settings:  optimizer=on
Optimizer status: Pivotal Optimizer (GPORCA) version 1.584
(5 rows)

```

```
explain select count(*) from part;
```

```

QUERY PLAN
-----
--
Aggregate  (cost=3519.05..3519.06 rows=1 width=8)
->  Gather Motion 2:1  (slicel1; segments: 2)  (cost=3518.99..3519.03 rows=1 width=8)
    ->  Aggregate  (cost=3518.99..3519.00 rows=1 width=8)
        ->  Seq Scan on part  (cost=0.00..3018.79 rows=100040 width=1)
Settings:  optimizer=on
Optimizer status: Postgres query optimizer
(5 rows)

```

For this query, the server configuration parameter `OPTIMIZER` is `off`.

```
explain select count(*) from part;
```

```

QUERY PLAN
-----
--
Aggregate  (cost=3519.05..3519.06 rows=1 width=8)
->  Gather Motion 2:1  (slicel1; segments: 2)  (cost=3518.99..3519.03 rows=1 width=8)
    ->  Aggregate  (cost=3518.99..3519.00 rows=1 width=8)
        ->  Seq Scan on part  (cost=0.00..3018.79 rows=100040 width=1)
Settings: optimizer=off
Optimizer status: Postgres query optimizer
(5 rows)

```

Examining Query Plans to Solve Problems

If a query performs poorly, examine its query plan and ask the following questions:

- **Do operations in the plan take an exceptionally long time?** Look for an operation consumes the majority of query processing time. For example, if an index scan takes longer than expected, the index could be out-of-date and need to be reindexed. Or, adjust `enable_<operator>` parameters to see if you can force the Postgres Planner to choose a different plan by disabling a particular query plan operator for that query.
- **Does the query planning time exceed query execution time?** When the query involves many table joins, the Postgres Planner uses a dynamic algorithm to plan the query that is in part based on the number of table joins. You can reduce the amount of time that the Postgres Planner spends planning the query by setting the `join_collapse_limit` and

`from_collapse_limit` server configuration parameters to a smaller value, such as 8. Note that while smaller values reduce planning time, they may also yield inferior query plans.

- **Are the optimizer's estimates close to reality?** Run `EXPLAIN ANALYZE` and see if the number of rows the optimizer estimates is close to the number of rows the query operation actually returns. If there is a large discrepancy, collect more statistics on the relevant columns.

See the *Greenplum Database Reference Guide* for more information on the `EXPLAIN ANALYZE` and `ANALYZE` commands.

- **Are selective predicates applied early in the plan?** Apply the most selective filters early in the plan so fewer rows move up the plan tree. If the query plan does not correctly estimate query predicate selectivity, collect more statistics on the relevant columns. See the `ANALYZE` command in the *Greenplum Database Reference Guide* for more information collecting statistics. You can also try reordering the `WHERE` clause of your SQL statement.
- **Does the optimizer choose the best join order?** When you have a query that joins multiple tables, make sure that the optimizer chooses the most selective join order. Joins that eliminate the largest number of rows should be done earlier in the plan so fewer rows move up the plan tree.

If the plan is not choosing the optimal join order, set `join_collapse_limit=1` and use explicit `JOIN` syntax in your SQL statement to force the Postgres Planner to the specified join order. You can also collect more statistics on the relevant join columns.

See the `ANALYZE` command in the *Greenplum Database Reference Guide* for more information collecting statistics.

- **Does the optimizer selectively scan partitioned tables?** If you use table partitioning, is the optimizer selectively scanning only the child tables required to satisfy the query predicates? Scans of the parent tables should return 0 rows since the parent tables do not contain any data. See [Verifying Your Partition Strategy](#) for an example of a query plan that shows a selective partition scan.
- **Does the optimizer choose hash aggregate and hash join operations where applicable?** Hash operations are typically much faster than other types of joins or aggregations. Row comparison and sorting is done in memory rather than reading/writing from disk. To enable the query optimizer to choose hash operations, there must be sufficient memory available to hold the estimated number of rows. Try increasing work memory to improve performance for a query. If possible, run an `EXPLAIN ANALYZE` for the query to show which plan operations spilled to disk, how much work memory they used, and how much memory was required to avoid spilling to disk. For example:

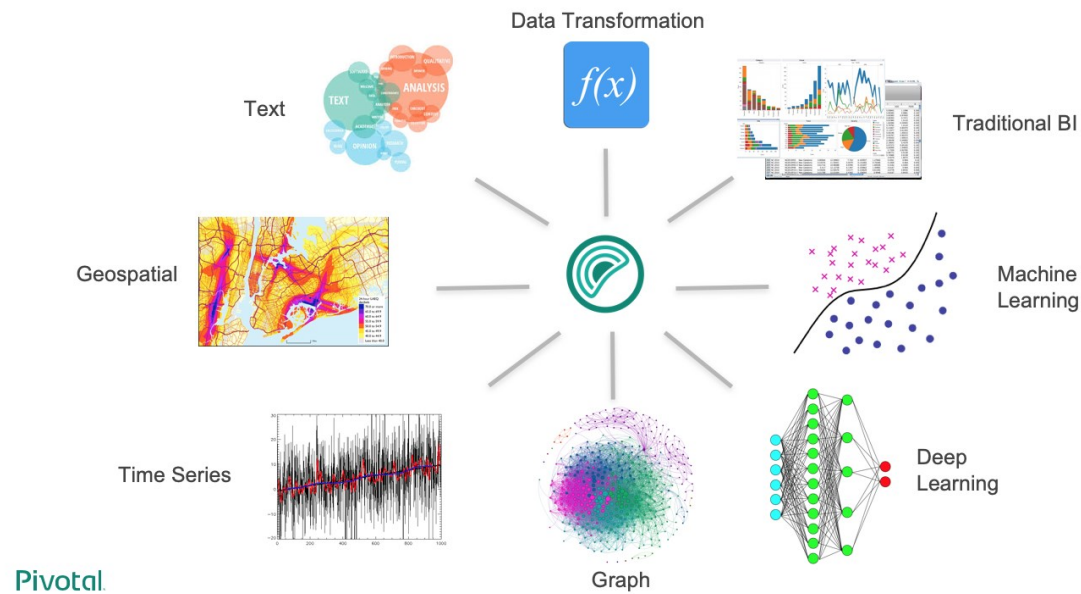

```
Work_mem used: 23430K bytes avg, 23430K bytes max (seg0). Work_mem wanted: 33649K
bytes avg, 33649K bytes max (seg0) to lessen workfile I/O affecting 2 workers.
```

The “bytes wanted” message from `EXPLAIN ANALYZE` is based on the amount of data written to work files and is not exact. The minimum `work_mem` needed can differ from the suggested value.

Overview of Greenplum Database Integrated Analytics

Greenplum offers a unique combination of a powerful, massively parallel processing (MPP) database and advanced data analytics. This combination creates an ideal framework for data scientists, data architects and business decision makers to explore artificial intelligence (AI), machine learning, deep learning, text analytics, and geospatial analytics.

The Greenplum Database Integrated Analytics Ecosystem

The following Greenplum Database analytics extensions are explored in different documentation sections, with installation and usage instructions:

Machine Learning and Deep Learning

The [Apache MADlib extension](#) allows Greenplum Database users to run different machine learning and deep learning functions, including feature engineering, model training, evaluation and scoring.

Geospatial Analytics

[PostGIS](#) is a spatial database extension for PostgreSQL that allows GIS (Geographic Information Systems) objects to be stored in the database. The Greenplum Database PostGIS extension includes support for GiST-based R-Tree spatial indexes and functions for analysis and processing of GIS objects.

Text Analytics

[Text Analytics and Search](#) enables processing of mass quantities of raw text data (such as social media feeds or e-mail databases) into mission-critical information that guides project and business decisions. Tanzu Greenplum Text joins the Greenplum Database massively parallel-processing database server with Apache SolrCloud enterprise search. Tanzu Greenplum Text includes powerful text search as well as support for text analysis.

Programming Language Extensions

Greenplum database supports a variety of procedural languages that you can use for programming database analytics. Refer to the linked documentation for installation and usage instructions.

- [PL/Container](#)
- [PL/Java](#)
- [PL/Perl](#)
- [PL/pgSQL](#)
- [PL/Python](#)
- [PL/R](#)

Why Greenplum Database in Integrated Analytics

The importance of advanced analytics in its various forms is growing rapidly in enterprise computing. Key enterprise data typically resides in relational and document form and it is inefficient to copy data between systems to perform analytical operations. Greenplum is able to run both traditional and advanced analytics workloads in-database. This integrated capability greatly reduces the cost and the silos created by procuring and maintaining multiple tools and libraries.

Greenplum Database advanced analytics can be used to address a wide variety of problems in many verticals including automotive, finance, manufacturing, energy, government, education, telecommunications, on-line and traditional retail.

The Greenplum analytics capabilities allow you to:

- Analyze a multitude of data types – structured, text, geospatial, and graph – in a single environment, which can scale to petabytes and run algorithms designed for parallelism.
- Leverage existing SQL knowledge: Tanzu Greenplum can run dozens of statistical, machine learning, and graph methods, via SQL.
- Train more models in less time by taking advantage of the parallelism in the MPP architecture and in-database analytics.
- Access the data where it lives, therefore integrate data and analytics in one place. Tanzu Greenplum is infrastructure-agnostic and runs on bare metal, private cloud, and public cloud deployments.
- Use a multitude of data extensions. Greenplum supports Apache [Kafka integration](#), extensions for HDFS, Hive, and HBase as well as reading/writing data from/to cloud storage, including Amazon S3 objects. Review the capabilities of the Greenplum [Platform Extension Framework \(PXF\)](#), which provides *connectors* that enable you to access data stored in sources external to your Greenplum Database deployment.
- Use familiar and leading BI and advanced analytics software that are ODBC/JDBC compatible, or have native integrations, including SAS, IBM Cognos, SAP Analytics Solutions, Qlik, Tableau, Apache Zeppelin, and Jupyter.
- Run deep learning algorithms using popular frameworks like Keras and TensorFlow in an MPP relational database, with GPU (Graphical Processing Unit) acceleration.
- Use containers capable of isolating executors from the host OS. Greenplum PL/Container implements a trusted language execution engine which permits customized data science workloads or environments created for different end user workloads.
- Use procedural languages to customize your analytics. Tanzu Greenplum supports development in R, Python, Java, and other standard languages allowing you to distribute execution across the entire cluster to take advantage of the scale and parallelism.

Machine Learning and Deep Learning using MADlib

Apache MADlib is an open-source library for scalable in-database analytics. The Greenplum MADlib extension provides the ability to run machine learning and deep learning workloads in a Greenplum Database.

This chapter includes the following information:

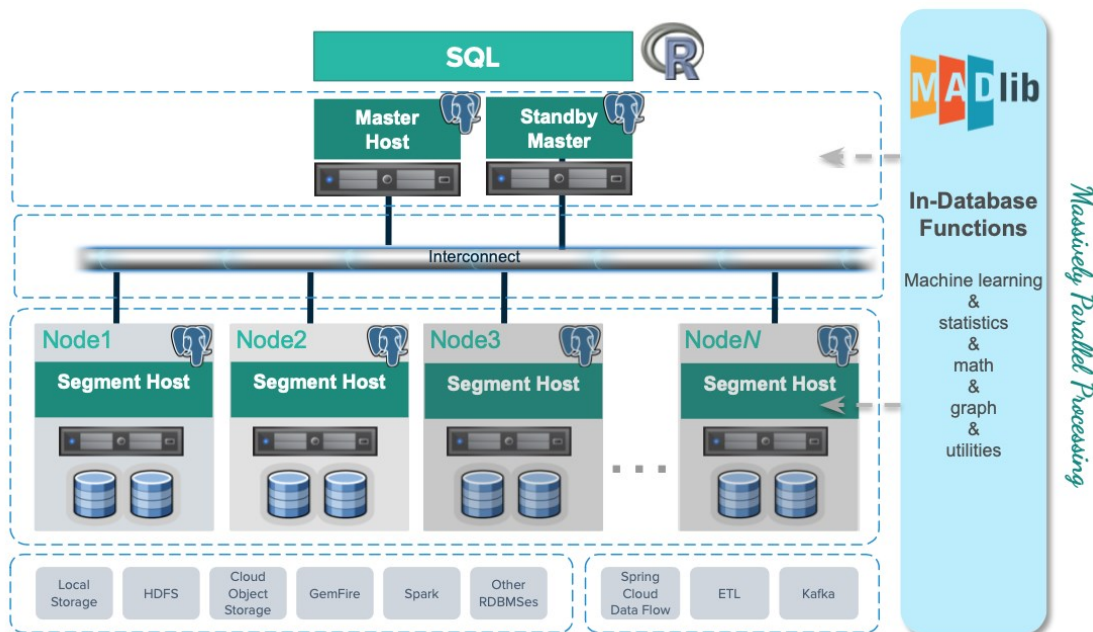

- [Installing MADlib](#)
- [Upgrading MADlib](#)
- [Uninstalling MADlib](#)

- [Examples](#)
- [References](#)

You can install it as an extension in a Greenplum Database system you can run data-parallel implementations of mathematical, statistical, graph, machine learning, and deep learning methods on structured and unstructured data. For Greenplum and MADlib version compatibility, refer to [MADlib FAQ](#).

MADlib's suite of SQL-based algorithms run at scale within a single Greenplum Database engine without needing to transfer data between the database and other tools.

MADlib is part of the database fabric with no changes to the Greenplum architecture. This makes it easy for database administrators to deploy and manage since it is not a separate daemon or separate software running outside the database.

Machine Learning

Apache MADlib consists of methods to support the full spectrum of data science activities. This includes data transformation and feature engineering, using methods in descriptive and inferential statistics, pivoting, sessionization and encoding categorical variables. There is also a comprehensive library of graph, supervised learning and unsupervised learning methods.

In the area of model selection, MADlib supports cross validation and the most common prediction metrics for evaluating the quality of predictions of a model. Please refer to the [MADlib user guide](#) for more information on these methods.

Deep Learning

Starting in Apache MADlib release 1.16, Greenplum Database supports using Keras and TensorFlow for deep learning. You can review the [supported libraries and configuration instructions](#) on the Apache MADlib pages as well as user documentation for [Keras API](#) using the Tensorflow backend. Note that it is not supported with RHEL 6.

MADlib supports Keras with a TensorFlow backend, with or without Graphics Processing Units (GPUs). GPUs can significantly accelerate the training of deep neural networks so they are typically used for enterprise level workloads. For further GPU information, visit the MADlib wiki,

<https://cwiki.apache.org/confluence/display/MADLIB/Deep+Learning>.

PivotalR

MADlib can be used with PivotalR, an R client package that enables users to interact with data resident in the Greenplum Database. PivotalR can be considered as a wrapper around MADlib that translates R code into SQL to run on MPP databases and is designed for users familiar with R but with data sets that are too large for R.

The R language is an open-source language that is used for statistical computing. PivotalR is an R package that enables users to interact with data resident in Greenplum Database using the R client. Using PivotalR requires that MADlib is installed on the Greenplum Database.

PivotalR allows R users to leverage the scalability and performance of in-database analytics without leaving the R command line. The computational work is run in-database, while the end user benefits from the familiar R interface. Compared with respective native R functions, there is an increase in scalability and a decrease in running time. Furthermore, data movement, which can take hours for very large data sets, is eliminated with PivotalR.

Key features of the PivotalR package:

- Explore and manipulate data in the database with R syntax. SQL translation is performed by PivotalR.
- Use the familiar R syntax for predictive analytics algorithms, for example linear and logistic regression. PivotalR accesses the MADlib in-database analytics function calls.
- Comprehensive documentation package with examples in standard R format accessible from an R client.
- The PivotalR package also supports access to the MADlib functionality.

For information about PivotalR, including supported MADlib functionality, see <https://cwiki.apache.org/confluence/display/MADLIB/PivotalR>.

The R package for PivotalR can be found at <https://cran.r-project.org/web/packages/PivotalR/index.html>.

Installing MADlib

Note: MADlib requires the `m4` macro processor version 1.4.13 or later.

To install MADlib on Greenplum Database, you first install a compatible Greenplum MADlib package and then install the MADlib function libraries on all databases that will use MADlib.

The `gppkg` utility installs Greenplum Database extensions, along with any dependencies, on all hosts across a cluster. It also automatically installs extensions on new hosts in the case of system expansion segment recovery.

If you have GPUs installed on some or across all hosts in the cluster, then the segments residing on those hosts can benefit from GPU acceleration. GPUs and deep learning libraries such as Keras, TensorFlow, cudNN, and CUDA are managed separately from MADlib. For more information see the [MADlib wiki instructions for deep learning](#) and the [MADlib user documentation for deep learning](#).

Installing the Greenplum Database MADlib Package

Before you install the MADlib package, make sure that your Greenplum database is running, you have sourced `greenplum_path.sh`, and that the `$MASTER_DATA_DIRECTORY` and `$GPHOME` variables are set.

1. Download the MADlib extension package from [VMware Tanzu Network](#).

2. Copy the MADlib package to the Greenplum Database master host.
3. Follow the instructions in [Verifying the Greenplum Database Software Download](#) to verify the integrity of the **Greenplum Advanced Analytics MADlib** software.
4. Unpack the MADlib distribution package. For example:

```
$ tar xzvf madlib-1.18.0+2-gp6-rhel7-x86_64.tar.gz
```

5. Install the software package by running the `gppkg` command. For example:

```
$ gppkg -i ./madlib-1.18.0+2-gp6-rhel7-x86_64/madlib-1.18.0+2-gp6-rhel7-x86_64.gppkg
```

Adding MADlib Functions to a Database

After installing the MADlib package, run the `madpack` command to add MADlib functions to Greenplum Database. `madpack` is in `$GPHOME/madlib/bin`.

```
$ madpack [-s <schema_name>] -p greenplum -c <user>@<host>:<port>/<database> install
```

For example, this command creates MADlib functions in the Greenplum database `testdb` running on server `mdw` on port `5432`. The `madpack` command logs in as the user `gpadmin` and prompts for password. The target schema is `madlib`.

```
$ madpack -s madlib -p greenplum -c gpadmin@mdw:5432/testdb install
```

After installing the functions, The Greenplum Database `gpadmin` superuser role should grant all privileges on the target schema (in the example `madlib`) to users who will be accessing MADlib functions. Users without access to the functions will get the error `ERROR: permission denied for schema MADlib`.

The `madpack install-check` option runs test using Madlib modules to check the MADlib installation:

```
$ madpack -s madlib -p greenplum -c gpadmin@mdw:5432/testdb install-check
```

Note: The command `madpack -h` displays information for the utility.

Upgrading MADlib

You upgrade an installed MADlib package with the Greenplum Database `gppkg` utility and the MADlib `madpack` command.

For information about the upgrade paths that MADlib supports, see the MADlib support and upgrade matrix in the [MADlib FAQ page](#).

Upgrading a MADlib Package

To upgrade MADlib, run the `gppkg` utility with the `-u` option. This command upgrades an installed MADlib package to MADlib 1.18.0+2.

```
$ gppkg -u madlib-1.18.0+2-gp6-rhel7-x86_64.gppkg
```

Upgrading MADlib Functions

After you upgrade the MADlib package from one major version to another, run `madpack upgrade` to

upgrade the MADlib functions in a database schema.

Note: Use `madpack upgrade` only if you upgraded a major MADlib package version, for example from 1.15 to 1.18.0. You do not need to update the functions within a patch version upgrade, for example from 1.16+1 to 1.16+3.

This example command upgrades the MADlib functions in the schema `madlib` of the Greenplum Database `test`.

```
madpack -s madlib -p greenplum -c gpadmin@mdw:5432/testdb upgrade
```

Uninstalling MADlib

- [Remove MADlib objects from the database](#)
- [Uninstall the Greenplum Database MADlib Package](#)

When you remove MADlib support from a database, routines that you created in the database that use MADlib functionality will no longer work.

Remove MADlib objects from the database

Use the `madpack uninstall` command to remove MADlib objects from a Greenplum database. For example, this command removes MADlib objects from the database `testdb`.

```
$ madpack -s madlib -p greenplum -c gpadmin@mdw:5432/testdb uninstall
```

Uninstall the Greenplum Database MADlib Package

If no databases use the MADlib functions, use the Greenplum `gppkg` utility with the `-r` option to uninstall the MADlib package. When removing the package you must specify the package and version. This example uninstalls MADlib package version 1.18.

```
$ gppkg -r madlib-1.18.0+2-gp5-rhel7-x86_64
```

You can run the `gppkg` utility with the options `-q --all` to list the installed extensions and their versions.

After you uninstall the package, restart the database.

```
$ gpstop -r
```

Examples

Following are examples using the Greenplum MADlib extension:

- [Linear Regression](#)
- [Association Rules](#)
- [Naive Bayes Classification](#)

See the MADlib documentation for additional examples.

Linear Regression

This example runs a linear regression on the table `regr_example`. The dependent variable data are in the `y` column and the independent variable data are in the `x1` and `x2` columns.

The following statements create the `regr_example` table and load some sample data:

```
DROP TABLE IF EXISTS regr_example;
CREATE TABLE regr_example (
  id int,
  y int,
  x1 int,
  x2 int
);
INSERT INTO regr_example VALUES
  (1, 5, 2, 3),
  (2, 10, 7, 2),
  (3, 6, 4, 1),
  (4, 8, 3, 4);
```

The MADlib `linregr_train()` function produces a regression model from an input table containing training data. The following `SELECT` statement runs a simple multivariate regression on the `regr_example` table and saves the model in the `regr_example_model` table.

```
SELECT madlib.linregr_train (
  'regr_example',          -- source table
  'regr_example_model',    -- output model table
  'y',                     -- dependent variable
  'ARRAY[1, x1, x2]'       -- independent variables
);
```

The `madlib.linregr_train()` function can have additional arguments to set grouping columns and to calculate the heteroskedasticity of the model.

Note: The intercept is computed by setting one of the independent variables to a constant 1, as shown in the preceding example.

Running this query against the `regr_example` table creates the `regr_example_model` table with one row of data:

```
SELECT * FROM regr_example_model;
-[ RECORD 1 ]-----+-----
coef                | {0.111111111111127,1.14814814814815,1.01851851851852}
r2                  | 0.968612680477111
std_err             | {1.49587911309236,0.207043331249903,0.346449758034495}
t_stats             | {0.0742781352708591,5.54544858420156,2.93987366103776}
p_values            | {0.952799748147436,0.113579771006374,0.208730790695278}
condition_no        | 22.650203241881
num_rows_processed  | 4
num_missing_rows_skipped | 0
variance_covariance | {{2.23765432098598,-0.257201646090342,-0.437242798353582},
                        {-0.257201646090342,0.042866941015057,0.0342935528120456},
                        {-0.437242798353582,0.0342935528120457,0.12002743484216}}
```

The model saved in the `regr_example_model` table can be used with the MADlib linear regression prediction function, `madlib.linregr_predict()`, to view the residuals:

```
SELECT regr_example.*,
  madlib.linregr_predict ( ARRAY[1, x1, x2], m.coef ) as predict,
  y - madlib.linregr_predict ( ARRAY[1, x1, x2], m.coef ) as residual
FROM regr_example, regr_example_model m;
 id | y | x1 | x2 | predict | residual
-----+-----
  1 | 5 | 2 | 3 | 5.46296296296297 | -0.462962962962971
  3 | 6 | 4 | 1 | 5.72222222222224 | 0.277777777777762
  2 | 10 | 7 | 2 | 10.1851851851852 | -0.185185185185201
```

```
4 | 8 | 3 | 4 | 7.62962962962964 | 0.370370370370364
(4 rows)
```

Association Rules

This example demonstrates the association rules data mining technique on a transactional data set. Association rule mining is a technique for discovering relationships between variables in a large data set. This example considers items in a store that are commonly purchased together. In addition to market basket analysis, association rules are also used in bioinformatics, web analytics, and other fields.

The example analyzes purchase information for seven transactions that are stored in a table with the MADlib function `MADlib.assoc_rules`. The function assumes that the data is stored in two columns with a single item and transaction ID per row. Transactions with multiple items consist of multiple rows with one row per item.

These commands create the table.

```
DROP TABLE IF EXISTS test_data;
CREATE TABLE test_data (
    trans_id INT,
    product text
);
```

This `INSERT` command adds the data to the table.

```
INSERT INTO test_data VALUES
(1, 'beer'),
(1, 'diapers'),
(1, 'chips'),
(2, 'beer'),
(2, 'diapers'),
(3, 'beer'),
(3, 'diapers'),
(4, 'beer'),
(4, 'chips'),
(5, 'beer'),
(6, 'beer'),
(6, 'diapers'),
(6, 'chips'),
(7, 'beer'),
(7, 'diapers');
```

The MADlib function `madlib.assoc_rules()` analyzes the data and determines association rules with the following characteristics.

- A support value of at least .40. Support is the ratio of transactions that contain X to all transactions.
- A confidence value of at least .75. Confidence is the ratio of transactions that contain X to transactions that contain Y. One could view this metric as the conditional probability of X given Y.

This `SELECT` command determines association rules, creates the table `assoc_rules`, and adds the statistics to the table.

```
SELECT * FROM madlib.assoc_rules (
    .40,          -- support
    .75,          -- confidence
    'trans_id',   -- transaction column
    'product',    -- product purchased column
```

```
'test_data', -- table name
'public',    -- schema name
false);      -- display processing details
```

This is the output of the `SELECT` command. There are two rules that fit the characteristics.

```
output_schema | output_table | total_rules | total_time
-----+-----+-----+-----
public        | assoc_rules   |          2 | 00:00:01.153283
(1 row)
```

To view the association rules, you can run this `SELECT` command.

```
SELECT pre, post, support FROM assoc_rules
ORDER BY support DESC;
```

This is the output. The `pre` and `post` columns are the itemsets of left and right hand sides of the association rule respectively.

```
pre      | post  | support
-----+-----+-----
{diapers} | {beer} | 0.714285714285714
{chips}   | {beer} | 0.428571428571429
(2 rows)
```

Based on the data, beer and diapers are often purchased together. To increase sales, you might consider placing beer and diapers closer together on the shelves.

Naive Bayes Classification

Naive Bayes analysis predicts the likelihood of an outcome of a class variable, or category, based on one or more independent variables, or attributes. The class variable is a non-numeric categorical variable, a variable that can have one of a limited number of values or categories. The class variable is represented with integers, each integer representing a category. For example, if the category can be one of “true”, “false”, or “unknown,” the values can be represented with the integers 1, 2, or 3.

The attributes can be of numeric types and non-numeric, categorical, types. The training function has two signatures – one for the case where all attributes are numeric and another for mixed numeric and categorical types. Additional arguments for the latter identify the attributes that should be handled as numeric values. The attributes are submitted to the training function in an array.

The MADlib Naive Bayes training functions produce a features probabilities table and a class priors table, which can be used with the prediction function to provide the probability of a class for the set of attributes.

Naive Bayes Example 1 - Simple All-numeric Attributes

In the first example, the `class` variable is either 1 or 2 and there are three integer attributes.

1. The following commands create the input table and load sample data.

```
DROP TABLE IF EXISTS class_example CASCADE;
CREATE TABLE class_example (
  id int, class int, attributes int[]);
INSERT INTO class_example VALUES
  (1, 1, '{1, 2, 3}'),
  (2, 1, '{1, 4, 3}'),
  (3, 2, '{0, 2, 2}'),
  (4, 1, '{1, 2, 1}'),
```

```
(5, 2, '{1, 2, 2}'),
(6, 2, '{0, 1, 3}');
```

Actual data in production scenarios is more extensive than this example data and yields better results. Accuracy of classification improves significantly with larger training data sets.

2. Train the model with the `create_nb_prepared_data_tables()` function.

```
SELECT * FROM madlib.create_nb_prepared_data_tables (
  'class_example',      -- name of the training table
  'class',              -- name of the class (dependent) column
  'attributes',         -- name of the attributes column
  3,                   -- the number of attributes
  'example_feature_probs', -- name for the feature probabilities output table
  'example_priors'      -- name for the class priors output table
);
```

3. Create a table with data to classify using the model.

```
DROP TABLE IF EXISTS class_example_topredict;
CREATE TABLE class_example_topredict (
  id int, attributes int[]);
INSERT INTO class_example_topredict VALUES
  (1, '{1, 3, 2}'),
  (2, '{4, 2, 2}'),
  (3, '{2, 1, 1}');
```

4. Create a classification view using the feature probabilities, class priors, and `class_example_topredict` tables.

```
SELECT madlib.create_nb_probs_view (
  'example_feature_probs', -- feature probabilities output table
  'example_priors',        -- class priors output table
  'class_example_topredict', -- table with data to classify
  'id',                    -- name of the key column
  'attributes',            -- name of the attributes column
  3,                      -- number of attributes
  'example_classified'     -- name of the view to create
);
```

5. Display the classification results.

```
SELECT * FROM example_classified;
 key | class | nb_prob
-----+-----+-----
  1 |    1 |    0.4
  1 |    2 |    0.6
  3 |    1 |    0.5
  3 |    2 |    0.5
  2 |    1 |    0.25
  2 |    2 |    0.75
(6 rows)
```

Naive Bayes Example 2 – Weather and Outdoor Sports

This example calculates the probability that the user will play an outdoor sport, such as golf or tennis, based on weather conditions.

The table `weather_example` contains the example values.

The identification column for the table is `day`, an integer type.

The `play` column holds the dependent variable and has two classifications:

- 0 - No
- 1 - Yes

There are four attributes: outlook, temperature, humidity, and wind. These are categorical variables. The MADlib `create_nb_classify_view()` function expects the attributes to be provided as an array of `INTEGER`, `NUMERIC`, or `FLOAT8` values, so the attributes for this example are encoded with integers as follows:

- *outlook* may be sunny (1), overcast (2), or rain (3).
- *temperature* may be hot (1), mild (2), or cool (3).
- *humidity* may be high (1) or normal (2).
- *wind* may be strong (1) or weak (2).

The following table shows the training data, before encoding the variables.

day	play	outlook	temperature	humidity	wind
2	No	Sunny	Hot	High	Strong
4	Yes	Rain	Mild	High	Weak
6	No	Rain	Cool	Normal	Strong
8	No	Sunny	Mild	High	Weak
10	Yes	Rain	Mild	Normal	Weak
12	Yes	Overcast	Mild	High	Strong
14	No	Rain	Mild	High	Strong
1	No	Sunny	Hot	High	Weak
3	Yes	Overcast	Hot	High	Weak
5	Yes	Rain	Cool	Normal	Weak
7	Yes	Overcast	Cool	Normal	Strong
9	Yes	Sunny	Cool	Normal	Weak
11	Yes	Sunny	Mild	Normal	Strong
13	Yes	Overcast	Hot	Normal	Weak

(14 rows)

1. Create the training table.

```
DROP TABLE IF EXISTS weather_example;
CREATE TABLE weather_example (
    day int,
    play int,
    attrs int[]
);
INSERT INTO weather_example VALUES
    ( 2, 0, '{1,1,1,1}' ), -- sunny, hot, high, strong
    ( 4, 1, '{3,2,1,2}' ), -- rain, mild, high, weak
    ( 6, 0, '{3,3,2,1}' ), -- rain, cool, normal, strong
    ( 8, 0, '{1,2,1,2}' ), -- sunny, mild, high, weak
    (10, 1, '{3,2,2,2}' ), -- rain, mild, normal, weak
    (12, 1, '{2,2,1,1}' ), -- etc.
    (14, 0, '{3,2,1,1}' ),
    ( 1, 0, '{1,1,1,2}' ),
    ( 3, 1, '{2,1,1,2}' ),
    ( 5, 1, '{3,3,2,2}' ),
    ( 7, 1, '{2,3,2,1}' ),
    ( 9, 1, '{1,3,2,2}' ),
    (11, 1, '{1,2,2,1}' ),
    (13, 1, '{2,1,2,2}');
```

2. Create the model from the training table.

```
SELECT madlib.create_nb_prepared_data_tables (
  'weather_example', -- training source table
  'play',            -- dependent class column
  'attrs',           -- attributes column
  4,                 -- number of attributes
  'weather_probs',   -- feature probabilities output table
  'weather_priors'    -- class priors
);
```

3. View the feature probabilities:

```
SELECT * FROM weather_probs;
```

class	attr	value	cnt	attr_cnt
1	3	2	6	2
1	1	2	4	3
0	1	1	3	3
0	1	3	2	3
0	3	1	4	2
1	4	1	3	2
1	2	3	3	3
1	2	1	2	3
0	2	2	2	3
0	4	2	2	2
0	3	2	1	2
0	1	2	0	3
1	1	1	2	3
1	1	3	3	3
1	3	1	3	2
0	4	1	3	2
0	2	3	1	3
0	2	1	2	3
1	2	2	4	3
1	4	2	6	2

(20 rows)

4. To classify a group of records with a model, first load the data into a table. In this example, the table `t1` has four rows to classify.

```
DROP TABLE IF EXISTS t1;
CREATE TABLE t1 (
  id integer,
  attributes integer[]);
insert into t1 values
(1, '{1, 2, 1, 1}'),
(2, '{3, 3, 2, 1}'),
(3, '{2, 1, 2, 2}'),
(4, '{3, 1, 1, 2}');
```

5. Use the MADlib `create_nb_classify_view()` function to classify the rows in the table.

```
SELECT madlib.create_nb_classify_view (
  'weather_probs', -- feature probabilities table
  'weather_priors', -- classPriorsName
  't1',            -- table containing values to classify
  'id',            -- key column
  'attributes',     -- attributes column
  4,               -- number of attributes
  't1_out'         -- output table name
);
```

The result is four rows, one for each record in the `t1` table.

```
SELECT * FROM t1_out ORDER BY key;
  key | nb_classification
-----+-----
  1  | {0}
  2  | {1}
  3  | {1}
  4  | {0}
(4 rows)
```

PivotalR is a first class R package that enables users to interact with data resident in Greenplum Database and MADLib using an R client.

Graph Analytics

Many modern business problems involve connections and relationships between entities, and are not solely based on discrete data. Graphs are powerful at representing complex interconnections, and graph data modeling is very effective and flexible when the number and depth of relationships increase exponentially.

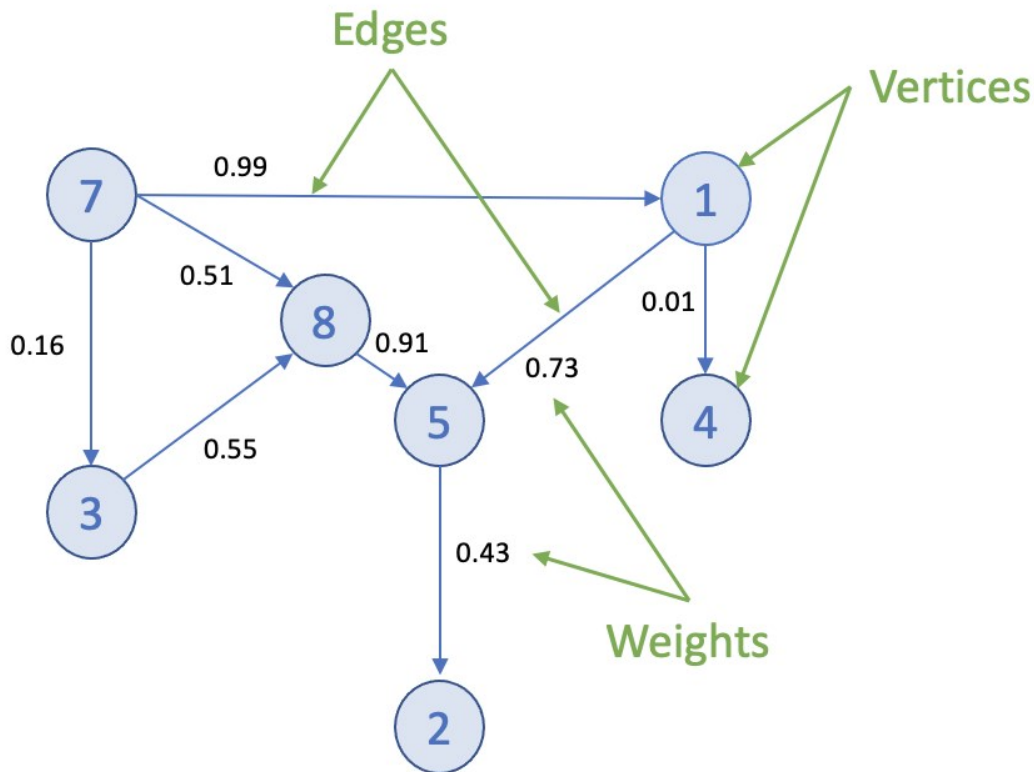

The use cases for graph analytics are diverse: social networks, transportation routes, autonomous vehicles, cyber security, criminal networks, fraud detection, health research, epidemiology, and so forth.

This chapter contains the following information:

- [What is a Graph?](#)
- [Graph Analytics on Greenplum](#)
- [Using Graph](#)
- [Graph Modules](#)
- [References](#)

What is a Graph?

Graphs represent the interconnections between objects (vertices) and their relationships (edges). Example objects could be people, locations, cities, computers, or components on a circuit board. Example connections could be roads, circuits, cables, or interpersonal relationships. Edges can have directions and weights, for example the distance between towns.

Graphs can be small and easily traversed - as with a small group of friends - or extremely large and complex, similar to contacts in a modern-day social network.

Graph Analytics on Greenplum

Efficient processing of very large graphs can be challenging. Greenplum offers a suitable environment for this work for these key reasons:

1. Using MADlib graph functions in Greenplum brings the graph computation close to where the data lives. Otherwise, large data sets need to be moved to a specialized graph database, requiring additional time and resources.
2. Specialized graph databases frequently use purpose-built languages. With Greenplum, you can invoke graph functions using the familiar SQL interface. For example, for the [PageRank](#) graph algorithm:

```

SELECT madlib.pagerank('vertex',      -- Vertex table
                      'id',           -- Vertex id column
                      'edge',         -- Edge table
                      'src=src, dest=dest', -- Comma delimited string of edge argument
s
                      'pagerank_out',  -- Output table of PageRank
                      0.5);           -- Damping factor
SELECT * FROM pagerank_out ORDER BY pagerank DESC;

```

3. A lot of data science problems are solved using a combination of models, with graphs being just one. Regression, clustering, and other methods available in Greenplum, make for a powerful combination.
4. Greenplum offers great benefits of scale, taking advantage of years of query execution and optimization research focused on large data sets.

Using Graph

Installing Graph Modules

To use the MADlib graph modules, install the version of MADlib corresponding to your Greenplum Database version. To download the software, access the VMware Tanzu Network. For Greenplum 6.x, see [Installing MADlib](#).

Graph modules on MADlib support many algorithms.

Creating a Graph in Greenplum

To represent a graph in Greenplum, create tables that represent the vertices, edges, and their properties.

Vertex Table

Vertex	Vertex Params	...
0	...	
1	...	
2	...	
3	...	
...	...	

Edge Table

Source Vertex	Dest Vertex	Edge Weight	Edge Params	...
0	3	1.0	...	
1	0	5.0	...	
1	2	3.0	...	
2	3	8.0	...	
3	0	3.0	...	
3	1	2.0	...	
...	

Using SQL, create the relevant tables in the database you want to use. This example uses `testdb`:

```
gpadmin@mdw ~]$ psql
dev=# \c testdb
```

Create a table for vertices, called `vertex`, and a table for edges and their weights, called `edge`:

```
testdb=# DROP TABLE IF EXISTS vertex, edge;
testdb=# CREATE TABLE vertex(id INTEGER);
testdb=# CREATE TABLE edge(
    src INTEGER,
    dest INTEGER,
    weight FLOAT8
);
```

Insert values related to your specific use case. For example :

```
testdb=#> INSERT INTO vertex VALUES
(0),
(1),
(2),
(3),
(4),
(5),
(6),
(7);
```

```
testdb#=> INSERT INTO edge VALUES
(0, 1, 1.0),
(0, 2, 1.0),
(0, 4, 10.0),
(1, 2, 2.0),
(1, 3, 10.0),
(2, 3, 1.0),
(2, 5, 1.0),
(2, 6, 3.0),
(3, 0, 1.0),
(4, 0, -2.0),
(5, 6, 1.0),
(6, 7, 1.0);
```

Now select the [Graph Module](#) that suits your analysis.

Graph Modules

This section lists the graph functions supported in MADlib. They include: [All Pairs Shortest Path \(APSP\)](#), [Breadth-First Search](#), [Hyperlink-Induced Topic Search \(HITS\)](#), [PageRank](#) and [Personalized PageRank](#), [Single Source Shortest Path \(SSSP\)](#), [Weakly Connected Components](#), and [Measures](#).

Explore each algorithm using the example `edge` and `vertex` tables already created.

All Pairs Shortest Path (APSP)

The all pairs shortest paths (APSP) algorithm finds the length (summed weights) of the shortest paths between all pairs of vertices, such that the sum of the weights of the path edges is minimized.

The function is:

```
graph_apsp( vertex_table,
vertex_id,
edge_table,
edge_args,
out_table,
grouping_cols
)
```

For details on the parameters, with examples, see the [All Pairs Shortest Path](#) in the Apache MADlib documentation.

Breadth-First Search

Given a graph and a source vertex, the breadth-first search (BFS) algorithm finds all nodes reachable from the source vertex by searching / traversing the graph in a breadth-first manner.

The function is:

```
graph_bfs( vertex_table,
           vertex_id,
           edge_table,
           edge_args,
           source_vertex,
           out_table,
           max_distance,
           directed,
           grouping_cols
)
```

For details on the parameters, with examples, see the [Breadth-First Search](#) in the Apache MADlib documentation.

Hyperlink-Induced Topic Search (HITS)

The all pairs shortest paths (APSP) algorithm finds the length (summed weights) of the shortest paths between all pairs of vertices, such that the sum of the weights of the path edges is minimized.

The function is:

```
graph_apsp( vertex_table,
            vertex_id,
            edge_table,
            edge_args,
            out_table,
            grouping_cols
            )
```

For details on the parameters, with examples, see the [Hyperlink-Induced Topic Search](#) in the Apache MADlib documentation.

PageRank and Personalized PageRank

Given a graph, the PageRank algorithm outputs a probability distribution representing a person's likelihood to arrive at any particular vertex while randomly traversing the graph.

MADlib graph also includes a personalized PageRank, where a notion of importance provides personalization to a query. For example, importance scores can be biased according to a specified set of graph vertices that are of interest or special in some way.

The function is:

```
pagerank( vertex_table,
          vertex_id,
          edge_table,
          edge_args,
          out_table,
          damping_factor,
          max_iter,
          threshold,
          grouping_cols,
          personalization_vertices
          )
```

For details on the parameters, with examples, see the [PageRank](#) in the Apache MADlib documentation.

Single Source Shortest Path (SSSP)

Given a graph and a source vertex, the single source shortest path (SSSP) algorithm finds a path from the source vertex to every other vertex in the graph, such that the sum of the weights of the path edges is minimized.

The function is:

```
graph_sssp ( vertex_table,
            vertex_id,
            edge_table,
            edge_args,
            source_vertex,
            out_table,
            grouping_cols
            )
```

For details on the parameters, with examples, see the [Single Source Shortest Path](#) in the Apache MADlib documentation.

Weakly Connected Components

Given a directed graph, a weakly connected component (WCC) is a subgraph of the original graph where all vertices are connected to each other by some path, ignoring the direction of edges.

The function is:

```
weakly_connected_components (
  vertex_table,
  vertex_id,
  edge_table,
  edge_args,
  out_table,
  grouping_cols
)
```

For details on the parameters, with examples, see the [Weakly Connected Components](#) in the Apache MADlib documentation.

Measures

These algorithms relate to metrics computed on a graph and include: [Average Path Length](#), [Closeness Centrality](#), [Graph Diameter](#), and [In-Out Degree](#).

Average Path Length

This function computes the shortest path average between pairs of vertices. Average path length is based on “reachable target vertices”, so it averages the path lengths in each connected component and ignores infinite-length paths between unconnected vertices. If the user requires the average path length of a particular component, the weakly connected components function may be used to isolate the relevant vertices.

The function is:

```
graph_avg_path_length( apsp_table,
                       output_table
)
```

This function uses a previously run APSP (All Pairs Shortest Path) output. For details on the parameters, with examples, see the [Average Path Length](#) in the Apache MADlib documentation.

Closeness Centrality

The closeness centrality algorithm helps quantify how much information passes through a given vertex. The function returns various closeness centrality measures and the k-degree for a given subset of vertices.

The function is:

```
graph_closeness( apsp_table,
                 output_table,
                 vertex_filter_expr
)
```

This function uses a previously run APSP (All Pairs Shortest Path) output. For details on the parameters, with examples, see the [Closeness](#) in the Apache MADlib documentation.

Graph Diameter

Graph diameter is defined as the longest of all shortest paths in a graph. The function is:

```
graph_diameter( apsp_table,
output_table
)
```

This function uses a previously run APSP (All Pairs Shortest Path) output. For details on the parameters, with examples, see the [Graph Diameter](#) in the Apache MADlib documentation.

In-Out Degree

This function computes the degree of each node. The node degree is the number of edges adjacent to that node. The node in-degree is the number of edges pointing in to the node and node out-degree is the number of edges pointing out of the node.

The function is:

```
graph_vertex_degrees( vertex_table,
vertex_id,
edge_table,
edge_args,
out_table,
grouping_cols
)
```

For details on the parameters, with examples, see the [In-out Degree](#) page in the Apache MADlib documentation.

Geospatial Analytics

This chapter contains the following information:

- [About PostGIS](#)
- [Greenplum PostGIS Extension](#)
- [Enabling and Removing PostGIS Support](#)
- [Usage](#)
- [PostGIS Extension Support and Limitations](#)

For information about upgrading PostGIS on Greenplum Database 6 systems, see [Upgrading PostGIS 2.1.5 or 2.5.4](#)

About PostGIS

PostGIS is a spatial database extension for PostgreSQL that allows GIS (Geographic Information Systems) objects to be stored in the database. The Greenplum PostGIS extension includes support for GiST-based R-Tree spatial indexes and functions for analysis and processing of GIS objects.

The Greenplum PostGIS extension supports some PostGIS optional extensions and includes support

for the PostGIS `raster` data type. With the PostGIS Raster objects, PostGIS `geometry` data type offers a single set of overlay SQL functions (such as `ST_Intersects`) operating seamlessly on vector and raster geospatial data. PostGIS Raster uses the GDAL (Geospatial Data Abstraction Library) translator library for raster geospatial data formats that presents a [single raster abstract data model](#) to a calling application.

For information about Greenplum Database PostGIS extension support, see [PostGIS Extension Support and Limitations](#).

For information about PostGIS, see <https://postgis.net/>

For information about GDAL, see <https://gdal.org/>.

Greenplum PostGIS Extension

The Greenplum PostGIS extension package is available from [VMware Tanzu Network](#). After you download the package, you can follow the instructions in [Verifying the Greenplum Database Software Download](#) to verify the integrity of the **Greenplum Advanced Analytics PostGIS** software. You can install the package using the Greenplum Package Manager (`gppkg`). For details, see `gppkg` in the *Greenplum Database Utility Guide*.

Greenplum Database supports the PostGIS extension with these component versions.

- PostGIS 2.5.4
- Proj 4.8.0
- Geos 3.10.2
- GDAL 1.11.1
- Json 0.12
- Expat 2.4.4

For the information about supported Greenplum extension packages and software versions, see [GUID-install_guide-platform-requirements.html](#).

There have been significant changes in PostGIS 2.5.4 compared with the previously supported version of 2.1.5. For a list of new and enhanced functions in PostGIS 2.5, see the PostGIS documentation [PostGIS Functions new or enhanced in 2.5](#).

For a comprehensive list of PostGIS changes in PostGIS 2.5.4 and earlier, see PostGIS 2.5 Appendix A [Release 2.5.4](#).

Note: If you installed Greenplum PostGIS 2.1.5, you cannot upgrade from PostGIS 2.1.5 to 2.5.4. You must uninstall PostGIS 2.1.5 and install PostGIS 2.5.4.

This table lists the PostGIS extensions support by Greenplum PostGIS.

Table 1. Greenplum PostGIS Extensions

PostGIS Extension	Greenplum PostGIS Notes
<code>postgis</code> PostGIS and PostGIS Raster support	Supported. Both PostGIS and PostGIS Raster are enabled when the Greenplum <code>postgis</code> extension is enabled.
<code>postgis_tiger_geocoder</code> The US TIGER geocoder	Supported. Installed with Greenplum PostGIS. Requires the <code>postgis</code> and <code>fuzzystrmatch</code> extensions. The US TIGER geocoder converts addresses (like a street address) to geographic coordinates.

Table 1. Greenplum PostGIS Extensions

PostGIS Extension	Greenplum PostGIS Notes
address_standardizer Rule-based address standardizer	Supported. Installed but not enabled with Greenplum PostGIS. Can be used with TIGER geocoder. A single line address parser that takes an input address and normalizes it based on a set of rules stored in a table and helper lex and gaz tables.
address_standardizer_data_us Sample rules tables for US address data	Supported. Installed but not enabled with Greenplum PostGIS. Can be used with the address standardizer. The extension contains gaz , lex , and rules tables for US address data. If you are using other types of tables, see PostGIS Extension Limitations .
fuzzystrmatch Fuzzy string matching	Supported. This extension is bundled but not enabled with Greenplum Database. Required for the PostGIS TIGER geocoder.

Note: The PostGIS topology extension [postgis_topology](#) and the PostGIS 3D and geoprocessing extension [postgis_sfcgal](#) are not supported by Greenplum PostGIS and are not included in the Greenplum PostGIS extension package.

For information about the PostGIS extensions, see the [PostGIS 2.5 documentation](#).

For information about Greenplum PostGIS feature support, see [PostGIS Extension Support and Limitations](#).

Enabling and Removing PostGIS Support

This section describes how to enable and remove PostGIS and the supported PostGIS extensions, and how to configure PostGIS Raster.

- [Enabling PostGIS Support](#)
- [Enabling GDAL Raster Drivers](#)
- [Enabling Out-of-Database Rasters](#)
- [Removing PostGIS Support](#)

For information about upgrading PostGIS on Greenplum Database 6 systems, see [Upgrading PostGIS 2.1.5 or 2.5.4](#)

Enabling PostGIS Support

To enable PostGIS support, install the Greenplum PostGIS extension package into the Greenplum Database system, and then use the `CREATE EXTENSION` command to enable PostGIS support for an individual database.

Installing the Greenplum PostGIS Extension Package

Install Greenplum PostGIS extension package with the `gppkg` utility. For example, this command installs the package for RHEL 7.

```
gppkg -i postgis-2.5.4+pivotal.2.build.1-gp6-rhel7-x86_64.gppkg
```

After installing the package, source the `greenplum_path.sh` file and restart Greenplum Database. This command restarts Greenplum Database.

```
gpstop -ra
```

Installing the Greenplum PostGIS extension package updates the Greenplum Database system, including installing the supported PostGIS extensions to the system and updating `greenplum_path.sh` file with these lines for PostGIS Raster support.

```
export GDAL_DATA=$GPHOME/share/gdal
export POSTGIS_ENABLE_OUTDB_RASTERS=0
export POSTGIS_GDAL_ENABLED_DRIVERS=DISABLE_ALL
```

Using the CREATE EXTENSION Command

These steps enable the PostGIS extension and the extensions that are used with PostGIS.

1. To enable PostGIS and PostGIS Raster in a database, run this command after logging into the database.

```
CREATE EXTENSION postgis ;
```

To enable PostGIS and PostGIS Raster in a specific schema, create the schema, set the `search_path` to the PostGIS schema, and then enable the `postgis` extension with the `WITH SCHEMA` clause.

```
SHOW search_path ; -- display the current search_path
CREATE SCHEMA <schema_name> ;
SET search_path TO <schema_name> ;
CREATE EXTENSION postgis WITH SCHEMA <schema_name> ;
```

After enabling the extension, reset the `search_path` and include the PostGIS schema in the `search_path` if needed.

2. If needed, enable the PostGIS TIGER geocoder after enabling the `postgis` extension.

To enable the PostGIS TIGER geocoder, you must enable the `fuzzystrmatch` extension before enabling `postgis_tiger_geocoder`. These two commands enable the extensions.

```
CREATE EXTENSION fuzzystrmatch ;
CREATE EXTENSION postgis_tiger_geocoder ;
```

3. If needed, enable the rules-based address standardizer and add rules tables for the standardizer. These commands enable the extensions.

```
CREATE EXTENSION address_standardizer ;
CREATE EXTENSION address_standardizer_data_us ;
```

Enabling GDAL Raster Drivers

PostGIS uses GDAL raster drivers when processing raster data with commands such as `ST_AsJPEG()`. As the default, PostGIS disables all raster drivers. You enable raster drivers by setting the value of the `POSTGIS_GDAL_ENABLED_DRIVERS` environment variable in the `greenplum_path.sh` file on all Greenplum Database hosts.

Alternatively, you can do it at the session level by setting `postgis.gdal_enabled_drivers`. For a Greenplum Database session, this example `SET` command enables three GDAL raster drivers.

```
SET postgis.gdal_enabled_drivers TO 'GTiff PNG JPEG';
```

This `SET` command sets the enabled drivers to the default for a session.

```
SET postgis.gdal_enabled_drivers = default;
```

To see the list of supported GDAL raster drivers for a Greenplum Database system, run the `raster2pgsql` utility with the `-G` option on the Greenplum Database master.

```
raster2pgsql -G
```

The command lists the driver long format name. The *GDAL Raster* table at <https://gdal.org/drivers/raster/index.html> lists the long format names and the corresponding codes that you specify as the value of the environment variable. For example, the code for the long name Portable Network Graphics is `PNG`. This example `export` line enables four GDAL raster drivers.

```
export POSTGIS_GDAL_ENABLED_DRIVERS="GTiff PNG JPEG GIF"
```

The `gpstop -r` command restarts the Greenplum Database system to use the updated settings in the `greenplum_path.sh` file.

After you have updated the `greenplum_path.sh` file on all hosts, and have restarted the Greenplum Database system, you can display the enabled raster drivers with the `ST_GDALDrivers()` function. This `SELECT` command lists the enabled raster drivers.

```
SELECT short_name, long_name FROM ST_GDALDrivers();
```

Enabling Out-of-Database Rasters

After installing PostGIS, the default setting `POSTGIS_ENABLE_OUTDB_RASTERS=0` in the `greenplum_path.sh` file disables support for out-of-database rasters. To enable this feature, you can set the value to true (a non-zero value) on all hosts and restart the Greenplum Database system.

You can also enable or disable this feature for a Greenplum Database session. For example, this `SET` command enables the feature for the current session.

```
SET postgis.enable_outdb_rasters = true;
```

Note: When the feature is enabled, the server configuration parameter `postgis.gdal_enabled_drivers` determines the accessible raster formats.

Removing PostGIS Support

You use the `DROP EXTENSION` command to remove support for the PostGIS extension and the extensions that are used with PostGIS.

Removing PostGIS support from a database does not remove these PostGIS Raster environment variables from the `greenplum_path.sh` file: `GDAL_DATA`, `POSTGIS_ENABLE_OUTDB_RASTERS`, `POSTGIS_GDAL_ENABLED_DRIVERS`. The environment variables are removed when you uninstall the PostGIS extension package.

Warning: Removing PostGIS support from a database drops PostGIS database objects from the database without warning. Users accessing PostGIS objects might interfere with the dropping of PostGIS objects. See [Notes](#).

Using the DROP EXTENSION Command

Depending on the extensions you enabled for PostGIS, drop support for the extensions in the database.

1. If you enabled the address standardizer and sample rules tables, these commands drop support for those extensions from the current database.

```
DROP EXTENSION IF EXISTS address_standardizer_data_us;
DROP EXTENSION IF EXISTS address_standardizer;
```

2. If you enabled the TIGER geocoder and the `fuzzystrmatch` extension to use the TIGER geocoder, these commands drop support for those extensions.

```
DROP EXTENSION IF EXISTS postgis_tiger_geocoder;
DROP EXTENSION IF EXISTS fuzzystrmatch;
```

3. Drop support for PostGIS and PostGIS Raster. This command drops support for those extensions.

```
DROP EXTENSION IF EXISTS postgis;
```

If you enabled support for PostGIS and specified a specific schema with the `CREATE EXTENSION` command, you can update the `search_path` and drop the PostGIS schema if required.

Uninstalling the Greenplum PostGIS Extension Package

After PostGIS support has been removed from all databases in the Greenplum Database system, you can remove the PostGIS extension package. For example, this `gppkg` command removes the PostGIS extension package.

```
gppkg -r postgis-2.5.4+pivotal.2
```

After removing the package, ensure that these lines for PostGIS Raster support are removed from the `greenplum_path.sh` file.

```
export GDAL_DATA=$GPHOME/share/gdal
export POSTGIS_ENABLE_OUTDB_RASTERS=0
export POSTGIS_GDAL_ENABLED_DRIVERS=DISABLE_ALL
```

Source the `greenplum_path.sh` file and restart Greenplum Database. This command restarts Greenplum Database.

```
gpstop -ra
```

Notes

Removing PostGIS support from a database drops PostGIS objects from the database. Dropping the PostGIS objects cascades to objects that reference the PostGIS objects. Before removing PostGIS support, ensure that no users are accessing the database. Users accessing PostGIS objects might interfere with dropping PostGIS objects.

For example, this `CREATE TABLE` command creates a table with column `b` that is defined with the PostGIS `geometry` data type.

```
# CREATE TABLE test(a int, b geometry) DISTRIBUTED RANDOMLY;
```

This is the table definition in a database with PostGIS enabled.

```
# \d test
```

```
Table "public.test"
Column |    Type    | Modifiers
-----+-----+-----
a      | integer    |
b      | geometry   |
Distributed randomly
```

This is the table definition in a database after PostGIS support has been removed.

```
# \d test
Table "public.test"
Column |    Type    | Modifiers
-----+-----+-----
a      | integer    |
Distributed randomly
```

Usage

The following example SQL statements create non-OpenGIS tables and geometries.

```
CREATE TABLE geom_test ( gid int4, geom geometry,
                          name varchar(25) );

INSERT INTO geom_test ( gid, geom, name )
VALUES ( 1, 'POLYGON((0 0 0,0 5 0,5 5 0,5 0 0,0 0 0))', '3D Square');
INSERT INTO geom_test ( gid, geom, name )
VALUES ( 2, 'LINESTRING(1 1 1,5 5 5,7 7 5)', '3D Line' );
INSERT INTO geom_test ( gid, geom, name )
VALUES ( 3, 'MULTIPOINT(3 4,8 9)', '2D Aggregate Point' );

SELECT * from geom_test WHERE geom &&
Box3D(ST_GeomFromEWKT('LINESTRING(2 2 0, 3 3 0)'));
```

The following example SQL statements create a table and add a geometry column to the table with a SRID integer value that references an entry in the `SPATIAL_REF_SYS` table. The `INSERT` statements add two geopoints to the table.

```
CREATE TABLE geotest (id INT4, name VARCHAR(32) );
SELECT AddGeometryColumn('geotest','geopoint', 4326,'POINT',2);

INSERT INTO geotest (id, name, geopoint)
VALUES (1, 'Olympia', ST_GeometryFromText('POINT(-122.90 46.97)', 4326));
INSERT INTO geotest (id, name, geopoint)
VALUES (2, 'Renton', ST_GeometryFromText('POINT(-122.22 47.50)', 4326));

SELECT name,ST_AsText(geopoint) FROM geotest;
```

Spatial Indexes

PostgreSQL provides support for GiST spatial indexing. The GiST scheme offers indexing even on large objects. It uses a system of lossy indexing in which smaller objects act as proxies for larger ones in the index. In the PostGIS indexing system, all objects use their bounding boxes as proxies in the index.

Building a Spatial Index

You can build a GiST index as follows:

```
CREATE INDEX indexname
```

```
ON tablename
USING GIST ( geometryfield );
```

PostGIS Extension Support and Limitations

This section describes Greenplum PostGIS extension feature support and limitations.

- [Supported PostGIS Data Types](#)
- [Supported PostGIS Raster Data Types](#)
- [Supported PostGIS Index](#)
- [PostGIS Extension Limitations](#)

In general, the Greenplum PostGIS extension does not support the following features:

- The PostGIS topology extension `postgis_topology`
- The PostGIS 3D and geoprocessing extension `postgis_sfcgal`
- A small number of user defined functions and aggregates
- PostGIS long transactions

For the PostGIS extensions supported by Greenplum PostGIS, see [Greenplum PostGIS Extension](#).

Supported PostGIS Data Types

Greenplum PostGIS extension supports these PostGIS data types:

- box2d
- box3d
- geometry
- geography

For a list of PostGIS data types, operators, and functions, see the [PostGIS reference documentation](#).

Supported PostGIS Raster Data Types

Greenplum PostGIS supports these PostGIS Raster data types.

- geomval
- addbandarg
- rastbandarg
- raster
- reclassarg
- summarystats
- unionarg

For information about PostGIS Raster data Management, queries, and applications, see https://postgis.net/docs/manual-2.5/using_raster_dataman.html.

For a list of PostGIS Raster data types, operators, and functions, see the [PostGIS Raster reference documentation](#).

Supported PostGIS Index

Greenplum PostGIS extension supports the GiST (Generalized Search Tree) index.

PostGIS Extension Limitations

This section lists the Greenplum PostGIS extension limitations for user-defined functions (UDFs), data types, and aggregates.

- Data types and functions related to PostGIS topology functionality, such as TopoGeometry, are not supported by Greenplum Database.
- These PostGIS aggregates are not supported by Greenplum Database:
 - ST_Collect
 - ST_MakeLine

On a Greenplum Database with multiple segments, the aggregate might return different answers if it is called several times repeatedly.

- Greenplum Database does not support PostGIS long transactions.

PostGIS relies on triggers and the PostGIS table `public.authorization_table` for long transaction support. When PostGIS attempts to acquire locks for long transactions, Greenplum Database reports errors citing that the function cannot access the relation, `authorization_table`.

- Greenplum Database does not support type modifiers for user defined types.

The workaround is to use the `AddGeometryColumn` function for PostGIS geometry. For example, a table with PostGIS geometry cannot be created with the following SQL command:

```
CREATE TABLE geometries(id INTEGER, geom geometry(LINESTRING));
```

Use the `AddGeometryColumn` function to add PostGIS geometry to a table. For example, these following SQL statements create a table and add PostGIS geometry to the table:

```
CREATE TABLE geometries(id INTEGER);
SELECT AddGeometryColumn('public', 'geometries', 'geom', 0, 'LINESTRING', 2);
```

- The `_postgis_index_extent` function is not supported on Greenplum Database 6 due to its dependence on spatial index operations.
- The `<->` operator (`geometry <-> geometry`) returns the centroid/centroid distance for Greenplum Database 6.
- The TIGER geocoder extension is supported. However, upgrading the TIGER geocoder extension is not supported.
- The `standardize_address()` function uses `lex`, `gaz` or `rules` tables as parameters. If you are using tables apart from `us_lex`, `us_gaz` or `us_rules`, you should create them with the distribution policy `DISTRIBUTED REPLICATED` to work for Greenplum.

Upgrading PostGIS 2.1.5 or 2.5.4

For Greenplum Database 6, you can upgrade from PostGIS 2.1.5 to 2.5.4, or from a PostGIS 2.5.4 package to a newer PostGIS 2.5.4 package.

- [Upgrading from PostGIS 2.1.5 to the PostGIS 2.5.4 pivotal.3 Package](#)
- [Upgrade a PostGIS 2.5.4 Package from pivotal.1 or pivotal.2 to pivotal.3](#)
- [Checking the PostGIS Version](#)

Note: For Greenplum Database 6, you can upgrade from PostGIS 2.1.5 to 2.5.4, or from a PostGIS 2.5.4 package to a newer PostGIS 2.5.4 package using the `postgis_manager.sh` script described in the upgrade instructions.

Upgrading PostGIS using the `postgis_manager.sh` script does not require you to remove PostGIS support and re-enable it.

Removing PostGIS support from a database drops PostGIS database objects from the database without warning. Users accessing PostGIS objects might interfere with the dropping of PostGIS objects. See the Notes section in [Removing PostGIS Support](#).

Upgrading from PostGIS 2.1.5 to the PostGIS 2.5.4 pivotal.3 Package

A PostGIS 2.5.4 `pivotal.3` package contains PostGIS 2.5.4. Also, the PostGIS 2.5.4 `pivotal.3` package supports using the `CREATE EXTENSION` command and the `DROP EXTENSION` command to enable and remove PostGIS support in a database. See [Notes](#).

After upgrading the Greenplum PostGIS package, you can remove the PostGIS 2.1.5 package (`gppkg`) from the Greenplum system. See [Removing the PostGIS 2.1.5 package](#).

1. Confirm you have a PostGIS 2.1.5 package such as `postgis-2.1.5+pivotal.1` installed in a Greenplum Database system. See [Checking the PostGIS Version](#).
2. Install the PostGIS 2.5.4 package into the Greenplum Database system with the `gppkg` utility.

```
gppkg -i postgis-2.5.4+pivotal.3.build.1-gp6-rhel7-x86_64.gppkg
```

Run the `gppkg -q --all` command to verify the updated package version is installed in the Greenplum Database system.

3. For all databases with PostGIS enabled, run the PostGIS 2.5.4 `postgis_manager.sh` script in the directory `$GPHOME/share/postgresql/contrib/postgis-2.5` to upgrade PostGIS in that database. This command upgrades PostGIS that is enabled in the database `mytest` in the Greenplum Database system.

```
$GPHOME/share/postgresql/contrib/postgis-2.5/postgis_manager.sh mytest upgrade
```

4. After running the script, you can verify that PostGIS 2.5.4 is installed and enabled as an extension in a database with this query.

```
# SELECT * FROM pg_available_extensions WHERE name = 'postgis' ;
```

5. You can validate that PostGIS 2.5 is enabled in the database with the `postgis_version()` function.

After you have completed the upgrade to PostGIS 2.5.4 `pivotal.3` for the Greenplum system and all the databases with PostGIS enabled, you enable PostGIS in a new database with the `CREATE EXTENSION postgis` command. To remove PostGIS support, use the `DROP EXTENSION postgis CASCADE` command.

Removing the PostGIS 2.1.5 package

After upgrading the databases in the Greenplum Database system, you can remove the PostGIS 2.1.5 package from the system. This command removes the `postgis-2.1.5+pivotal.2` package from a Greenplum Database system.

```
gppkg -r postgis-2.1.5+pivotal.2
```

Run the `gppkg -q --all` command to list the installed Greenplum packages.

Upgrade a PostGIS 2.5.4 Package from pivotal.1 or pivotal.2 to pivotal.3

You can upgrade the installed PostGIS 2.5.4 package from `pivotal.1` or `pivotal.2` to `pivotal.3` (a minor release upgrade). The upgrade updates the PostGIS 2.5.4 package to the minor release (`pivotal.3`) that uses the same PostGIS version (2.5.4).

The `pivotal.3` minor release supports using the `CREATE EXTENSION` command and the `DROP EXTENSION` command to enable and remove PostGIS support in a database. See [Notes](#).

1. Confirm you have a PostGIS 2.5.4 package `postgis-2.5.4+**pivotal.1**` or `postgis-2.5.4+**pivotal.2**` installed in a Greenplum Database system. See [Checking the PostGIS Version](#).
2. Upgrade the PostGIS package in the Greenplum Database system using the `gppkg` option `-u`. The command updates the package to the `postgis-2.5.4+pivotal.3.build.1` package.

```
gppkg -u postgis-2.5.4+pivotal.3.build.1-gp6-rhel7-x86_64.gppkg
```

3. Run the `gppkg -q --all` command to verify the updated package version is installed in the Greenplum Database system.
4. For all databases with PostGIS enabled, upgrade PostGIS with the PostGIS 2.5.4 `postgis_manager.sh` script that is in the directory `$GPHOME/share/postgresql/contrib/postgis-2.5` to upgrade PostGIS in that database. This command upgrades PostGIS that is enabled in the database `mytest` in the Greenplum Database system.

```
$GPHOME/share/postgresql/contrib/postgis-2.5/postgis_manager.sh mytest upgrade
```

After you have completed the upgrade to PostGIS 2.5.4 `pivotal.3` for the Greenplum system and all the databases with PostGIS enabled, you enable PostGIS in a new database with the `CREATE EXTENSION postgis` command. To remove PostGIS support, use the `DROP EXTENSION postgis CASCADE` command.

Checking the PostGIS Version

When upgrading PostGIS you must check the version of the Greenplum PostGIS package installed on the Greenplum Database system and the version of PostGIS enabled in the database.

- Check the installed PostGIS package version with the `gppkg` utility. This command lists all installed Greenplum packages.

```
gppkg -q --all
```

- Check the enabled PostGIS version in a database with the `postgis_version()` function. This `psql` command displays the version PostGIS that is enabled for the database `testdb`.

```
psql -d testdb -c 'select postgis_version();'
```

If PostGIS is not enabled for the database, Greenplum returns a `function does not exist` error.

- For the Greenplum PostGIS package `postgis-2.5.4+pivotal.2` and later, you can display the PostGIS extension version and state in a database with this query.

```
# SELECT * FROM pg_available_extensions WHERE name = 'postgis' ;
```

The query displays the version whether the extension is installed and enabled in a database. If the PostGIS package is not installed, no rows are returned.

Notes

Starting with the Greenplum `postgis-2.5.4+pivotal.2` package, you enable support for PostGIS in a database with the `CREATE EXTENSION` command. For previous PostGIS 2.5.4 packages and all PostGIS 2.1.5 packages, you use an SQL script.

Text Analytics and Search

Greenplum Database offers two different methods for text search and analytics, **Greenplum Database full text search** and **Tanzu Greenplum Text**.

Greenplum Database Full Text Search

Greenplum Database text search is PostgreSQL text search ported to the Greenplum Database MPP platform. Greenplum Database text search is immediately available to you, with no need to install and maintain additional software. For full details on this topic, see [Greenplum Database text search](#).

Tanzu Greenplum Text

For advanced text analysis applications, VMware also offers [Tanzu Greenplum Text](#), which integrates Greenplum Database with the Apache Solr text search platform. Tanzu Greenplum Text installs an Apache Solr cluster alongside your Greenplum Database cluster and provides Greenplum Database functions you can use to create Solr indexes, query them, and receive results in the database session.

Both of these systems provide powerful, enterprise-quality document indexing and searching services. Tanzu Greenplum Text, with Solr, has many capabilities that are not available with Greenplum Database text search. In particular, Tanzu Greenplum Text is better for advanced text analysis applications. For a comparative between these methods, see [Comparing Greenplum Database Text Search with Tanzu Greenplum Text](#).

Procedural Languages

Greenplum supports a pluggable procedural language architecture by virtue of its PostgreSQL heritage. This allows user-defined functions to be written in languages other than SQL and C. It may be more convenient to develop analytics functions in a familiar procedural language compared to using only SQL constructs. For example, suppose you have existing Python code that you want to use on data in Greenplum, you can wrap this code in a PL/Python function and call it from SQL.

The available Greenplum procedural languages are typically packaged as extensions. You register a language in a database using the `CREATE EXTENSION` command. You remove a language from a database with `DROP EXTENSION`.

The Greenplum Database distribution supports the following procedural languages; refer to the linked language documentation for installation and usage instructions:

- [PL/Container](#)

- [PL/Java](#)
- [PL/Perl](#)
- [PL/pgSQL](#)
- [PL/Python](#)
- [PL/R](#)

PL/Container Language

PL/Container enables users to run Greenplum procedural language functions inside a Docker container, to avoid security risks associated with running Python or R code on Greenplum segment hosts. This topic covers information about the architecture, installation, and setup of PL/Container:

- [About the PL/Container Language Extension](#)
- [Install PL/Container](#)
- [Upgrade PL/Container](#)
- [Uninstall PL/Container](#)
- [Docker References](#)

For detailed information about using PL/Container, refer to:

- [PL/Container Resource Management](#)
- [PL/Container Functions](#)

The PL/Container language extension is available as an open source module. For information about the module, see the README file in the GitHub repository at <https://github.com/greenplum-db/plcontainer>.

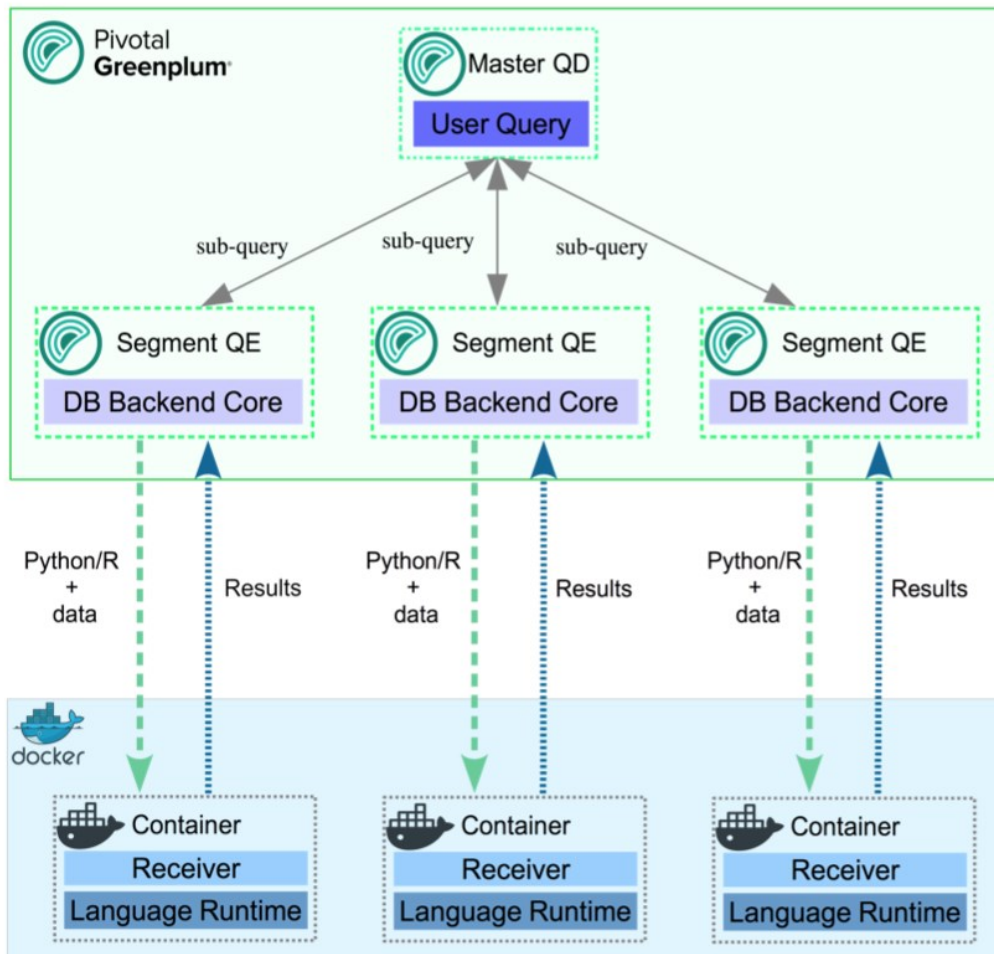

About the PL/Container Language Extension

The Greenplum Database PL/Container language extension allows users to create and run PL/Python or PL/R user-defined functions (UDFs) securely, inside a Docker container. Docker provides the ability to package and run an application in a loosely isolated environment called a container. For information about Docker, see the [Docker web site](#).

Running UDFs inside the Docker container ensures that:

- The function execution process takes place in a separate environment and allows decoupling of the data processing. SQL operators such as “scan,” “filter,” and “project” are run at the query executor (QE) side, and advanced data analysis is run at the container side.
- User code cannot access the OS or the file system of the local host.
- User code cannot introduce any security risks.
- Functions cannot connect back to the Greenplum Database if the container is started with limited or no network access.

PL/Container Architecture

Example of the process flow:

Consider a query that selects table data using all available segments, and transforms the data using a PL/Container function. On the first call to a function in a segment container, the query executor on the master host starts the container on that segment host. It then contacts the running container to obtain the results. The container might respond with a Service Provider Interface (SPI) - a SQL query run by the container to get some data back from the database - returning the result to the query executor.

A container running in standby mode waits on the socket and does not consume any CPU resources. PL/Container memory consumption depends on the amount of data cached in global dictionaries.

The container connection is closed by closing the Greenplum Database session that started the container, and the container shuts down.

About PL/Container 3 Beta

Greenplum Database 6.5 introduces PL/Container version 3 Beta, which:

- Provides support for the new GreenplumR interface.
- Reduces the number of processes created by PL/Container, in order to save system resources.
- Supports more containers running concurrently.
- Includes improved log messages to help diagnose problems.
- Supports the `DO` command (anonymous code block).

PL/Container 3 is currently a Beta feature, and provides only a Beta R Docker image for running functions; Python images are not yet available. Save and uninstall any existing PL/Container software before you install PL/Container 3 Beta.

Install PL/Container

This topic includes how to:

- [Install Docker](#)
- [Install PL/Container](#)
- [Install the PL/Container Docker images](#)
- [Test the PL/Container installation](#)

The following sections describe these tasks in detail.

Prerequisites

- For PL/Container 2.1.x use Greenplum Database 6 on CentOS 7.x (or later), RHEL 7.x (or later), or Ubuntu 18.04.
Note: PL/Container 2.1.x supports Docker images with Python 3 installed.
- For PL/Container 3 Beta use Greenplum Database 6.1 or later on CentOS 7.x (or later), RHEL 7.x (or later), or Ubuntu 18.04.
- The minimum Linux OS kernel version supported is 3.10. To verify your kernel release use:

```
$ uname -r
```

- The minimum Docker versions on all hosts needs to be Docker 19.03.

Install Docker

To use PL/Container you need to install Docker on all Greenplum Database host systems. These instructions show how to set up the Docker service on CentOS 7 but RHEL 7 is a similar process.

These steps install the docker package and start the Docker service as a user with sudo privileges.

1. Ensure the user has sudo privileges or is root.
2. Install the dependencies required for Docker:

```
sudo yum install -y yum-utils device-mapper-persistent-data lvm2
```

3. Add the Docker repo:

```
sudo yum-config-manager --add-repo https://download.docker.com/linux/centos/docker-ce.repo
```

4. Update yum cache:

```
sudo yum makecache fast
```

5. Install Docker:

```
sudo yum -y install docker-ce
```

6. Start Docker daemon:

```
sudo systemctl start docker
```

- On each Greenplum Database host, the `gpadmin` user should be part of the `docker` group for the user to be able to manage Docker images and containers. Assign the Greenplum Database administrator `gpadmin` to the group `docker`:

```
sudo usermod -aG docker gpadmin
```

- Exit the session and login again to update the privileges.
- Configure Docker to start when the host system starts:

```
sudo systemctl enable docker.service
```

```
sudo systemctl start docker.service
```

- Run a Docker command to test the Docker installation. This command lists the currently running Docker containers.

```
docker ps
```

- After you install Docker on all Greenplum Database hosts, restart the Greenplum Database system to give Greenplum Database access to Docker.

```
gpstop -ra
```

For a list of observations while using Docker and PL/Container, see the [Notes](#) section. For a list of Docker reference documentation, see [Docker References](#).

Install PL/Container

Install the PL/Container language extension using the `gppkg` utility.

- Download the “PL/Container for RHEL 7” package that applies to your Greenplum Database version, from the [VMware Tanzu Network](#). PL/Container is listed under Greenplum Procedural Languages.
- As `gpadmin`, copy the PL/Container language extension package to the master host.
- Follow the instructions in [Verifying the Greenplum Database Software Download](#) to verify the integrity of the **Greenplum Procedural Languages PL/Container** software.
- Run the package installation command:

```
gppkg -i plcontainer-2.1.1-rhel7-x86_64.gppkg
```

- Source the file `$GPHOME/greenplum_path.sh`:

```
source $GPHOME/greenplum_path.sh
```

- Make sure Greenplum Database is up and running:

```
gpstate -s
```

If it's not, start it:

```
gpstart -a
```

- For PL/Container version 3 Beta only, add the `plc_coordinator` shared library to the Greenplum Database `shared_preload_libraries` server configuration parameter. Be sure to retain any previous setting of the parameter. For example:

```
gpconfig -s shared_preload_libraries
Values on all segments are consistent
GUC          : shared_preload_libraries
Coordinator value: diskquota
Segment      value: diskquota
gpconfig -c shared_preload_libraries -v 'diskquota,plc_coordinator'
```

- Restart Greenplum Database:

```
gpstop -ra
```

- Login into one of the available databases, for example:

```
psql postgres
```

- Register the PL/Container extension, which installs the `plcontainer` utility:

```
CREATE EXTENSION plcontainer;
```

You'll need to register the utility separately on each database that might need the PL/Container functionality.

Install PL/Container Docker Images

Install the Docker images that PL/Container will use to create language-specific containers to run the UDFs.

Note: The PL/Container open source module contains dockerfiles to build Docker images that can be used with PL/Container. You can build a Docker image to run PL/Python UDFs and a Docker image to run PL/R UDFs. See the dockerfiles in the GitHub repository at <https://github.com/greenplum-db/plcontainer>.

- Download the files that contain the Docker images from the [VMware Tanzu Network](#). For example, for Greenplum 6.5, click on "PL/Container Docker Image for Python 2.1.1" which downloads `plcontainer-python-image-2.1.1-gp6.tar.gz` with Python 2.7.12 and the *Python Data Science Module Package*.

If you require different images from the ones provided by Tanzu Greenplum, you can create custom Docker images, install the image and add the image to the PL/Container configuration.

- If you are using PL/Container 3 Beta, note that this Beta version is compatible only with the associated `plcontainer-r-image-3.0.0-beta-gp6.tar.gz` image.
- Follow the instructions in [Verifying the Greenplum Database Software Download](#) to verify the integrity of the **Greenplum Procedural Languages PL/Container Image** software.
- Use the `plcontainer image-add` command to install an image on all Greenplum Database hosts. Provide the `-f` option to specify the file system location of a downloaded image file. For example:

```
# Install a Python 2 based Docker image
plcontainer image-add -f /home/gpadmin/plcontainer-python-image-2.1.1-gp6.tar.gz
z

# Install a Python 3 based Docker image
```

```
plcontainer image-add -f /home/gpadmin/plcontainer-python3-image-2.1.1-gp6.tar.gz

# Install an R based Docker image
plcontainer image-add -f /home/gpadmin/plcontainer-r-image-2.1.1-gp6.tar.gz

# Install the Beta R image for use with PL/Container 3.0.0 Beta
plcontainer image-add -f /home/gpadmin/plcontainer-r-image-3.0.0-beta-gp6.tar.gz
```

The utility displays progress information, similar to:

```
20200127:21:54:43:004607 plcontainer:mdw:gpadmin-[INFO]:-Checking whether docker
r is installed on all hosts...
20200127:21:54:43:004607 plcontainer:mdw:gpadmin-[INFO]:-Distributing image file
/home/gpadmin/plcontainer-python-images-1.5.0.tar to all hosts...
20200127:21:54:55:004607 plcontainer:mdw:gpadmin-[INFO]:-Loading image on all hosts...
20200127:21:55:37:004607 plcontainer:mdw:gpadmin-[INFO]:-Removing temporary image
files on all hosts...
```

By default, the `image-add` command copies the image to each Greenplum Database segment and standby master host, and installs the image. When you specify the `[-ulc | --use_local_copy]` option, `plcontainer` installs the image only on the host on which you run the command. Use this option when the PL/Container image already resides on disk on a host.

For more information on `image-add` options, visit the [plcontainer](#) reference page.

- To display the installed Docker images on the local host use:

```
$ plcontainer image-list
```

REPOSITORY	TAG	IMAGE ID	CREATED
pivotaldata/plcontainer_r_shared	devel	7427f920669d	10 months ago
pivotaldata/plcontainer_python_shared	devel	e36827eba53e	10 months ago
pivotaldata/plcontainer_python3_shared	devel	y32827ebe55b	5 months ago

- Add the image information to the PL/Container configuration file using `plcontainer runtime-add`, to allow PL/Container to associate containers with specified Docker images.

Use the `-r` option to specify your own user defined runtime ID name, use the `-i` option to specify the Docker image, and the `-l` option to specify the Docker image language. When there are multiple versions of the same docker image, for example 1.0.0 or 1.2.0, specify the TAG version using “:” after the image name.

```
# Add a Python 2 based runtime
plcontainer runtime-add -r plc_python_shared -i pivotaldata/plcontainer_python_shared:devel -l python

# Add a Python 3 based runtime that is supported with PL/Container 2.1.x
plcontainer runtime-add -r plc_python3_shared -i pivotaldata/plcontainer_python3_shared:devel -l python3

# Add an R based runtime
plcontainer runtime-add -r plc_r_shared -i pivotaldata/plcontainer_r_shared:devel -l r
```

The utility displays progress information as it updates the PL/Container configuration file on

the Greenplum Database instances.

For details on other `runtime-add` options, see the [plcontainer](#) reference page.

- Optional: Use Greenplum Database resource groups to manage and limit the total CPU and memory resources of containers in PL/Container runtimes. In this example, the Python runtime will be used with a preconfigured resource group 16391:

```
plcontainer runtime-add -r plc_python_shared -i pivotaldata/plcontainer_python_
shared:devel -l
python -s resource_group_id=16391
```

For more information about enabling, configuring, and using Greenplum Database resource groups with PL/Container, see [PL/Container Resource Management](#).

You can now create a simple function to test your PL/Container installation.

Test the PL/Container Installation

List the names of the runtimes you created and added to the PL/Container XML file:

```
plcontainer runtime-show
```

which will show a list of all installed runtimes:

```
PL/Container Runtime Configuration:
-----
Runtime ID: plc_python_shared
Linked Docker Image: pivotaldata/plcontainer_python_shared:devel
Runtime Setting(s):
Shared Directory:
---- Shared Directory From HOST '/usr/local/greenplum-db/bin/plcontainer_clients'
to Container '/clientdir', access mode is 'ro'
-----
```

You can also view the PL/Container configuration information with the `plcontainer runtime-show -r <runtime_id>` command. You can view the PL/Container configuration XML file with the `plcontainer runtime-edit` command.

Use the `psql` utility and select an existing database:

```
psql postgres;
```

If the PL/Container extension is not registered with the selected database, first enable it using:

```
postgres=# CREATE EXTENSION plcontainer;
```

Create a simple function to test your installation; in the example, the function will use the runtime `plc_python_shared`:

```
postgres=# CREATE FUNCTION dummyPython() RETURNS text AS $$
# container: plc_python_shared
return 'hello from Python'
$$ LANGUAGE plcontainer;
```

And test the function using:

```
postgres=# SELECT dummyPython();
```

```

dummypython
-----
hello from Python
(1 row)

```

Similarly, to test the R runtime:

```

postgres=# CREATE FUNCTION dummyR() RETURNS text AS $$
# container: plc_r_shared
return ('hello from R')
$$ LANGUAGE plcontainer;
CREATE FUNCTION
postgres=# select dummyR();
         dummyr
-----
hello from R
(1 row)

```

For further details and examples about using PL/Container functions, see [PL/Container Functions](#).

Upgrade PL/Container

To upgrade PL/Container, you save the current configuration, upgrade PL/Container, and then restore the configuration after upgrade. There is no need to update the Docker images when you upgrade PL/Container.

Note: Before you perform this upgrade procedure, ensure that you have migrated your PL/Container package from your previous Greenplum Database installation to your new Greenplum Database installation. Refer to the [gppkg](#) command for package installation and migration information.

Note: You cannot upgrade to PL/Container 3 Beta. To install PL/Container 3 Beta, first save and then uninstall your existing PL/Container software. Then follow the instructions in [Install PL/Container](#).

To upgrade, perform the following procedure:

1. Save the PL/Container configuration. For example, to save the configuration to a file named `plcontainer202-backup.xml` in the local directory:

```
$ plcontainer runtime-backup -f plcontainer202-backup.xml
```

2. Use the Greenplum Database `gppkg` utility with the `-u` option to update the PL/Container language extension. For example, the following command updates the PL/Container language extension to version 2.1.1 on a Linux system:

```
$ gppkg -u plcontainer-2.1.1-gp6-rhel7_x86_64.gppkg
```

3. Source the Greenplum Database environment file `$GPHOME/greenplum_path.sh`.

```
$ source $GPHOME/greenplum_path.sh
```

4. Restore the PL/Container configuration that you saved in a previous step:

```
$ plcontainer runtime-restore -f plcontainer202-backup.xml
```

5. Restart Greenplum Database.

```
$ gpstop -ra
```

- You do not need to re-register the PL/Container extension in the databases in which you previously created the extension but ensure that you register the PL/Container extension in each new database that will run PL/Container UDFs. For example, the following command registers PL/Container in a database named `mytest`:

```
$ psql -d mytest -c 'CREATE EXTENSION plcontainer;'
```

The command also creates PL/Container-specific functions and views.

Uninstall PL/Container

To uninstall PL/Container, remove Docker containers and images, and then remove the PL/Container support from Greenplum Database.

When you remove support for PL/Container, the `plcontainer` user-defined functions that you created in the database will no longer work.

Uninstall Docker Containers and Images

On the Greenplum Database hosts, uninstall the Docker containers and images that are no longer required.

The `plcontainer image-list` command lists the Docker images that are installed on the local Greenplum Database host.

The `plcontainer image-delete` command deletes a specified Docker image from all Greenplum Database hosts.

Some Docker containers might exist on a host if the containers were not managed by PL/Container. You might need to remove the containers with Docker commands. These `docker` commands manage Docker containers and images on a local host.

- The command `docker ps -a` lists all containers on a host. The command `docker stop` stops a container.
- The command `docker images` lists the images on a host.
- The command `docker rmi` removes images.
- The command `docker rm` removes containers.

Remove PL/Container Support for a Database

To remove support for PL/Container, drop the extension from the database. Use the `psql` utility with `DROP EXTENSION` command (using `-c`) to remove PL/Container from `mytest` database.

```
psql -d mytest -c 'DROP EXTENSION plcontainer CASCADE;'
```

The `CASCADE` keyword drops PL/Container-specific functions and views.

Remove PL/Container 3 Beta Shared Library

This step is required only if you have installed PL/Container 3 Beta. Before you remove the extension from your system with `gppkg`, remove the shared library configuration for the `plc_coordinator` process:

- Examine the `shared_preload_libraries` server configuration parameter setting.

```
$ gpconfig -s shared_preload_libraries
```

- If `plc_coordinator` is the only library listed, remove the configuration parameter setting:

```
$ gpconfig -r shared_preload_libraries
```

Removing a server configuration parameter comments out the setting in the `postgresql.conf` file.

- If there are multiple libraries listed, remove `plc_coordinator` from the list and re-set the configuration parameter. For example, if `shared_preload_libraries` is set to `'diskquota,plc_coordinator'`:

```
$ gpconfig -c shared_preload_libraries -v 'diskquota'
```

2. Restart the Greenplum Database cluster:

```
$ gpstop -ra
```

Uninstall the PL/Container Language Extension

If no databases have `plcontainer` as a registered language, uninstall the Greenplum Database PL/Container language extension with the `gppkg` utility.

1. Use the Greenplum Database `gppkg` utility with the `-r` option to uninstall the PL/Container language extension. This example uninstalls the PL/Container language extension on a Linux system:

```
$ gppkg -r plcontainer-2.1.1
```

You can run the `gppkg` utility with the options `-q --all` to list the installed extensions and their versions.

2. Reload `greenplum_path.sh`.

```
$ source $GPHOME/greenplum_path.sh
```

3. Restart the database.

```
$ gpstop -ra
```

Notes

Docker Notes

- If a PL/Container Docker container exceeds the maximum allowed memory, it is terminated and an out of memory warning is displayed.
- PL/Container does not limit the Docker base device size, the size of the Docker container. In some cases, the Docker daemon controls the base device size. For example, if the Docker storage driver is `devicemapper`, the Docker daemon `--storage-opt` option flag `dm.basesize` controls the base device size. The default base device size for `devicemapper` is 10GB. The Docker command `docker info` displays Docker system information including the storage driver. The base device size is displayed in Docker 1.12 and later. For information about Docker storage drivers, see the Docker information [Daemon storage-driver](#).

When setting the Docker base device size, the size must be set on all Greenplum Database hosts.

- *Known issue:*

Occasionally, when PL/Container is running in a high concurrency environment, the Docker daemon hangs with log entries that indicate a memory shortage. This can happen even when the system seems to have adequate free memory.

The issue seems to be triggered by the aggressive virtual memory requirement of the Go language (golang) runtime that is used by PL/Container, and the Greenplum Database Linux server kernel parameter setting for *overcommit_memory*. The parameter is set to 2 which does not allow memory overcommit.

A workaround that might help is to increase the amount of swap space and increase the Linux server kernel parameter *overcommit_ratio*. If the issue still occurs after the changes, there might be memory shortage. You should check free memory on the system and add more RAM if needed. You can also decrease the cluster load.

Control and configure Docker with systemd <https://docs.docker.com/engine/admin/systemd/>

Using PL/Container

This topic covers further details on:

- [PL/Container Resource Management](#)
- [PL/Container Functions](#)

PL/Container Resource Management

The Docker containers and the Greenplum Database servers share CPU and memory resources on the same hosts. In the default case, Greenplum Database is unaware of the resources consumed by running PL/Container instances. You can use Greenplum Database resource groups to control overall CPU and memory resource usage for running PL/Container instances.

PL/Container manages resource usage at two levels - the container level and the runtime level. You can control container-level CPU and memory resources with the *memory_mb* and *cpu_share* settings that you configure for the PL/Container runtime. *memory_mb* governs the memory resources available to each container instance. The *cpu_share* setting identifies the relative weighting of a container's CPU usage compared to other containers. See [plcontainer Configuration File](#) for further details.

You cannot, by default, restrict the number of running PL/Container container instances, nor can you restrict the total amount of memory or CPU resources that they consume.

Using Resource Groups to Manage PL/Container Resources

With PL/Container 1.2.0 and later, you can use Greenplum Database resource groups to manage and limit the total CPU and memory resources of containers in PL/Container runtimes. For more information about enabling, configuring, and using Greenplum Database resource groups, refer to [Using Resource Groups](#) in the *Greenplum Database Administrator Guide*.

Note: If you do not explicitly configure resource groups for a PL/Container runtime, its container instances are limited only by system resources. The containers may consume resources at the expense of the Greenplum Database server.

Resource groups for external components such as PL/Container use Linux control groups (cgroups) to manage component-level use of memory and CPU resources. When you manage PL/Container resources with resource groups, you configure both a memory limit and a CPU limit that Greenplum Database applies to all container instances that share the same PL/Container runtime configuration.

When you create a resource group to manage the resources of a PL/Container runtime, you must specify `MEMORY_AUDITOR=cgroup` and `CONCURRENCY=0` in addition to the required CPU and memory limits. For example, the following command creates a resource group named `plpy_run1_rg` for a PL/Container runtime:

```
CREATE RESOURCE GROUP plpy_run1_rg WITH (MEMORY_AUDITOR=cgroup, CONCURRENCY=0,
                                         CPU_RATE_LIMIT=10, MEMORY_LIMIT=10);
```

PL/Container does not use the `MEMORY_SHARED_QUOTA` and `MEMORY_SPILL_RATIO` resource group memory limits. Refer to the [CREATE RESOURCE GROUP](#) reference page for detailed information about this SQL command.

You can create one or more resource groups to manage your running PL/Container instances. After you create a resource group for PL/Container, you assign the resource group to one or more PL/Container runtimes. You make this assignment using the `groupid` of the resource group. You can determine the `groupid` for a given resource group name from the `gp_resgroup_config gp_toolkit` view. For example, the following query displays the `groupid` of a resource group named `plpy_run1_rg`:

```
SELECT groupname, groupid FROM gp_toolkit.gp_resgroup_config
WHERE groupname='plpy_run1_rg';

groupname | groupid
-----+-----
plpy_run1_rg | 16391
(1 row)
```

You assign a resource group to a PL/Container runtime configuration by specifying the `-s resource_group_id=rg\groupid` option to the `plcontainer runtime-add` (new runtime) or `plcontainer runtime-replace` (existing runtime) commands. For example, to assign the `plpy_run1_rg` resource group to a new PL/Container runtime named `python_run1`:

```
plcontainer runtime-add -r python_run1 -i pivotaldata/plcontainer_python_shared:devel
-l python -s resource_group_id=16391
```

You can also assign a resource group to a PL/Container runtime using the `plcontainer runtime-edit` command. For information about the `plcontainer` command, see [plcontainer](#) reference page.

After you assign a resource group to a PL/Container runtime, all container instances that share the same runtime configuration are subject to the memory limit and the CPU limit that you configured for the group. If you decrease the memory limit of a PL/Container resource group, queries running in containers in the group may fail with an out of memory error. If you drop a PL/Container resource group while there are running container instances, Greenplum Database terminates the running containers.

Configuring Resource Groups for PL/Container

To use Greenplum Database resource groups to manage PL/Container resources, you must explicitly configure both resource groups and PL/Container.

Perform the following procedure to configure PL/Container to use Greenplum Database resource groups for CPU and memory resource management:

1. If you have not already configured and enabled resource groups in your Greenplum Database deployment, configure cgroups and enable Greenplum Database resource groups as described in [Using Resource Groups](#) in the *Greenplum Database Administrator Guide*.
Note: If you have previously configured and enabled resource groups in your deployment, ensure that the Greenplum Database resource group `gpdb.conf` cgroups configuration file includes a `memory { }` block as described in the previous link.
2. Analyze the resource usage of your Greenplum Database deployment. Determine the percentage of resource group CPU and memory resources that you want to allocate to PL/Container Docker containers.
3. Determine how you want to distribute the total PL/Container CPU and memory resources that you identified in the step above among the PL/Container runtimes. Identify:
 - The number of PL/Container resource group(s) that you require.
 - The percentage of memory and CPU resources to allocate to each resource group.
 - The resource-group-to-PL/Container-runtime assignment(s).
4. Create the PL/Container resource groups that you identified in the step above. For example, suppose that you choose to allocate 25% of both memory and CPU Greenplum Database resources to PL/Container. If you further split these resources among 2 resource groups 60/40, the following SQL commands create the resource groups:

```
CREATE RESOURCE GROUP plr_run1_rg WITH (MEMORY_AUDITOR=cgroup, CONCURRENCY=0,
                                         CPU_RATE_LIMIT=15, MEMORY_LIMIT=15);
CREATE RESOURCE GROUP plpy_run1_rg WITH (MEMORY_AUDITOR=cgroup, CONCURRENCY=0,
                                         CPU_RATE_LIMIT=10, MEMORY_LIMIT=10);
```

5. Find and note the `groupid` associated with each resource group that you created. For example:

```
SELECT groupname, groupid FROM gp_toolkit.gp_resgroup_config
WHERE groupname IN ('plpy_run1_rg', 'plr_run1_rg');

groupname | groupid
-----+-----
plpy_run1_rg | 16391
plr_run1_rg | 16393
(1 row)
```

6. Assign each resource group that you created to the desired PL/Container runtime configuration. If you have not yet created the runtime configuration, use the `plcontainer runtime-add` command. If the runtime already exists, use the `plcontainer runtime-replace` or `plcontainer runtime-edit` command to add the resource group assignment to the runtime configuration. For example:

```
plcontainer runtime-add -r python_run1 -i pivotaldata/plcontainer_python_shared
:devel -l python -s resource_group_id=16391
plcontainer runtime-replace -r r_run1 -i pivotaldata/plcontainer_r_shared:devel
-l r -s resource_group_id=16393
```

For information about the `plcontainer` command, see [plcontainer](#) reference page.

Notes

PL/Container logging

When PL/Container logging is enabled, you can set the log level with the Greenplum Database server configuration parameter `log_min_messages`. The default log level is `warning`. The parameter controls the PL/Container log level and also controls the Greenplum Database log level.

- PL/Container logging is enabled or disabled for each runtime ID with the `setting` attribute `use_container_logging`. The default is no logging.
- The PL/Container log information is the information from the UDF that is run in the Docker container. By default, the PL/Container log information is sent to a system service. On Red Hat 7 or CentOS 7 systems, the log information is sent to the `journald` service.
- The Greenplum Database log information is sent to log file on the Greenplum Database master.
- When testing or troubleshooting a PL/Container UDF, you can change the Greenplum Database log level with the `SET` command. You can set the parameter in the session before you run your PL/Container UDF. This example sets the log level to `debug1`.

```
SET log_min_messages='debug1' ;
```

Note: The parameter `log_min_messages` controls both the Greenplum Database and PL/Container logging, increasing the log level might affect Greenplum Database performance even if a PL/Container UDF is not running.

PL/Container Functions

When you enable PL/Container in a database of a Greenplum Database system, the language `plcontainer` is registered in that database. Specify `plcontainer` as a language in a UDF definition to create and run user-defined functions in the procedural languages supported by the PL/Container Docker images.

Limitations

Review the following limitations when creating and using PL/Container PL/Python and PL/R functions:

- Greenplum Database domains are not supported.
- Multi-dimensional arrays are not supported.
- Python and R call stack information is not displayed when debugging a UDF.
- The `plpy.execute()` methods `nrows()` and `status()` are not supported.
- The PL/Python function `plpy.SPIError()` is not supported.
- Running the `SAVEPOINT` command with `plpy.execute()` is not supported.
- The `DO` command (anonymous code block) is supported only with PL/Container 3 (currently a Beta feature).
- Container flow control is not supported.
- Triggers are not supported.

- `OUT` parameters are not supported.
- The Python `dict` type cannot be returned from a PL/Python UDF. When returning the Python `dict` type from a UDF, you can convert the `dict` type to a Greenplum Database user-defined data type (UDT).

Using PL/Container functions

A UDF definition that uses PL/Container must have the these items.

- The first line of the UDF must be `# container: ID`
- The `LANGUAGE` attribute must be `plcontainer`

The ID is the name that PL/Container uses to identify a Docker image. When Greenplum Database runs a UDF on a host, the Docker image on the host is used to start a Docker container that runs the UDF. In the XML configuration file `plcontainer_configuration.xml`, there is a `runtime` XML element that contains a corresponding `id` XML element that specifies the Docker container startup information. See [../utility_guide/ref/plcontainer-configuration.md#](#) for information about how PL/Container maps the ID to a Docker image.

The PL/Container configuration file is read only on the first invocation of a PL/Container function in each Greenplum Database session that runs PL/Container functions. You can force the configuration file to be re-read by performing a `SELECT` command on the view `plcontainer_refresh_config` during the session. For example, this `SELECT` command forces the configuration file to be read.

```
SELECT * FROM plcontainer_refresh_config;
```

The command runs a PL/Container function that updates the configuration on the master and segment instances and returns the status of the refresh.

```
gp_segment_id | plcontainer_refresh_local_config
-----+-----
1 | ok
0 | ok
-1 | ok
(3 rows)
```

Also, you can show all the configurations in the session by performing a `SELECT` command on the view `plcontainer_show_config`. For example, this `SELECT` command returns the PL/Container configurations.

```
SELECT * FROM plcontainer_show_config;
```

Running the command executes a PL/Container function that displays configuration information from the master and segment instances. This is an example of the start and end of the view output.

```

tainer_clients' to container '/clientdir' (seg0 slice3 192.168.180.45:40000 pid=3304)
INFO: plcontainer:      access = readonly (seg0 slice3 192.168.180.45:40000 pid=
3304)
gp_segment_id | plcontainer_show_local_config
-----+-----
0 | ok
-1 | ok
1 | ok

```

The PL/Container function `plcontainer_containers_summary()` displays information about the currently running Docker containers.

```
SELECT * FROM plcontainer_containers_summary();
```

If a normal (non-superuser) Greenplum Database user runs the function, the function displays information only for containers created by the user. If a Greenplum Database superuser runs the function, information for all containers created by Greenplum Database users is displayed. This is sample output when 2 containers are running.

```

SEGMENT_ID | CONTAINER_ID | UP_

minutes | gpadmin | 13628
(2 rows)

```

When Greenplum Database runs a PL/Container UDF, Query Executer (QE) processes start Docker containers and reuse them as needed. After a certain amount of idle time, a QE process quits and destroys its Docker containers. You can control the amount of idle time with the Greenplum Database server configuration parameter `gp_vmem_idle_resource_timeout`. Controlling the idle time might help with Docker container reuse and avoid the overhead of creating and starting a Docker container.

Warning: Changing `gp_vmem_idle_resource_timeout` value, might affect performance due to resource issues. The parameter also controls the freeing of Greenplum Database resources other than Docker containers.

Examples

The values in the `# container` lines of the examples, `plc_python_shared` and `plc_r_shared`, are the `id` XML elements defined in the `plcontainer_config.xml` file. The `id` element is mapped to the `image` element that specifies the Docker image to be started. If you configured PL/Container with a different ID, change the value of the `# container` line. For information about configuring PL/Container and viewing the configuration settings, see [plcontainer Configuration File](#).

This is an example of PL/Python function that runs using the `plc_python_shared` container that contains Python 2:

```
CREATE OR REPLACE FUNCTION pylog100() RETURNS double precision AS $$
# container: plc_python_shared
import math
return math.log10(100)
$$ LANGUAGE plcontainer;
```

This is an example of a similar function using the `plc_r_shared` container:

```
CREATE OR REPLACE FUNCTION rlog100() RETURNS text AS $$
# container: plc_r_shared
return(log10(100))
$$ LANGUAGE plcontainer;
```

If the `# container` line in a UDF specifies an ID that is not in the PL/Container configuration file, Greenplum Database returns an error when you try to run the UDF.

About PL/Container Running PL/Python

In the Python language container, the module `plpy` is implemented. The module contains these methods:

- `plpy.execute(stmt)` - Runs the query string `stmt` and returns query result in a list of dictionary objects. To be able to access the result fields ensure your query returns named fields.
- `plpy.prepare(stmt[, argtypes])` - Prepares the execution plan for a query. It is called with a query string and a list of parameter types, if you have parameter references in the query.
- `plpy.execute(plan[, argtypes])` - Runs a prepared plan.
- `plpy.debug(msg)` - Sends a DEBUG2 message to the Greenplum Database log.
- `plpy.log(msg)` - Sends a LOG message to the Greenplum Database log.
- `plpy.info(msg)` - Sends an INFO message to the Greenplum Database log.
- `plpy.notice(msg)` - Sends a NOTICE message to the Greenplum Database log.
- `plpy.warning(msg)` - Sends a WARNING message to the Greenplum Database log.
- `plpy.error(msg)` - Sends an ERROR message to the Greenplum Database log. An ERROR message raised in Greenplum Database causes the query execution process to stop and the transaction to rollback.
- `plpy.fatal(msg)` - Sends a FATAL message to the Greenplum Database log. A FATAL message causes Greenplum Database session to be closed and transaction to be rolled back.
- `plpy.subtransaction()` - Manages `plpy.execute` calls in an explicit subtransaction. See [Explicit Subtransactions](#) in the PostgreSQL documentation for additional information about `plpy.subtransaction()`.

If an error of level `ERROR` or `FATAL` is raised in a nested Python function call, the message includes the list of enclosing functions.

The Python language container supports these string quoting functions that are useful when constructing ad-hoc queries.

- `plpy.quote_literal(string)` - Returns the string quoted to be used as a string literal in an SQL statement string. Embedded single-quotes and backslashes are properly doubled. `quote_literal()` returns null on null input (empty input). If the argument might be null, `quote_nullable()` might be more appropriate.
- `plpy.quote_nullable(string)` - Returns the string quoted to be used as a string literal in an

SQL statement string. If the argument is null, returns `NULL`. Embedded single-quotes and backslashes are properly doubled.

- `plpy.quote_ident(string)` - Returns the string quoted to be used as an identifier in an SQL statement string. Quotes are added only if necessary (for example, if the string contains non-identifier characters or would be case-folded). Embedded quotes are properly doubled.

When returning text from a PL/Python function, PL/Container converts a Python unicode object to text in the database encoding. If the conversion cannot be performed, an error is returned.

PL/Container does not support this Greenplum Database PL/Python feature:

- Multi-dimensional arrays.

Also, the Python module has two global dictionary objects that retain the data between function calls. They are named GD and SD. GD is used to share the data between all the function running within the same container, while SD is used for sharing the data between multiple calls of each separate function. Be aware that accessing the data is possible only within the same session, when the container process lives on a segment or master. Be aware that for idle sessions Greenplum Database terminates segment processes, which means the related containers would be shut down and the data from GD and SD lost.

For information about PL/Python, see [PL/Python Language](#).

For information about the `plpy` methods, see <https://www.postgresql.org/docs/9.4/plpython-database.htm>.

About PL/Container Running PL/Python with Python 3

PL/Container for Greenplum Database 5 supports Python version 3.6+. PL/Container for Greenplum Database 6 supports Python 3.7+.

If you want to use PL/Container to run the same function body in both Python2 and Python3, you must create 2 different user-defined functions.

Keep in mind that UDFs that you created for Python 2 may not run in PL/Container with Python 3. The following Python references may be useful:

- Changes to Python - [What's New in Python 3](#)
- Porting from Python 2 to 3 - [Porting Python 2 Code to Python 3](#)

About PL/Container Running PL/R

In the R language container, the module `pg.spi` is implemented. The module contains these methods:

- `pg.spi.exec(stmt)` - Runs the query string `stmt` and returns query result in R `data.frame`. To be able to access the result fields make sure your query returns named fields.
- `pg.spi.prepare(stmt[, argtypes])` - Prepares the execution plan for a query. It is called with a query string and a list of parameter types if you have parameter references in the query.
- `pg.spi.execp(plan[, argtypes])` - Runs a prepared plan.
- `pg.spi.debug(msg)` - Sends a DEBUG2 message to the Greenplum Database log.
- `pg.spi.log(msg)` - Sends a LOG message to the Greenplum Database log.
- `pg.spi.info(msg)` - Sends an INFO message to the Greenplum Database log.
- `pg.spi.notice(msg)` - Sends a NOTICE message to the Greenplum Database log.

- `pg.spi.warning(msg)` - Sends a WARNING message to the Greenplum Database log.
- `pg.spi.error(msg)` - Sends an ERROR message to the Greenplum Database log. An ERROR message raised in Greenplum Database causes the query execution process to stop and the transaction to rollback.
- `pg.spi.fatal(msg)` - Sends a FATAL message to the Greenplum Database log. A FATAL message causes Greenplum Database session to be closed and transaction to be rolled back.

PL/Container does not support this PL/R feature:

- Multi-dimensional arrays.

For information about PL/R, see [PL/R Language](#).

For information about the `pg.spi` methods, see <http://www.joeconway.com/plr/doc/plr-spi-rsupport-funcs-normal.html>

PL/Java Language

This section contains an overview of the Greenplum Database PL/Java language.

About PL/Java

With the Greenplum Database PL/Java extension, you can write Java methods using your favorite Java IDE and install the JAR files that contain those methods into Greenplum Database.

Greenplum Database PL/Java package is based on the open source PL/Java 1.5.0. Greenplum Database PL/Java provides the following features.

- Ability to run PL/Java functions with Java 8 or Java 11.
- Ability to specify Java runtime.
- Standardized utilities (modeled after the SQL 2003 proposal) to install and maintain Java code in the database.
- Standardized mappings of parameters and result. Complex types as well as sets are

supported.

- An embedded, high performance, JDBC driver utilizing the internal Greenplum Database SPI routines.
- Metadata support for the JDBC driver. Both `DatabaseMetaData` and `ResultSetMetaData` are included.
- The ability to return a `ResultSet` from a query as an alternative to building a `ResultSet` row by row.
- Full support for savepoints and exception handling.
- The ability to use IN, INOUT, and OUT parameters.
- Two separate Greenplum Database languages:
 - ◊ `pljava`, TRUSTED PL/Java language
 - ◊ `pljavau`, UNTRUSTED PL/Java language
- Transaction and Savepoint listeners enabling code execution when a transaction or savepoint is committed or rolled back.
- Integration with GNU GCJ on selected platforms.

A function in SQL will appoint a static method in a Java class. In order for the function to run, the appointed class must be available on the class path specified by the Greenplum Database server configuration parameter `pljava_classpath`. The PL/Java extension adds a set of functions that help installing and maintaining the Java classes. Classes are stored in normal Java archives, JAR files. A JAR file can optionally contain a deployment descriptor that in turn contains SQL commands to be run when the JAR is deployed or undeployed. The functions are modeled after the standards proposed for SQL 2003.

PL/Java implements a standardized way of passing parameters and return values. Complex types and sets are passed using the standard JDBC `ResultSet` class.

A JDBC driver is included in PL/Java. This driver calls Greenplum Database internal SPI routines. The driver is essential since it is common for functions to make calls back to the database to fetch data. When PL/Java functions fetch data, they must use the same transactional boundaries that are used by the main function that entered PL/Java execution context.

PL/Java is optimized for performance. The Java virtual machine runs within the same process as the backend to minimize call overhead. PL/Java is designed with the objective to enable the power of Java to the database itself so that database intensive business logic can run as close to the actual data as possible.

The standard Java Native Interface (JNI) is used when bridging calls between the backend and the Java VM.

About Greenplum Database PL/Java

There are a few key differences between the implementation of PL/Java in standard PostgreSQL and Greenplum Database.

Functions

The following functions are not supported in Greenplum Database. The classpath is handled differently in a distributed Greenplum Database environment than in the PostgreSQL environment.

- `sqlj.install_jar`
- `sqlj.replace_jar`

- `sqlj.remove_jar`
- `sqlj.get_classpath`
- `sqlj.set_classpath`

Greenplum Database uses the `pljava_classpath` server configuration parameter in place of the `sqlj.set_classpath` function.

Server Configuration Parameters

The following server configuration parameters are used by PL/Java in Greenplum Database. These parameters replace the `pljava.*` parameters that are used in the standard PostgreSQL PL/Java implementation:

- `pljava_classpath`

A colon (:) separated list of the jar files containing the Java classes used in any PL/Java functions. The jar files must be installed in the same locations on all Greenplum Database hosts. With the trusted PL/Java language handler, jar file paths must be relative to the `$GPHOME/lib/postgresql/java/` directory. With the untrusted language handler (javaU language tag), paths may be relative to `$GPHOME/lib/postgresql/java/` or absolute.

The server configuration parameter `pljava_classpath_insecure` controls whether the server configuration parameter `pljava_classpath` can be set by a user without Greenplum Database superuser privileges. When `pljava_classpath_insecure` is enabled, Greenplum Database developers who are working on PL/Java functions do not have to be database superusers to change `pljava_classpath`.

Warning: Enabling `pljava_classpath_insecure` exposes a security risk by giving non-administrator database users the ability to run unauthorized Java methods.

- `pljava_statement_cache_size`

Sets the size in KB of the Most Recently Used (MRU) cache for prepared statements.

- `pljava_release_lingering_savepoints`

If `TRUE`, lingering savepoints will be released on function exit. If `FALSE`, they will be rolled back.

- `pljava_vmoptions`

Defines the start up options for the Greenplum Database Java VM.

See the *Greenplum Database Reference Guide* for information about the Greenplum Database server configuration parameters.

Installing Java

PL/Java requires a Java runtime environment on each Greenplum Database host. Ensure that the same Java environment is at the same location on all hosts: masters and segments. The command `java -version` displays the Java version.

The commands that you use to install Java depend on the host system operating system and Java version. This list describes how to install OpenJDK 8 or 11 (Java 8 JDK or Java 11 JDK) on RHEL/CentOS or Ubuntu.

- RHEL 7/CentOS 7 - This `yum` command installs OpenJDK 8 or 11.

```
$ sudo yum install java-<version>-openjdk-devel
```

For OpenJDK 8 the version is **1.8.0**, for OpenJDK 11 the version is **11**.

- RHEL 6/CentOS 6

- Java 8 - This **yum** command installs OpenJDK 8.

```
$ sudo yum install java-1.8.0-openjdk-devel
```

- Java 11 - Download the OpenJDK 11 tar file from <http://jdk.java.net/archive/> and install and configure the operating system to use Java 11.

1. This example **tar** command installs the OpenJDK 11 in **/usr/lib/jvm**.

```
$ sudo tar xzf openjdk-11.0.2_linux-x64_bin.tar.gz --directory /usr/lib/jvm
```

2. Run these two commands to add OpenJDK 11 to the **update-alternatives** command. The **update-alternatives** command maintains symbolic links that determine the default version of operating system commands.

```
$ sudo sh -c 'for bin in /usr/lib/jvm/jdk-11.0.2/bin/*; do update-alternatives --install /usr/bin/$(basename $bin) $(basename $bin) $bin 100; done'
$ sudo sh -c 'for bin in /usr/lib/jvm/jdk-11.0.2/bin/*; do update-alternatives --set $(basename $bin) $bin; done'
```

The second command returns some **failed to read link** errors that can be ignored.

- Ubuntu - These **apt** commands install OpenJDK 8 or 11.

```
$ sudo apt update
$ sudo apt install openjdk-<version>-jdk
```

For OpenJDK 8 the version is **8**, for OpenJDK 11 the version is **11**.

After installing OpenJDK on a RHEL or CentOS system, run this **update-alternatives** command to change the default Java. Enter the number that represents the OpenJDK version to use as the default.

```
$ sudo update-alternatives --config java
```

The **update-alternatives** command is not required on Ubuntu systems.

Note: When configuring host systems, you can use the **gpssh** utility to run bash shell commands on multiple remote hosts.

Installing PL/Java

For Greenplum Database, the PL/Java extension is available as a package. Download the package from the Greenplum Database page on [VMware Tanzu Network](#) and then install the software with the Greenplum Package Manager (**gppkg**).

The **gppkg** utility installs Greenplum Database extensions, along with any dependencies, on all hosts across a cluster. It also automatically installs extensions on new hosts in the case of system expansion and segment recovery.

To install and use PL/Java:

1. Specify the Java version used by PL/Java. Set the environment variables **JAVA_HOME** and

`LD_LIBRARY_PATH` in the `greenplum_path.sh`.

2. Install the Greenplum Database PL/Java extension.
3. Enable the language for each database where you intend to use PL/Java.
4. Install user-created JAR files containing Java methods into the same directory on all Greenplum Database hosts.
5. Add the name of the JAR file to the Greenplum Database server configuration parameter `pljava_classpath`. The parameter lists the installed JAR files. For information about the parameter, see the *Greenplum Database Reference Guide*.

Installing the Greenplum PL/Java Extension

Before you install the PL/Java extension, make sure that your Greenplum database is running, you have sourced `greenplum_path.sh`, and that the `$MASTER_DATA_DIRECTORY` and `$GPHOME` variables are set.

1. Download the PL/Java extension package from [VMware Tanzu Network](#) then copy it to the master host.
2. Follow the instructions in [Verifying the Greenplum Database Software Download](#) to verify the integrity of the **Greenplum Procedural Languages PL/Java** software.
3. Install the software extension package by running the `gppkg` command. This example installs the PL/Java extension package on a Linux system:

```
$ gppkg -i pljava-1.4.3-gp5-rhel<osversion>_x86_64.gppkg
```

4. Ensure that the environment variables `JAVA_HOME` and `LD_LIBRARY_PATH` are set properly in `$GPHOME/greenplum_path.sh` on all Greenplum Database hosts.
 - Set the `JAVA_HOME` variable to the directory where your Java Runtime is installed. For example, for Oracle JRE this directory would be `/usr/java/latest`. For OpenJDK, the directory is `/usr/lib/jvm`. This example changes the environment variable to use `/usr/lib/jvm`.

```
export JAVA_HOME=/usr/lib/jvm
```

- Set the `LD_LIBRARY_PATH` to include the directory with the Java server runtime libraries. PL/Java depends on `libjvm.so` and the shared object should be in your `LD_LIBRARY_PATH`. By default, `libjvm.so` is available in `$JAVA_HOME/lib/server` with JDK 11, or in `$JAVA_HOME/jre/lib/amd64/server` with JDK 8. This example adds the JDK 11 directory to the environment variable.

```
export LD_LIBRARY_PATH=$GPHOME/lib:$GPHOME/ext/python/lib:$JAVA_HOME/lib/server:$LD_LIBRARY_PATH
```

This example `gpscp` command copies the file to all hosts specified in the file `gphosts_file`.

```
$ gpscp -f gphosts_file $GPHOME/greenplum_path.sh
=:$GPHOME/greenplum_path.sh
```

5. Reload `greenplum_path.sh`.

```
$ source $GPHOME/greenplum_path.sh
```

6. Restart Greenplum Database.

```
$ gpstop -r
```

Enabling PL/Java and Installing JAR Files

Perform the following steps as the Greenplum Database administrator `gpadmin`.

1. Enable PL/Java in a database by running the `CREATE EXTENSION` command to register the language. For example, this command enables PL/Java in the `testdb` database:

```
$ psql -d testdb -c 'CREATE EXTENSION pljava;'
```

Note: The PL/Java `install.sql` script, used in previous releases to register the language, is deprecated.

2. Copy your Java archives (JAR files) to the same directory on all Greenplum Database hosts. This example uses the Greenplum Database `gpscp` utility to copy the file `myclasses.jar` to the directory `$GPHOME/lib/postgresql/java/`:

```
$ gpscp -f gphosts_file myclasses.jar
=:/usr/local/greenplum-db/lib/postgresql/java/
```

The file `gphosts_file` contains a list of the Greenplum Database hosts.

3. Set the `pljava_classpath` server configuration parameter in the master `postgresql.conf` file. For this example, the parameter value is a colon (:) separated list of the JAR files. For example:

```
$ gpconfig -c pljava_classpath -v 'examples.jar:myclasses.jar'
```

The file `examples.jar` is installed when you install the PL/Java extension package with the `gppkg` utility.

Note: If you install JAR files in a directory other than `$GPHOME/lib/postgresql/java/`, you must specify the absolute path to the JAR file. Each JAR file must be in the same location on all Greenplum Database hosts. For more information about specifying the location of JAR files, see the information about the `pljava_classpath` server configuration parameter in the *Greenplum Database Reference Guide*.

4. Reload the `postgresql.conf` file.

```
$ gpstop -u
```

5. (optional) Greenplum provides an `examples.sql` file containing sample PL/Java functions that you can use for testing. Run the commands in this file to create the test functions (which use the Java classes in `examples.jar`).

```
$ psql -f $GPHOME/share/postgresql/pljava/examples.sql
```

Uninstalling PL/Java

- [Remove PL/Java Support for a Database](#)
- [Uninstall the Java JAR files and Software Package](#)

Remove PL/Java Support for a Database

Use the `DROP EXTENSION` command to remove support for PL/Java from a database. For example, this command disables the PL/Java language in the `testdb` database:

```
$ psql -d testdb -c 'DROP EXTENSION pljava;'
```

The default command fails if any existing objects (such as functions) depend on the language. Specify the `CASCADE` option to also drop all dependent objects, including functions that you created with PL/Java.

Note: The PL/Java `uninstall.sql` script, used in previous releases to remove the language registration, is deprecated.

Uninstall the Java JAR files and Software Package

If no databases have PL/Java as a registered language, remove the Java JAR files and uninstall the Greenplum PL/Java extension with the `gppkg` utility.

1. Remove the `pljava_classpath` server configuration parameter from the `postgresql.conf` file on all Greenplum Database hosts. For example:

```
$ gpconfig -r pljava_classpath
```

2. Remove the JAR files from the directories where they were installed on all Greenplum Database hosts. For information about JAR file installation directories, see [Enabling PL/Java and Installing JAR Files](#).
3. Use the Greenplum `gppkg` utility with the `-r` option to uninstall the PL/Java extension. This example uninstalls the PL/Java extension on a Linux system:

```
$ gppkg -r pljava-1.4.3
```

You can run the `gppkg` utility with the options `-q --all` to list the installed extensions and their versions.

4. Remove any updates you made to `greenplum_path.sh` for PL/Java.
5. Reload `greenplum_path.sh` and restart the database

```
$ source $GPHOME/greenplum_path.sh
$ gpstop -r
```

Writing PL/Java functions

Information about writing functions with PL/Java.

- [SQL Declaration](#)
- [Type Mapping](#)
- [NULL Handling](#)
- [Complex Types](#)
- [Returning Complex Types](#)
- [Returning Complex Types](#)
- [Functions That Return Sets](#)
- [Returning a SETOF <scalar type>](#)
- [Returning a SETOF <complex type>](#)

SQL Declaration

A Java function is declared with the name of a class and a static method on that class. The class will be resolved using the classpath that has been defined for the schema where the function is declared. If no classpath has been defined for that schema, the public schema is used. If no classpath is found there either, the class is resolved using the system classloader.

The following function can be declared to access the static method `getProperty` on `java.lang.System` class:

```
CREATE FUNCTION getsysprop(VARCHAR)
  RETURNS VARCHAR
  AS 'java.lang.System.getProperty'
  LANGUAGE java;
```

Run the following command to return the Java `user.home` property:

```
SELECT getsysprop('user.home');
```

Type Mapping

Scalar types are mapped in a straight forward way. This table lists the current mappings.

PostgreSQL	Java
bool	boolean
char	byte
int2	short
int4	int
int8	long
varchar	java.lang.String
text	java.lang.String
bytea	byte[]
date	java.sql.Date
time	java.sql.Time (stored value treated as local time)
timetz	java.sql.Time
timestamp	java.sql.Timestamp (stored value treated as local time)
timestampz	java.sql.Timestamp
complex	java.sql.ResultSet
setof complex	java.sql.ResultSet

All other types are mapped to `java.lang.String` and will utilize the standard `textin/textout` routines registered for respective type.

NULL Handling

The scalar types that map to Java primitives can not be passed as `NULL` values. To pass `NULL` values, those types can have an alternative mapping. You enable this mapping by explicitly denoting it in the method reference.

```
CREATE FUNCTION trueIfEvenOrNull(integer)
  RETURNS bool
  AS 'foo.fee.Fum.trueIfEvenOrNull(java.lang.Integer)'
  LANGUAGE java;
```

The Java code would be similar to this:

```
package foo.fee;
public class Fum
{
    static boolean trueIfEvenOrNull(Integer value)
    {
        return (value == null)
            ? true
            : (value.intValue() % 2) == 0;
    }
}
```

The following two statements both yield true:

```
SELECT trueIfEvenOrNull(NULL);
SELECT trueIfEvenOrNull(4);
```

In order to return **NULL** values from a Java method, you use the object type that corresponds to the primitive (for example, you return `java.lang.Integer` instead of `int`). The PL/Java resolve mechanism finds the method regardless. Since Java cannot have different return types for methods with the same name, this does not introduce any ambiguity.

Complex Types

A complex type will always be passed as a read-only `java.sql.ResultSet` with exactly one row. The `ResultSet` is positioned on its row so a call to `next()` should not be made. The values of the complex type are retrieved using the standard getter methods of the `ResultSet`.

Example:

```
CREATE TYPE complexTest
  AS(base integer, incbase integer, ctime timestamptz);
CREATE FUNCTION useComplexTest(complexTest)
  RETURNS VARCHAR
  AS 'foo.fee.Fum.useComplexTest'
  IMMUTABLE LANGUAGE java;
```

In the Java class `Fum`, we add the following static method:

```
public static String useComplexTest(ResultSet complexTest)
  throws SQLException
{
    int base = complexTest.getInt(1);
    int incbase = complexTest.getInt(2);
    Timestamp ctime = complexTest.getTimestamp(3);
    return "Base = \"" + base +
        "\", incbase = \"" + incbase +
        "\", ctime = \"" + ctime + "\"";
}
```

Returning Complex Types

Java does not stipulate any way to create a `ResultSet`. Hence, returning a `ResultSet` is not an option. The SQL-2003 draft suggests that a complex return value should be handled as an IN/OUT

parameter. PL/Java implements a `ResultSet` that way. If you declare a function that returns a complex type, you will need to use a Java method with boolean return type with a last parameter of type `java.sql.ResultSet`. The parameter will be initialized to an empty updateable `ResultSet` that contains exactly one row.

Assume that the `complexTest` type in previous section has been created.

```
CREATE FUNCTION createComplexTest(int, int)
  RETURNS complexTest
  AS 'foo.fee.Fum.createComplexTest'
  IMMUTABLE LANGUAGE java;
```

The PL/Java method resolve will now find the following method in the `Fum` class:

```
public static boolean complexReturn(int base, int increment,
    ResultSet receiver)
    throws SQLException
{
    receiver.updateInt(1, base);
    receiver.updateInt(2, base + increment);
    receiver.updateTimestamp(3, new
        Timestamp(System.currentTimeMillis()));
    return true;
}
```

The return value denotes if the receiver should be considered as a valid tuple (true) or NULL (false).

Functions That Return Sets

When returning result sets, you should not build a result set before returning it, because building a large result set would consume a large amount of resources. It is better to produce one row at a time. Incidentally, that is what the Greenplum Database backend expects a function with `SETOF` return to do. You can return a `SETOF` a scalar type such as an `int`, `float` or `varchar`, or you can return a `SETOF` a complex type.

Returning a SETOF <scalar type>

In order to return a set of a scalar type, you need create a Java method that returns something that implements the `java.util.Iterator` interface. Here is an example of a method that returns a `SETOF varchar`:

```
CREATE FUNCTION javatest.getSystemProperties()
  RETURNS SETOF varchar
  AS 'foo.fee.Bar.getNames'
  IMMUTABLE LANGUAGE java;
```

This simple Java method returns an iterator:

```
package foo.fee;
import java.util.Iterator;

public class Bar
{
    public static Iterator getNames()
    {
        ArrayList names = new ArrayList();
        names.add("Lisa");
        names.add("Bob");
        names.add("Bill");
        names.add("Sally");
    }
}
```

```

        return names.iterator();
    }
}

```

Returning a SETOF <complex type>

A method returning a SETOF <complex type> must use either the interface `org.postgresql.pljava.ResultSetProvider` or `org.postgresql.pljava.ResultSetHandle`. The reason for having two interfaces is that they cater for optimal handling of two distinct use cases. The former is for cases when you want to dynamically create each row that is to be returned from the SETOF function. The latter makes sense in cases where you want to return the result of a query after it runs.

Using the ResultSetProvider Interface

This interface has two methods. The boolean `assignRowValues(java.sql.ResultSet tupleBuilder, int rowNum)` and the `void close()` method. The Greenplum Database query evaluator will call the `assignRowValues` repeatedly until it returns false or until the evaluator decides that it does not need any more rows. Then it calls `close`.

You can use this interface the following way:

```

CREATE FUNCTION javatest.listComplexTests(int, int)
RETURNS SETOF complexTest
AS 'foo.fee.Fum.listComplexTest'
IMMUTABLE LANGUAGE java;

```

The function maps to a static java method that returns an instance that implements the `ResultSetProvider` interface.

```

public class Fum implements ResultSetProvider
{
    private final int m_base;
    private final int m_increment;
    public Fum(int base, int increment)
    {
        m_base = base;
        m_increment = increment;
    }
    public boolean assignRowValues(ResultSet receiver, int
currentRow)
    throws SQLException
    {
        // Stop when we reach 12 rows.
        //
        if(currentRow >= 12)
            return false;
        receiver.updateInt(1, m_base);
        receiver.updateInt(2, m_base + m_increment * currentRow);
        receiver.updateTimestamp(3, new
Timestamp(System.currentTimeMillis()));
        return true;
    }
    public void close()
    {
        // Nothing needed in this example
    }
    public static ResultSetProvider listComplexTests(int base,
int increment)
    throws SQLException
    {

```

```

        return new Fum(base, increment);
    }
}

```

The `listComplexTests` method is called once. It may return `NULL` if no results are available or an instance of the `ResultSetProvider`. Here the Java class `Fum` implements this interface so it returns an instance of itself. The method `assignRowValues` will then be called repeatedly until it returns false. At that time, `close` will be called.

Using the ResultSetHandle Interface

This interface is similar to the `ResultSetProvider` interface in that it has a `close()` method that will be called at the end. But instead of having the evaluator call a method that builds one row at a time, this method has a method that returns a `ResultSet`. The query evaluator will iterate over this set and deliver the `ResultSet` contents, one tuple at a time, to the caller until a call to `next()` returns false or the evaluator decides that no more rows are needed.

Here is an example that runs a query using a statement that it obtained using the default connection. The SQL suitable for the deployment descriptor looks like this:

```

CREATE FUNCTION javatest.listSupers()
  RETURNS SETOF pg_user
  AS 'org.postgresql.pljava.example.Users.listSupers'
  LANGUAGE java;
CREATE FUNCTION javatest.listNonSupers()
  RETURNS SETOF pg_user
  AS 'org.postgresql.pljava.example.Users.listNonSupers'
  LANGUAGE java;

```

And in the Java package `org.postgresql.pljava.example` a class `Users` is added:

```

public class Users implements ResultSetHandle
{
    private final String m_filter;
    private Statement m_statement;
    public Users(String filter)
    {
        m_filter = filter;
    }
    public ResultSet getResultSet()
    throws SQLException
    {
        m_statement =
            DriverManager.getConnection("jdbc:default:connection").createStatement();
        return m_statement.executeQuery("SELECT * FROM pg_user
            WHERE " + m_filter);
    }

    public void close()
    throws SQLException
    {
        m_statement.close();
    }

    public static ResultSetHandle listSupers()
    {
        return new Users("usesuper = true");
    }

    public static ResultSetHandle listNonSupers()
    {

```

```

    return new Users("usesuper = false");
}
}

```

Using JDBC

PL/Java contains a JDBC driver that maps to the PostgreSQL SPI functions. A connection that maps to the current transaction can be obtained using the following statement:

```

Connection conn =
    DriverManager.getConnection("jdbc:default:connection");

```

After obtaining a connection, you can prepare and run statements similar to other JDBC connections. These are limitations for the PL/Java JDBC driver:

- The transaction cannot be managed in any way. Thus, you cannot use methods on the connection such as:
 - ◊ `commit()`
 - ◊ `rollback()`
 - ◊ `setAutoCommit()`
 - ◊ `setTransactionIsolation()`
- Savepoints are available with some restrictions. A savepoint cannot outlive the function in which it was set and it must be rolled back or released by that same function.
- A `ResultSet` returned from `executeQuery()` are always `FETCH_FORWARD` and `CONCUR_READ_ONLY`.
- Metadata is only available in PL/Java 1.1 or higher.
- `CallableStatement` (for stored procedures) is not implemented.
- The types `Clob` or `Blob` are not completely implemented, they need more work. The types `byte[]` and `String` can be used for `bytea` and `text` respectively.

Exception Handling

You can catch and handle an exception in the Greenplum Database backend just like any other exception. The backend `ErrorData` structure is exposed as a property in a class called `org.postgresql.pljava.ServerException` (derived from `java.sql.SQLException`) and the Java try/catch mechanism is synchronized with the backend mechanism.

Important: You will not be able to continue running backend functions until your function has returned and the error has been propagated when the backend has generated an exception unless you have used a savepoint. When a savepoint is rolled back, the exceptional condition is reset and you can continue your execution.

Savepoints

Greenplum Database savepoints are exposed using the `java.sql.Connection` interface. Two restrictions apply.

- A savepoint must be rolled back or released in the function where it was set.
- A savepoint must not outlive the function where it was set.

Logging

PL/Java uses the standard Java Logger. Hence, you can write things like:

```
Logger.getAnonymousLogger().info( "Time is " + new
Date(System.currentTimeMillis()));
```

At present, the logger uses a handler that maps the current state of the Greenplum Database configuration setting `log_min_messages` to a valid Logger level and that outputs all messages using the Greenplum Database backend function `eelog()`.

Note: The `log_min_messages` setting is read from the database the first time a PL/Java function in a session is run. On the Java side, the setting does not change after the first PL/Java function execution in a specific session until the Greenplum Database session that is working with PL/Java is restarted.

The following mapping apply between the Logger levels and the Greenplum Database backend levels.

java.util.logging.Level	Greenplum Database Level
SEVERE ERROR	ERROR
WARNING	WARNING
CONFIG	LOG
INFO	INFO
FINE	DEBUG1
FINER	DEBUG2
FINEST	DEBUG3

Security

- [Installation](#)
- [Trusted Language](#)

Installation

Only a database superuser can install PL/Java. The PL/Java utility functions are installed using SECURITY DEFINER so that they run with the access permissions that were granted to the creator of the functions.

Trusted Language

PL/Java is a *trusted* language. The trusted PL/Java language has no access to the file system as stipulated by PostgreSQL definition of a trusted language. Any database user can create and access functions in a trusted language.

PL/Java also installs a language handler for the language `javau`. This version is *not trusted* and only a superuser can create new functions that use it. Any user can call the functions.

To install both the trusted and untrusted languages, register the extension by running the `'CREATE EXTENSION pljava'` command when [Enabling PL/Java and Installing JAR Files](#).

To install only the trusted language, register the extension by running the `'CREATE EXTENSION pljavat'` command when [Enabling PL/Java and Installing JAR Files](#).

Some PL/Java Issues and Solutions

When writing the PL/Java, mapping the JVM into the same process-space as the Greenplum Database backend code, some concerns have been raised regarding multiple threads, exception handling, and memory management. Here are brief descriptions explaining how these issues were resolved.

- [Multi-threading](#)
- [Exception Handling](#)
- [Java Garbage Collector Versus palloc\(\) and Stack Allocation](#)

Multi-threading

Java is inherently multi-threaded. The Greenplum Database backend is not. There is nothing stopping a developer from utilizing multiple `Threads` class in the Java code. Finalizers that call out to the backend might have been spawned from a background Garbage Collection thread. Several third party Java-packages that are likely to be used make use of multiple threads. How can this model coexist with the Greenplum Database backend in the same process?

Solution

The solution is simple. PL/Java defines a special object called the `Backend.THREADLOCK`. When PL/Java is initialized, the backend immediately grabs this object's monitor (i.e. it will synchronize on this object). When the backend calls a Java function, the monitor is released and then immediately regained when the call returns. All calls from Java out to backend code are synchronized on the same lock. This ensures that only one thread at a time can call the backend from Java, and only at a time when the backend is awaiting the return of a Java function call.

Exception Handling

Java makes frequent use of try/catch/finally blocks. Greenplum Database sometimes uses an exception mechanism that calls `longjmp` to transfer control to a known state. Such a jump would normally effectively bypass the JVM.

Solution

The backend now allows errors to be caught using the macros `PG_TRY/PG_CATCH/PG_END_TRY` and in the catch block, the error can be examined using the `ErrorData` structure. PL/Java implements a `java.sql.SQLException` subclass called `org.postgresql.pljava.ServerException`. The `ErrorData` can be retrieved and examined from that exception. A catch handler is allowed to issue a rollback to a savepoint. After a successful rollback, execution can continue.

Java Garbage Collector Versus palloc() and Stack Allocation

Primitive types are always passed by value. This includes the `String` type (this is a must since Java uses double byte characters). Complex types are often wrapped in Java objects and passed by reference. For example, a Java object can contain a pointer to a `palloc`'ed or stack allocated memory and use native JNI calls to extract and manipulate data. Such data will become stale once a call has ended. Further attempts to access such data will at best give very unpredictable results but more likely cause a memory fault and a crash.

Solution

The PL/Java contains code that ensures that stale pointers are cleared when the `MemoryContext` or stack where they were allocated goes out of scope. The Java wrapper objects might live on but any

attempt to use them will result in a stale native handle exception.

Example

The following simple Java example creates a JAR file that contains a single method and runs the method.

Note: The example requires Java SDK to compile the Java file.

The following method returns a substring.

```
{
public static String substring(String text, int beginIndex,
int endIndex)
{
return text.substring(beginIndex, endIndex);
}
}
```

Enter the java code in a text file `example.class`.

Contents of the file `manifest.txt`:

```
Manifest-Version: 1.0
Main-Class: Example
Specification-Title: "Example"
Specification-Version: "1.0"
Created-By: 1.6.0_35-b10-428-11M3811
Build-Date: 01/20/2013 10:09 AM
```

Compile the java code:

```
javac *.java
```

Create a JAR archive named `analytics.jar` that contains the class file and the manifest file `MANIFEST` file in the JAR.

```
jar cfm analytics.jar manifest.txt *.class
```

Upload the jar file to the Greenplum master host.

Run the `gpscp` utility to copy the jar file to the Greenplum Java directory. Use the `-f` option to specify the file that contains a list of the master and segment hosts.

```
gpscp -f gphosts_file analytics.jar
=:/usr/local/greenplum-db/lib/postgresql/java/
```

Use the `gpconfig` utility to set the Greenplum `pljava_classpath` server configuration parameter. The parameter lists the installed jar files.

```
gpconfig -c pljava_classpath -v 'analytics.jar'
```

Run the `gpstop` utility with the `-u` option to reload the configuration files.

```
gpstop -u
```

From the `psql` command line, run the following command to show the installed jar files.

```
show pljava_classpath
```

The following SQL commands create a table and define a Java function to test the method in the jar file:

```
create table temp (a varchar) distributed randomly;
insert into temp values ('my string');
--Example function
create or replace function java_substring(varchar, int, int)
returns varchar as 'Example.substring' language java;
--Example execution
select java_substring(a, 1, 5) from temp;
```

You can place the contents in a file, `mysample.sql` and run the command from a `psql` command line:

```
> \i mysample.sql
```

The output is similar to this:

```
java_substring
-----
 y st
(1 row)
```

PL/Perl Language

This chapter includes the following information:

- [About Greenplum PL/Perl](#)
- [Greenplum Database PL/Perl Limitations](#)
- [Trusted/Untrusted Language](#)
- [Developing Functions with PL/Perl](#)

About Greenplum PL/Perl

With the Greenplum Database PL/Perl extension, you can write user-defined functions in Perl that take advantage of its advanced string manipulation operators and functions. PL/Perl provides both trusted and untrusted variants of the language.

PL/Perl is embedded in your Greenplum Database distribution. Greenplum Database PL/Perl requires Perl to be installed on the system of each database host.

Refer to the [PostgreSQL PL/Perl documentation](#) for additional information.

Greenplum Database PL/Perl Limitations

Limitations of the Greenplum Database PL/Perl language include:

- Greenplum Database does not support PL/Perl triggers.
- PL/Perl functions cannot call each other directly.
- SPI is not yet fully implemented.

- If you fetch very large data sets using `spi_exec_query()`, you should be aware that these will all go into memory. You can avoid this problem by using `spi_query()/spi_fetchrow()`. A similar problem occurs if a set-returning function passes a large set of rows back to Greenplum Database via a `return` statement. Use `return_next` for each row returned to avoid this problem.
- When a session ends normally, not due to a fatal error, PL/Perl runs any `END` blocks that you have defined. No other actions are currently performed. (File handles are not automatically flushed and objects are not automatically destroyed.)

Trusted/Untrusted Language

PL/Perl includes trusted and untrusted language variants.

The PL/Perl trusted language is named `plperl`. The trusted PL/Perl language restricts file system operations, as well as `require`, `use`, and other statements that could potentially interact with the operating system or database server process. With these restrictions in place, any Greenplum Database user can create and run functions in the trusted `plperl` language.

The PL/Perl untrusted language is named `plperlu`. You cannot restrict the operation of functions you create with the `plperlu` untrusted language. Only database superusers have privileges to create untrusted PL/Perl user-defined functions. And only database superusers and other database users that are explicitly granted the permissions can run untrusted PL/Perl user-defined functions.

PL/Perl has limitations with respect to communication between interpreters and the number of interpreters running in a single process. Refer to the PostgreSQL [Trusted and Untrusted PL/Perl](#) documentation for additional information.

Enabling and Removing PL/Perl Support

You must register the PL/Perl language with a database before you can create and run a PL/Perl user-defined function within that database. To remove PL/Perl support, you must explicitly remove the extension from each database in which it was registered. You must be a database superuser or owner to register or remove trusted languages in Greenplum databases.

Note: Only database superusers may register or remove support for the *untrusted* PL/Perl language `plperlu`.

Before you enable or remove PL/Perl support in a database, ensure that:

- Your Greenplum Database is running.
- You have sourced `greenplum_path.sh`.
- You have set the `$MASTER_DATA_DIRECTORY` and `$GPHOME` environment variables.

Enabling PL/Perl Support

For each database in which you want to enable PL/Perl, register the language using the SQL `CREATE EXTENSION` command. For example, run the following command as the `gpadmin` user to register the trusted PL/Perl language for the database named `testdb`:

```
$ psql -d testdb -c 'CREATE EXTENSION plperl;'
```

Removing PL/Perl Support

To remove support for PL/Perl from a database, run the SQL `DROP EXTENSION` command. For example, run the following command as the `gpadmin` user to remove support for the trusted PL/Perl

language from the database named `testdb`:

```
$ psql -d testdb -c 'DROP EXTENSION plperl;'
```

The default command fails if any existing objects (such as functions) depend on the language.

Specify the `CASCADE` option to also drop all dependent objects, including functions that you created with PL/Perl.

Developing Functions with PL/Perl

You define a PL/Perl function using the standard SQL `CREATE FUNCTION` syntax. The body of a PL/Perl user-defined function is ordinary Perl code. The PL/Perl interpreter wraps this code inside a Perl subroutine.

You can also create an anonymous code block with PL/Perl. An anonymous code block, called with the SQL `DO` command, receives no arguments, and whatever value it might return is discarded. Otherwise, a PL/Perl anonymous code block behaves just like a function. Only database superusers create an anonymous code block with the untrusted `plperl` language.

The syntax of the `CREATE FUNCTION` command requires that you write the PL/Perl function body as a string constant. While it is more convenient to use dollar-quoting, you can choose to use escape string syntax (`E''`) provided that you double any single quote marks and backslashes used in the body of the function.

PL/Perl arguments and results are handled as they are in Perl. Arguments you pass in to a PL/Perl function are accessed via the `@_` array. You return a result value with the `return` statement, or as the last expression evaluated in the function. A PL/Perl function cannot directly return a non-scalar type because you call it in a scalar context. You can return non-scalar types such as arrays, records, and sets in a PL/Perl function by returning a reference.

PL/Perl treats null argument values as “undefined”. Adding the `STRICT` keyword to the `LANGUAGE` subclause instructs Greenplum Database to immediately return null when any of the input arguments are null. When created as `STRICT`, the function itself need not perform null checks.

The following PL/Perl function utilizes the `STRICT` keyword to return the greater of two integers, or null if any of the inputs are null:

```
CREATE FUNCTION perl_max (integer, integer) RETURNS integer AS $$
    if ($_[0] > $_[1]) { return $_[0]; }
    return $_[1];
$$ LANGUAGE plperl STRICT;

SELECT perl_max( 1, 3 );
 perl_max
-----
        3
(1 row)

SELECT perl_max( 1, null );
 perl_max
-----

(1 row)
```

PL/Perl considers anything in a function argument that is not a reference to be a string, the standard Greenplum Database external text representation. The argument values supplied to a PL/Perl function are simply the input arguments converted to text form (just as if they had been displayed by

a `SELECT` statement). In cases where the function argument is not an ordinary numeric or text type, you must convert the Greenplum Database type to a form that is more usable by Perl. Conversely, the `return` and `return_next` statements accept any string that is an acceptable input format for the function's declared return type.

Refer to the PostgreSQL [PL/Perl Functions and Arguments](#) documentation for additional information, including composite type and result set manipulation.

Built-in PL/Perl Functions

PL/Perl includes built-in functions to access the database, including those to prepare and perform queries and manipulate query results. The language also includes utility functions for error logging and string manipulation.

The following example creates a simple table with an integer and a text column. It creates a PL/Perl user-defined function that takes an input string argument and invokes the `spi_exec_query()` built-in function to select all columns and rows of the table. The function returns all rows in the query results where the `v` column includes the function input string.

```
CREATE TABLE test (
    i int,
    v varchar
);
INSERT INTO test (i, v) VALUES (1, 'first line');
INSERT INTO test (i, v) VALUES (2, 'line2');
INSERT INTO test (i, v) VALUES (3, '3rd line');
INSERT INTO test (i, v) VALUES (4, 'different');

CREATE OR REPLACE FUNCTION return_match(varchar) RETURNS SETOF test AS $$
# store the input argument
$ss = $_[0];

# run the query
my $rv = spi_exec_query('select i, v from test;');

# retrieve the query status
my $status = $rv->{status};

# retrieve the number of rows returned in the query
my $nrows = $rv->{processed};

# loop through all rows, comparing column v value with input argument
foreach my $rn (0 .. $nrows - 1) {
    my $row = $rv->{rows}[$rn];
    my $textstr = $row->{v};
    if( index($textstr, $ss) != -1 ) {
        # match! return the row.
        return_next($row);
    }
}
return undef;
$$ LANGUAGE plperl EXECUTE ON MASTER ;

SELECT return_match( 'iff' );
   return_match
-----
(4,different)
(1 row)
```

Refer to the PostgreSQL PL/Perl [Built-in Functions](#) documentation for a detailed discussion of

available functions.

Global Values in PL/Perl

You can use the global hash map `%_SHARED` to share data, including code references, between PL/Perl function calls for the lifetime of the current session.

The following example uses `%_SHARED` to share data between the user-defined `set_var()` and `get_var()` PL/Perl functions:

```
CREATE OR REPLACE FUNCTION set_var(name text, val text) RETURNS text AS $$
    if ($_SHARED{$_[0]} = $_[1]) {
        return 'ok';
    } else {
        return "cannot set shared variable $_[0] to $_[1]";
    }
$$ LANGUAGE plperl;

CREATE OR REPLACE FUNCTION get_var(name text) RETURNS text AS $$
    return $_SHARED{$_[0]};
$$ LANGUAGE plperl;

SELECT set_var('key1', 'value1');
 set_var
-----
    ok
(1 row)

SELECT get_var('key1');
 get_var
-----
value1
(1 row)
```

For security reasons, PL/Perl creates a separate Perl interpreter for each role. This prevents accidental or malicious interference by one user with the behavior of another user's PL/Perl functions. Each such interpreter retains its own value of the `%_SHARED` variable and other global state. Two PL/Perl functions share the same value of `%_SHARED` if and only if they are run by the same SQL role.

There are situations where you must take explicit steps to ensure that PL/Perl functions can share data in `%_SHARED`. For example, if an application runs under multiple SQL roles (via `SECURITY DEFINER` functions, use of `SET ROLE`, etc.) in a single session, make sure that functions that need to communicate are owned by the same user, and mark these functions as `SECURITY DEFINER`.

Notes

Additional considerations when developing PL/Perl functions:

- PL/Perl internally utilizes the UTF-8 encoding. It converts any arguments provided in other encodings to UTF-8, and converts return values from UTF-8 back to the original encoding.
- Nesting named PL/Perl subroutines retains the same dangers as in Perl.
- Only the untrusted PL/Perl language variant supports module import. Use `plperl_u` with care.
- Any module that you use in a `plperl_u` function must be available from the same location on all Greenplum Database hosts.

PL/pgSQL Language

This section contains an overview of the Greenplum Database PL/pgSQL language.

- [About Greenplum Database PL/pgSQL](#)
- [PL/pgSQL Plan Caching](#)
- [PL/pgSQL Examples](#)
- [References](#)

About Greenplum Database PL/pgSQL

Greenplum Database PL/pgSQL is a loadable procedural language that is installed and registered by default with Greenplum Database. You can create user-defined functions using SQL statements, functions, and operators.

With PL/pgSQL you can group a block of computation and a series of SQL queries inside the database server, thus having the power of a procedural language and the ease of use of SQL. Also, with PL/pgSQL you can use all the data types, operators and functions of Greenplum Database SQL.

The PL/pgSQL language is a subset of Oracle PL/SQL. Greenplum Database PL/pgSQL is based on Postgres PL/pgSQL. The Postgres PL/pgSQL documentation is at <https://www.postgresql.org/docs/9.4/plpgsql.html>

When using PL/pgSQL functions, function attributes affect how Greenplum Database creates query plans. You can specify the attribute `IMMUTABLE`, `STABLE`, or `VOLATILE` as part of the `LANGUAGE` clause to classify the type of function. For information about the creating functions and function attributes, see the [CREATE FUNCTION](#) command in the *Greenplum Database Reference Guide*.

You can run PL/SQL code blocks as anonymous code blocks. See the `DO` command in the *Greenplum Database Reference Guide*.

Greenplum Database SQL Limitations

When using Greenplum Database PL/pgSQL, limitations include

- Triggers are not supported
- Cursors are forward moving only (not scrollable)
- Updatable cursors (`UPDATE...WHERE CURRENT OF` and `DELETE...WHERE CURRENT OF`) are not supported.
- Parallel retrieve cursors (`DECLARE...PARALLEL RETRIEVE`) are not supported.

For information about Greenplum Database SQL conformance, see [Summary of Greenplum Features](#) in the *Greenplum Database Reference Guide*.

The PL/pgSQL Language

PL/pgSQL is a block-structured language. The complete text of a function definition must be a block. A block is defined as:

```
[ <label> ]
[ DECLARE
    declarations ]
BEGIN
    statements
END [ <label> ];
```

Each declaration and each statement within a block is terminated by a semicolon (;). A block that

appears within another block must have a semicolon after `END`, as shown in the previous block. The `END` that concludes a function body does not require a semicolon.

A label is required only if you want to identify the block for use in an `EXIT` statement, or to qualify the names of variables declared in the block. If you provide a label after `END`, it must match the label at the block's beginning.

Important: Do not confuse the use of the `BEGIN` and `END` keywords for grouping statements in PL/pgSQL with the database commands for transaction control. The PL/pgSQL `BEGIN` and `END` keywords are only for grouping; they do not start or end a transaction. Functions are always run within a transaction established by an outer query — they cannot start or commit that transaction, since there would be no context for them to run in. However, a PL/pgSQL block that contains an `EXCEPTION` clause effectively forms a subtransaction that can be rolled back without affecting the outer transaction. For more about the `EXCEPTION` clause, see the PostgreSQL documentation on trapping errors at <https://www.postgresql.org/docs/9.4/plpgsql-control-structures.html#PLPGSQL-ERROR-TRAPPING>.

Keywords are case-insensitive. Identifiers are implicitly converted to lowercase unless double-quoted, just as they are in ordinary SQL commands.

Comments work the same way in PL/pgSQL code as in ordinary SQL:

- A double dash (--) starts a comment that extends to the end of the line.
- A /* starts a block comment that extends to the matching occurrence of */.

Block comments nest.

Any statement in the statement section of a block can be a subblock. Subblocks can be used for logical grouping or to localize variables to a small group of statements.

Variables declared in a subblock mask any similarly-named variables of outer blocks for the duration of the subblock. You can access the outer variables if you qualify their names with their block's label. For example this function declares a variable named `quantity` several times:

```
CREATE FUNCTION testfunc() RETURNS integer AS $$
<< outerblock >>
DECLARE
    quantity integer := 30;
BEGIN
    RAISE NOTICE 'Quantity here is %', quantity; -- Prints 30
    quantity := 50;
    --
    -- Create a subblock
    --
    DECLARE
        quantity integer := 80;
    BEGIN
        RAISE NOTICE 'Quantity here is %', quantity; -- Prints 80
        RAISE NOTICE 'Outer quantity here is %', outerblock.quantity; -- Prints 50
    END;
    RAISE NOTICE 'Quantity here is %', quantity; -- Prints 50
    RETURN quantity;
END;
$$ LANGUAGE plpgsql;
```

Running SQL Commands

You can run SQL commands with PL/pgSQL statements such as `EXECUTE`, `PERFORM`, and `SELECT ... INTO`. For information about the PL/pgSQL statements, see <https://www.postgresql.org/docs/9.4/plpgsql-statements.html>.

Note: The PL/pgSQL statement `SELECT INTO` is not supported in the `EXECUTE` statement.

PL/pgSQL Plan Caching

A PL/pgSQL function's volatility classification has implications on how Greenplum Database caches plans that reference the function. Refer to [Function Volatility and Plan Caching](#) in the *Greenplum Database Administrator Guide* for information on plan caching considerations for Greenplum Database function volatility categories.

When a PL/pgSQL function runs for the first time in a database session, the PL/pgSQL interpreter parses the function's SQL expressions and commands. The interpreter creates a prepared execution plan as each expression and SQL command is first run in the function. The PL/pgSQL interpreter reuses the execution plan for a specific expression and SQL command for the life of the database connection. While this reuse substantially reduces the total amount of time required to parse and generate plans, errors in a specific expression or command cannot be detected until run time when that part of the function is run.

Greenplum Database will automatically re-plan a saved query plan if there is any schema change to any relation used in the query, or if any user-defined function used in the query is redefined. This makes the re-use of a prepared plan transparent in most cases.

The SQL commands that you use in a PL/pgSQL function must refer to the same tables and columns on every execution. You cannot use a parameter as the name of a table or a column in an SQL command.

PL/pgSQL caches a separate query plan for each combination of actual argument types in which you invoke a polymorphic function to ensure that data type differences do not cause unexpected failures.

Refer to the PostgreSQL [Plan Caching](#) documentation for a detailed discussion of plan caching considerations in the PL/pgSQL language.

PL/pgSQL Examples

The following are examples of PL/pgSQL user-defined functions.

Example: Aliases for Function Parameters

Parameters passed to functions are named with identifiers such as `$1`, `$2`. Optionally, aliases can be declared for `$n` parameter names for increased readability. Either the alias or the numeric identifier can then be used to refer to the parameter value.

There are two ways to create an alias. The preferred way is to give a name to the parameter in the `CREATE FUNCTION` command, for example:

```
CREATE FUNCTION sales_tax(subtotal real) RETURNS real AS $$
BEGIN
    RETURN subtotal * 0.06;
END;
$$ LANGUAGE plpgsql;
```

You can also explicitly declare an alias, using the declaration syntax:

```
name ALIAS FOR $n;
```

This example, creates the same function with the `DECLARE` syntax.

```
CREATE FUNCTION sales_tax(real) RETURNS real AS $$
DECLARE
```

```

    subtotal ALIAS FOR $1;
BEGIN
    RETURN subtotal * 0.06;
END;
$$ LANGUAGE plpgsql;

```

Example: Using the Data Type of a Table Column

When declaring a variable, you can use the `%TYPE` construct to specify the data type of a variable or table column. This is the syntax for declaring a variable whose type is the data type of a table column:

```
name table.column_name%TYPE;
```

You can use the `%TYPE` construct to declare variables that will hold database values. For example, suppose you have a column named `user_id` in your `users` table. To declare a variable named `my_userid` with the same data type as the `users.user_id` column:

```
my_userid users.user_id%TYPE;
```

`%TYPE` is particularly valuable in polymorphic functions, since the data types needed for internal variables may change from one call to the next. Appropriate variables can be created by applying `%TYPE` to the function's arguments or result placeholders.

Example: Composite Type Based on a Table Row

A variable of a composite type is called a row variable. The following syntax declares a composite variable based on table row:

```
name table_name%ROWTYPE;
```

Such a row variable can hold a whole row of a `SELECT` or `FOR` query result, so long as that query's column set matches the declared type of the variable. The individual fields of the row value are accessed using the usual dot notation, for example `rowvar.column`.

Parameters to a function can be composite types (complete table rows). In that case, the corresponding identifier `$n` will be a row variable, and fields can be selected from it, for example `$1.user_id`.

Only the user-defined columns of a table row are accessible in a row-type variable, not the OID or other system columns. The fields of the row type inherit the table's field size or precision for data types such as `char(n)`.

The next example function uses a row variable composite type. Before creating the function, create the table that is used by the function with this command.

```

CREATE TABLE table1 (
    f1 text,
    f2 numeric,
    f3 integer
) distributed by (f1);

```

This `INSERT` command adds data to the table.

```

INSERT INTO table1 values
('test1', 14.1, 3),
('test2', 52.5, 2),
('test3', 32.22, 6),

```

```
('test4', 12.1, 4) ;
```

This function uses a column `%TYPE` variable and `%ROWTYPE` composite variable based on `table1`.

```
CREATE OR REPLACE FUNCTION t1_calc( name text) RETURNS integer
AS $$
DECLARE
    t1_row    table1%ROWTYPE;
    calc_int  table1.f3%TYPE;
BEGIN
    SELECT * INTO t1_row FROM table1 WHERE table1.f1 = $1 ;
    calc_int = (t1_row.f2 * t1_row.f3)::integer ;
    RETURN calc_int ;
END;
$$ LANGUAGE plpgsql VOLATILE;
```

Note: The previous function is classified as a `VOLATILE` function because function values could change within a single table scan.

The following `SELECT` command uses the function.

```
select t1_calc( 'test1' );
```

Note: The example PL/pgSQL function uses `SELECT` with the `INTO` clause. It is different from the SQL command `SELECT INTO`. If you want to create a table from a `SELECT` result inside a PL/pgSQL function, use the SQL command `CREATE TABLE AS`.

Example: Using a Variable Number of Arguments

You can declare a PL/pgSQL function to accept variable numbers of arguments, as long as all of the optional arguments are of the same data type. You must mark the last argument of the function as `VARIADIC` and declare the argument using an array type. You can refer to a function that includes `VARIADIC` arguments as a variadic function.

For example, this variadic function returns the minimum value of a variable array of numerics:

```
CREATE FUNCTION mleast (VARIADIC numeric[])
    RETURNS numeric AS $$
    DECLARE minval numeric;
    BEGIN
        SELECT min($1[i]) FROM generate_subscripts( $1, 1) g(i) INTO minval;
        RETURN minval;
    END;
$$ LANGUAGE plpgsql;

CREATE FUNCTION

SELECT mleast(10, -1, 5, 4.4);
 mleast
-----
      -1
(1 row)
```

Effectively, all of the actual arguments at or beyond the `VARIADIC` position are gathered up into a one-dimensional array.

You can pass an already-constructed array into a variadic function. This is particularly useful when you want to pass arrays between variadic functions. Specify `VARIADIC` in the function call as follows:

```
SELECT mleast(VARIADIC ARRAY[10, -1, 5, 4.4]);
```

This prevents PL/pgSQL from expanding the function's variadic parameter into its element type.

Example: Using Default Argument Values

You can declare PL/pgSQL functions with default values for some or all input arguments. The default values are inserted whenever the function is called with fewer than the declared number of arguments. Because arguments can only be omitted from the end of the actual argument list, you must provide default values for all arguments after an argument defined with a default value.

For example:

```
CREATE FUNCTION use_default_args(a int, b int DEFAULT 2, c int DEFAULT 3)
    RETURNS int AS $$
DECLARE
    sum int;
BEGIN
    sum := $1 + $2 + $3;
    RETURN sum;
END;
$$ LANGUAGE plpgsql;

SELECT use_default_args(10, 20, 30);
 use_default_args
-----
              60
(1 row)

SELECT use_default_args(10, 20);
 use_default_args
-----
              33
(1 row)

SELECT use_default_args(10);
 use_default_args
-----
              15
(1 row)
```

You can also use the `=` sign in place of the keyword `DEFAULT`.

Example: Using Polymorphic Data Types

PL/pgSQL supports the polymorphic *anyelement*, *anyarray*, *anyenum*, and *anynonarray* types. Using these types, you can create a single PL/pgSQL function that operates on multiple data types. Refer to [Greenplum Database Data Types](#) for additional information on polymorphic type support in Greenplum Database.

A special parameter named `$0` is created when the return type of a PL/pgSQL function is declared as a polymorphic type. The data type of `$0` identifies the return type of the function as deduced from the actual input types.

In this example, you create a polymorphic function that returns the sum of two values:

```
CREATE FUNCTION add_two_values(v1 anyelement,v2 anyelement)
    RETURNS anyelement AS $$
DECLARE
    sum ALIAS FOR $0;
BEGIN
    sum := v1 + v2;
    RETURN sum;
END;
```

```
END;
$$ LANGUAGE plpgsql;
```

Run `add_two_values()` providing integer input values:

```
SELECT add_two_values(1, 2);
 add_two_values
-----
              3
(1 row)
```

The return type of `add_two_values()` is integer, the type of the input arguments. Now execute `add_two_values()` providing float input values:

```
SELECT add_two_values (1.1, 2.2);
 add_two_values
-----
              3.3
(1 row)
```

The return type of `add_two_values()` in this case is float.

You can also specify `VARIADIC` arguments in polymorphic functions.

Example: Anonymous Block

This example runs the statements in the `t1_calc()` function from a previous example as an anonymous block using the `DO` command. In the example, the anonymous block retrieves the input value from a temporary table.

```
CREATE TEMP TABLE list AS VALUES ('test1') DISTRIBUTED RANDOMLY;

DO $$
DECLARE
    t1_row    table1%ROWTYPE;
    calc_int  table1.f3%TYPE;
BEGIN
    SELECT * INTO t1_row FROM table1, list WHERE table1.f1 = list.column1 ;
    calc_int = (t1_row.f2 * t1_row.f3)::integer ;
    RAISE NOTICE 'calculated value is %', calc_int ;
END $$ LANGUAGE plpgsql ;
```

PL/Python Language

This section contains an overview of the Greenplum Database PL/Python Language.

- [About Greenplum PL/Python](#)
- [Enabling and Removing PL/Python support](#)
- [Developing Functions with PL/Python](#)
- [Installing Python Modules](#)
- [Examples](#)
- [References](#)

About Greenplum PL/Python

PL/Python is a loadable procedural language. With the Greenplum Database PL/Python extension, you can write a Greenplum Database user-defined functions in Python that take advantage of Python features and modules to quickly build robust database applications.

You can run PL/Python code blocks as anonymous code blocks. See the [DO](#) command in the *Greenplum Database Reference Guide*.

The Greenplum Database PL/Python extension is installed by default with Greenplum Database. Greenplum Database installs a version of Python and PL/Python. This is location of the Python installation that Greenplum Database uses:

```
$GPHOME/ext/python/
```

Greenplum Database PL/Python Limitations

- Greenplum Database does not support PL/Python triggers.
- PL/Python is available only as a Greenplum Database untrusted language.
- Updatable cursors (`UPDATE...WHERE CURRENT OF` and `DELETE...WHERE CURRENT OF`) are not supported.

Enabling and Removing PL/Python support

The PL/Python language is installed with Greenplum Database. To create and run a PL/Python user-defined function (UDF) in a database, you must register the PL/Python language with the database.

Enabling PL/Python Support

For each database that requires its use, register the PL/Python language with the SQL command `CREATE EXTENSION`. Because PL/Python is an untrusted language, only superusers can register PL/Python with a database. For example, running this command as the `gpadmin` user registers PL/Python with the database named `testdb`:

```
$ psql -d testdb -c 'CREATE EXTENSION plpythonu;'
```

PL/Python is registered as an untrusted language.

Removing PL/Python Support

For a database that no longer requires the PL/Python language, remove support for PL/Python with the SQL command `DROP EXTENSION`. Because PL/Python is an untrusted language, only superusers can remove support for the PL/Python language from a database. For example, running this command as the `gpadmin` user removes support for PL/Python from the database named `testdb`:

```
$ psql -d testdb -c 'DROP EXTENSION plpythonu;'
```

The default command fails if any existing objects (such as functions) depend on the language. Specify the `CASCADE` option to also drop all dependent objects, including functions that you created with PL/Python.

Developing Functions with PL/Python

The body of a PL/Python user-defined function is a Python script. When the function is called, its arguments are passed as elements of the array `args[]`. Named arguments are also passed as ordinary variables to the Python script. The result is returned from the PL/Python function with `return` statement, or `yield` statement in case of a result-set statement.

PL/Python translates Python's `None` into the SQL `null` value.

Data Type Mapping

The Greenplum to Python data type mapping follows.

Greenplum Primitive Type	Python Data Type
boolean ¹	bool
bytea	bytes
smallint, bigint, oid	int
real, double	float
numeric	decimal
<i>other primitive types</i>	string
SQL null value	None

¹ When the UDF return type is `boolean`, the Greenplum Database evaluates the return value for truth according to Python rules. That is, `0` and empty string are `false`, but notably `'f'` is `true`.

Example:

```
CREATE OR REPLACE FUNCTION pybool_func(a int) RETURNS boolean AS $$
# container: plc_python3_shared
    if (a > 0):
        return True
    else:
        return False
$$ LANGUAGE plcontainer;

SELECT pybool_func(-1);

 pybool_func
-----
 f
(1 row)
```

Arrays and Lists

You pass SQL array values into PL/Python functions with a Python list. Similarly, PL/Python functions return SQL array values as a Python list. In the typical PL/Python usage pattern, you will specify an

array with `[]`.

The following example creates a PL/Python function that returns an array of integers:

```
CREATE FUNCTION return_py_int_array()
  RETURNS int[]
AS $$
  return [1, 11, 21, 31]
$$ LANGUAGE plpythonu;

SELECT return_py_int_array();
       return_py_int_array
-----
{1,11,21,31}
(1 row)
```

PL/Python treats multi-dimensional arrays as lists of lists. You pass a multi-dimensional array to a PL/Python function using nested Python lists. When a PL/Python function returns a multi-dimensional array, the inner lists at each level must all be of the same size.

The following example creates a PL/Python function that takes a multi-dimensional array of integers as input. The function displays the type of the provided argument, and returns the multi-dimensional array:

```
CREATE FUNCTION return_multidim_py_array(x int4[])
  RETURNS int4[]
AS $$
  plpy.info(x, type(x))
  return x
$$ LANGUAGE plpythonu;

SELECT * FROM return_multidim_py_array(ARRAY[[1,2,3], [4,5,6]]);
INFO:  ([[1, 2, 3], [4, 5, 6]], <type 'list'>)
CONTEXT:  PL/Python function "return_multidim_py_type"
         return_multidim_py_array
-----
{{1,2,3},{4,5,6}}
(1 row)
```

PL/Python also accepts other Python sequences, such as tuples, as function arguments for backwards compatibility with Greenplum versions where multi-dimensional arrays were not supported. In such cases, the Python sequences are always treated as one-dimensional arrays because they are ambiguous with composite types.

Composite Types

You pass composite-type arguments to a PL/Python function using Python mappings. The element names of the mapping are the attribute names of the composite types. If an attribute has the null value, its mapping value is `None`.

You can return a composite type result as a sequence type (tuple or list). You must specify a composite type as a tuple, rather than a list, when it is used in a multi-dimensional array. You cannot return an array of composite types as a list because it would be ambiguous to determine whether the list represents a composite type or another array dimension. In the typical usage pattern, you will specify composite type tuples with `()`.

In the following example, you create a composite type and a PL/Python function that returns an array of the composite type:

```
CREATE TYPE type_record AS (
  first text,
```

```

    second int4
);

CREATE FUNCTION composite_type_as_list()
  RETURNS type_record[]
AS $$
  return [(['first', 1), ('second', 1)], [(['first', 2), ('second', 2)], [(['first', 3),
    ('second', 3)]];
$$ LANGUAGE plpythonu;

SELECT * FROM composite_type_as_list();
               composite_type_as_list
-----
{('first',1),"(second,1)"},{('first,2)","(second,2)"},{('first,3)","(second,3)"}
(1 row)

```

Refer to the PostgreSQL [Arrays, Lists](#) documentation for additional information on PL/Python handling of arrays and composite types.

Set-Returning Functions

A Python function can return a set of scalar or composite types from any sequence type (for example: tuple, list, set).

In the following example, you create a composite type and a Python function that returns a [SETOF](#) of the composite type:

```

CREATE TYPE greeting AS (
  how text,
  who text
);

CREATE FUNCTION greet (how text)
  RETURNS SETOF greeting
AS $$
  # return tuple containing lists as composite types
  # all other combinations work also
  return ( {"how": how, "who": "World"}, {"how": how, "who": "Greenplum"} )
$$ LANGUAGE plpythonu;

select greet('hello');
      greet
-----
(hello,World)
(hello,Greenplum)
(2 rows)

```

Running and Preparing SQL Queries

The PL/Python [plpy](#) module provides two Python functions to run an SQL query and prepare an execution plan for a query, [plpy.execute](#) and [plpy.prepare](#). Preparing the execution plan for a query is useful if you run the query from multiple Python functions.

PL/Python also supports the [plpy.subtransaction\(\)](#) function to help manage [plpy.execute](#) calls in an explicit subtransaction. See [Explicit Subtransactions](#) in the PostgreSQL documentation for additional information about [plpy.subtransaction\(\)](#).

plpy.execute

Calling [plpy.execute](#) with a query string and an optional limit argument causes the query to be run and the result to be returned in a Python result object. The result object emulates a list or dictionary

object. The rows returned in the result object can be accessed by row number and column name. The result set row numbering starts with 0 (zero). The result object can be modified. The result object has these additional methods:

- `nrows` that returns the number of rows returned by the query.
- `status` which is the `SPI_execute()` return value.

For example, this Python statement in a PL/Python user-defined function runs a query.

```
rv = plpy.execute("SELECT * FROM my_table", 5)
```

The `plpy.execute` function returns up to 5 rows from `my_table`. The result set is stored in the `rv` object. If `my_table` has a column `my_column`, it would be accessed as:

```
my_col_data = rv[i]["my_column"]
```

Since the function returns a maximum of 5 rows, the index `i` can be an integer between 0 and 4.

plpy.prepare

The function `plpy.prepare` prepares the execution plan for a query. It is called with a query string and a list of parameter types, if you have parameter references in the query. For example, this statement can be in a PL/Python user-defined function:

```
plan = plpy.prepare("SELECT last_name FROM my_users WHERE  
first_name = $1", [ "text" ])
```

The string `text` is the data type of the variable that is passed for the variable `$1`. After preparing a statement, you use the function `plpy.execute` to run it:

```
rv = plpy.execute(plan, [ "Fred" ], 5)
```

The third argument is the limit for the number of rows returned and is optional.

When you prepare an execution plan using the PL/Python module the plan is automatically saved. See the Postgres Server Programming Interface (SPI) documentation for information about the execution plans <https://www.postgresql.org/docs/9.4/spi.html>.

To make effective use of saved plans across function calls you use one of the Python persistent storage dictionaries SD or GD.

The global dictionary SD is available to store data between function calls. This variable is private static data. The global dictionary GD is public data, available to all Python functions within a session. Use GD with care.

Each function gets its own execution environment in the Python interpreter, so that global data and function arguments from `myfunc` are not available to `myfunc2`. The exception is the data in the GD dictionary, as mentioned previously.

This example uses the SD dictionary:

```
CREATE FUNCTION usesavedplan() RETURNS trigger AS $$  
if SD.has_key("plan"):  
    plan = SD["plan"]  
else:  
    plan = plpy.prepare("SELECT 1")  
    SD["plan"] = plan  
  
# rest of function
```

```
$$ LANGUAGE plpythonu;
```

Handling Python Errors and Messages

The Python module `plpy` implements these functions to manage errors and messages:

- `plpy.debug`
- `plpy.log`
- `plpy.info`
- `plpy.notice`
- `plpy.warning`
- `plpy.error`
- `plpy.fatal`
- `plpy.debug`

The message functions `plpy.error` and `plpy.fatal` raise a Python exception which, if uncaught, propagates out to the calling query, causing the current transaction or subtransaction to be cancelled. The functions `raise plpy.ERROR(msg)` and `raise plpy.FATAL(msg)` are equivalent to calling `plpy.error` and `plpy.fatal`, respectively. The other message functions only generate messages of different priority levels.

Whether messages of a particular priority are reported to the client, written to the server log, or both is controlled by the Greenplum Database server configuration parameters `log_min_messages` and `client_min_messages`. For information about the parameters see the *Greenplum Database Reference Guide*.

Using the dictionary GD To Improve PL/Python Performance

In terms of performance, importing a Python module is an expensive operation and can affect performance. If you are importing the same module frequently, you can use Python global variables to load the module on the first invocation and not require importing the module on subsequent calls. The following PL/Python function uses the GD persistent storage dictionary to avoid importing a module if it has already been imported and is in the GD.

```
psql=#
CREATE FUNCTION pytest() returns text as $$
    if 'mymodule' not in GD:
        import mymodule
        GD['mymodule'] = mymodule
    return GD['mymodule'].sumd([1,2,3])
$$;
```

Installing Python Modules

When you install a Python module on Greenplum Database, the Greenplum Database Python environment must have the module added to it across all segment hosts and mirror hosts in the cluster. When expanding Greenplum Database, you must add the Python modules to the new segment hosts. You can use the Greenplum Database utilities `gpssh` and `gpscp` run commands on Greenplum Database hosts and copy files to the hosts. For information about the utilities, see the *Greenplum Database Utility Guide*.

As part of the Greenplum Database installation, the `gpadmin` user environment is configured to use Python that is installed with Greenplum Database.

To check the Python environment, you can use the `which` command:

```
which python
```

The command returns the location of the Python installation. The Python installed with Greenplum Database is in the Greenplum Database `ext/python` directory.

```
/<path_to_greenplum-db>/ext/python/bin/python
```

When running shell commands on remote hosts with `gpssh`, you can specify the `-s` option. When the option is specified, `gpssh` sources the `greenplum_path.sh` file before running commands on the remote hosts. For example, this command should display the Python installed with Greenplum Database on each host.

```
gpssh -f gpdb_hosts which python
```

If it does not, you can add the `-s` to source `greenplum_path.sh` on the remote hosts before running the command.

```
gpssh -s -f gpdb_hosts which python
```

To display the list of currently installed Python modules, run this command.

```
python -c "help('modules')"
```

Run `gpssh` in interactive mode to display Python modules on remote hosts. This example starts `gpssh` in interactive mode and lists the Python modules on the Greenplum Database host `sdw1`.

```
$ gpssh -s -h sdw1
=> python -c "help('modules')"
. . .
=> exit
$
```

Greenplum Database provides a collection of data science-related Python libraries that can be used with the Greenplum Database PL/Python language. You can download these libraries in `.gppkg` format from [VMware Tanzu Network](#). For information about the libraries, see [Python Data Science Module Package](#).

These sections describe installing and testing Python modules:

- [Installing Python pip](#)
- [Installing Python Packages with pip](#)
- [Building and Installing Python Modules Locally](#)
- [Testing Installed Python Modules](#)

Installing Python pip

The Python utility `pip` installs Python packages that contain Python modules and other resource files from versioned archive files.

Run this command to install `pip`.

```
python -m ensurepip --default-pip
```

The command runs the `ensurepip` module to bootstrap (install and configure) the `pip` utility from the

local Python installation.

You can run this command to ensure the `pip`, `setuptools` and `wheel` projects are current. Current Python projects ensure that you can install Python packages from source distributions or pre-built distributions (wheels).

```
python -m pip install --upgrade pip setuptools wheel
```

You can use `gpssh` to run the commands on the Greenplum Database hosts. This example runs `gpssh` in interactive mode to install `pip` on the hosts listed in the file `gpdb_hosts`.

```
$ gpssh -s -f gpdb_hosts
=> python -m ensurepip --default-pip
[centos6-mdw1] Ignoring indexes: https://pypi.python.org/simple
[centos6-mdw1] Collecting setuptools
[centos6-mdw1] Collecting pip
[centos6-mdw1] Installing collected packages: setuptools, pip
[centos6-mdw1] Successfully installed pip-8.1.1 setuptools-20.10.1
[centos6-sdw1] Ignoring indexes: https://pypi.python.org/simple
[centos6-sdw1] Collecting setuptools
[centos6-sdw1] Collecting pip
[centos6-sdw1] Installing collected packages: setuptools, pip
[centos6-sdw1] Successfully installed pip-8.1.1 setuptools-20.10.1
=> exit
$
```

The `=>` is the inactive prompt for `gpssh`. The utility displays the output from each host. The `exit` command exits from `gpssh` interactive mode.

This `gpssh` command runs a single command on all hosts listed in the file `gpdb_hosts`.

```
gpssh -s -f gpdb_hosts python -m pip install --upgrade pip setuptools wheel
```

The utility displays the output from each host.

For more information about installing Python packages, see <https://packaging.python.org/tutorials/installing-packages/>.

Installing Python Packages with pip

After installing `pip`, you can install Python packages. This command installs the `numpy` and `scipy` packages.

```
python -m pip install --user numpy scipy
```

The `--user` option attempts to avoid conflicts when installing Python packages.

You can use `gpssh` to run the command on the Greenplum Database hosts.

For information about these and other Python packages, see [References](#).

Building and Installing Python Modules Locally

If you are building a Python module, you must ensure that the build creates the correct executable. For example on a Linux system, the build should create a 64-bit executable.

Before building a Python module to be installed, ensure that the appropriate software to build the module is installed and properly configured. The build environment is required only on the host where you build the module.

You can use the Greenplum Database utilities `gpssh` and `gpscp` to run commands on Greenplum

Database hosts and to copy files to the hosts.

Testing Installed Python Modules

You can create a simple PL/Python user-defined function (UDF) to validate that Python a module is available in the Greenplum Database. This example tests the NumPy module.

This PL/Python UDF imports the NumPy module. The function returns **SUCCESS** if the module is imported, and **FAILURE** if an import error occurs.

```
CREATE OR REPLACE FUNCTION plpy_test(x int)
returns text
as $$
    try:
        from numpy import *
        return 'SUCCESS'
    except ImportError, e:
        return 'FAILURE'
$$ language plpythonu;
```

Create a table that contains data on each Greenplum Database segment instance. Depending on the size of your Greenplum Database installation, you might need to generate more data to ensure data is distributed to all segment instances.

```
CREATE TABLE DIST AS (SELECT x FROM generate_series(1,50) x ) DISTRIBUTED RANDOMLY ;
```

This **SELECT** command runs the UDF on the segment hosts where data is stored in the primary segment instances.

```
SELECT gp_segment_id, plpy_test(x) AS status
FROM dist
GROUP BY gp_segment_id, status
ORDER BY gp_segment_id, status;
```

The **SELECT** command returns **SUCCESS** if the UDF imported the Python module on the Greenplum Database segment instance. If the **SELECT** command returns **FAILURE**, you can find the segment host of the segment instance host. The Greenplum Database system table **gp_segment_configuration** contains information about mirroring and segment configuration. This command returns the host name for a segment ID.

```
SELECT hostname, content AS seg_ID FROM gp_segment_configuration
WHERE content = <seg_id> ;
```

If **FAILURE** is returned, these are some possible causes:

- A problem accessing required libraries. For the NumPy example, a Greenplum Database might have a problem accessing the OpenBLAS libraries or the Python libraries on a segment host.

Make sure you get no errors when running command on the segment host as the **gpadmin** user. This **gpssh** command tests importing the numpy module on the segment host **mdw1**.

```
gpssh -s -h mdw1 python -c "import numpy"
```

- If the Python **import** command does not return an error, environment variables might not be configured in the Greenplum Database environment. For example, the Greenplum Database might not have been restarted after installing the Python Package on the host system.

Examples

This PL/Python UDF returns the maximum of two integers:

```
CREATE FUNCTION pymax (a integer, b integer)
  RETURNS integer
AS $$
  if (a is None) or (b is None):
    return None
  if a > b:
    return a
  return b
$$ LANGUAGE plpythonu;
```

You can use the `STRICT` property to perform the null handling instead of using the two conditional statements.

```
CREATE FUNCTION pymax (a integer, b integer)
  RETURNS integer AS $$
  return max(a,b)
$$ LANGUAGE plpythonu STRICT ;
```

You can run the user-defined function `pymax` with `SELECT` command. This example runs the UDF and shows the output.

```
SELECT ( pymax(123, 43));
column1
-----
      123
(1 row)
```

This example that returns data from an SQL query that is run against a table. These two commands create a simple table and add data to the table.

```
CREATE TABLE sales (id int, year int, qtr int, day int, region text)
  DISTRIBUTED BY (id) ;

INSERT INTO sales VALUES
(1, 2014, 1,1, 'usa'),
(2, 2002, 2,2, 'europe'),
(3, 2014, 3,3, 'asia'),
(4, 2014, 4,4, 'usa'),
(5, 2014, 1,5, 'europe'),
(6, 2014, 2,6, 'asia'),
(7, 2002, 3,7, 'usa') ;
```

This PL/Python UDF runs a `SELECT` command that returns 5 rows from the table. The Python function returns the `REGION` value from the row specified by the input value. In the Python function, the row numbering starts from 0. Valid input for the function is an integer between 0 and 4.

```
CREATE OR REPLACE FUNCTION mypytest(a integer)
  RETURNS setof text
AS $$
  rv = plpy.execute("SELECT * FROM sales ORDER BY id", 5)
  region =[]
  region.append(rv[a]["region"])
  return region
$$ language plpythonu EXECUTE ON MASTER;
```

Running this `SELECT` statement returns the `REGION` column value from the third row of the result set.

```
SELECT mypytest(2) ;
```

This command deletes the UDF from the database.

```
DROP FUNCTION mypytest(integer) ;
```

This example runs the PL/Python function in the previous example as an anonymous block with the `DO` command. In the example, the anonymous block retrieves the input value from a temporary table.

```
CREATE TEMP TABLE mytemp AS VALUES (2) DISTRIBUTED RANDOMLY;

DO $$
    temprow = plpy.execute("SELECT * FROM mytemp", 1)
    myval = temprow[0]["column1"]
    rv = plpy.execute("SELECT * FROM sales ORDER BY id", 5)
    region = rv[myval]["region"]
    plpy.notice("region is %s" % region)
$$ language plpythonu;
```

PL/R Language

This chapter contains the following information:

- [About Greenplum Database PL/R](#)
- [Installing R](#)
- [Installing PL/R](#)
- [Uninstalling PL/R](#)
- [Enabling PL/R Language Support](#)
- [Examples](#)
- [Downloading and Installing R Packages](#)
- [Displaying R Library Information](#)
- [Loading R Modules at Startup](#)

- [References](#)

About Greenplum Database PL/R

PL/R is a procedural language. With the Greenplum Database PL/R extension you can write database functions in the R programming language and use R packages that contain R functions and data sets.

For information about supported PL/R versions, see the *Greenplum Database Release Notes*.

Installing R

For RHEL and CentOS, installing the PL/R package installs R in `$GPHOME/ext/R-<version>` and updates `$GPHOME/greenplum_path.sh` for Greenplum Database to use R.

To use PL/R on Ubuntu host systems, you must install and configure R on all Greenplum Database host systems before installing PL/R.

Note: You can use the `gpssh` utility to run bash shell commands on multiple remote hosts.

1. To install R, run these `apt` commands on all host systems.

```
$ sudo apt update && sudo apt install r-base
```

Installing `r-base` also installs dependent packages including `r-base-core`.

2. To configure Greenplum Database to use R, add the `R_HOME` environment variable to `$GPHOME/greenplum_path.sh` on all hosts. This example command returns the R home directory.

```
$ R RHOME
/usr/lib/R
```

Using the previous R home directory as an example, add this line to the file on all hosts.

```
export R_HOME=/usr/lib/R
```

3. Source `$GPHOME/greenplum_path.sh` and restart Greenplum Database. For example, run these commands on the Greenplum Database master host.

```
$ source $GPHOME/greenplum_path.sh
$ gpstop -r
```

Installing PL/R

The PL/R extension is available as a package. Download the package from [VMware Tanzu Network](#) and install it with the Greenplum Package Manager (`gpkg`).

The `gpkg` utility installs Greenplum Database extensions, along with any dependencies, on all hosts across a cluster. It also automatically installs extensions on new hosts in the case of system expansion and segment recovery.

Installing the Extension Package

Before you install the PL/R extension, make sure that your Greenplum Database is running, you have sourced `greenplum_path.sh`, and that the `$MASTER_DATA_DIRECTORY` and `$GPHOME` variables are set.

1. Download the PL/R extension package from [VMware Tanzu Network](#).

2. Follow the instructions in [Verifying the Greenplum Database Software Download](#) to verify the integrity of the **Greenplum Procedural Languages PL/R** software.
3. Copy the PL/R package to the Greenplum Database master host.
4. Install the software extension package by running the `gppkg` command. This example installs the PL/R extension on a Linux system:

```
$ gppkg -i plr-3.0.3-gp6-rhel7_x86_64.gppkg
```

5. Source the file `$GPHOME/greenplum_path.sh`.
6. Restart Greenplum Database.

```
$ gpstop -r
```

Enabling PL/R Language Support

For each database that requires its use, register the PL/R language with the SQL command `CREATE EXTENSION`. Because PL/R is an untrusted language, only superusers can register PL/R with a database. For example, run this command as the `gpadmin` user to register the language with the database named `testdb`:

```
$ psql -d testdb -c 'CREATE EXTENSION plr;'
```

PL/R is registered as an untrusted language.

Uninstalling PL/R

- [Remove PL/R Support for a Database](#)
- [Uninstall the Extension Package](#)
- [Uninstall R \(Ubuntu\)](#)

When you remove PL/R language support from a database, the PL/R routines that you created in the database will no longer work.

Remove PL/R Support for a Database

For a database that no longer requires the PL/R language, remove support for PL/R with the SQL command `DROP EXTENSION`. Because PL/R is an untrusted language, only superusers can remove support for the PL/R language from a database. For example, run this command as the `gpadmin` user to remove support for PL/R from the database named `testdb`:

```
$ psql -d testdb -c 'DROP EXTENSION plr;'
```

The default command fails if any existing objects (such as functions) depend on the language. Specify the `CASCADE` option to also drop all dependent objects, including functions that you created with PL/R.

Uninstall the Extension Package

If no databases have PL/R as a registered language, uninstall the Greenplum PL/R extension with the `gppkg` utility. This example uninstalls PL/R package version 3.0.3.

```
$ gppkg -r plr-3.0.3
```

On RHEL and CentOS systems, uninstalling the extension uninstalls the R software that was installed with the extension.

You can run the `gppkg` utility with the options `-q --all` to list the installed extensions and their versions.

For Ubuntu systems, remove the `R_HOME` environment variable from `greenplum_path.sh` on all Greenplum Database host systems.

Source the file `$GPHOME/greenplum_path.sh` and restart the database.

```
$ gpstop -r
```

Uninstall R (Ubuntu)

For Ubuntu systems, remove R from all Greenplum Database host systems. These commands remove R from an Ubuntu system.

```
$ sudo apt remove r-base
$ sudo apt remove r-base-core
```

Removing `r-base` does not uninstall the R executable. Removing `r-base-core` uninstalls the R executable.

Examples

The following are simple PL/R examples.

Example 1: Using PL/R for single row operators

This function generates an array of numbers with a normal distribution using the R function `rnorm()`.

```
CREATE OR REPLACE FUNCTION r_norm(n integer, mean float8,
    std_dev float8) RETURNS float8[ ] AS
$$
    x<-rnorm(n,mean,std_dev)
    return(x)
$$
LANGUAGE 'plr';
```

The following `CREATE TABLE` command uses the `r_norm()` function to populate the table. The `r_norm()` function creates an array of 10 numbers.

```
CREATE TABLE test_norm_var
AS SELECT id, r_norm(10,0,1) as x
FROM (SELECT generate_series(1,30:: bigint) AS ID) foo
DISTRIBUTED BY (id);
```

Example 2: Returning PL/R data.frames in Tabular Form

Assuming your PL/R function returns an R `data.frame` as its output, unless you want to use arrays of arrays, some work is required to see your `data.frame` from PL/R as a simple SQL table:

- Create a `TYPE` in a Greenplum database with the same dimensions as your R `data.frame`:

```
CREATE TYPE t1 AS ...
```

- Use this `TYPE` when defining your PL/R function

```
... RETURNS SET OF t1 AS ...
```

Sample SQL for this is given in the next example.

Example 3: Hierarchical Regression using PL/R

The SQL below defines a `TYPE` and runs hierarchical regression using PL/R:

```
--Create TYPE to store model results
DROP TYPE IF EXISTS wj_model_results CASCADE;
CREATE TYPE wj_model_results AS (
  cs text, coefext float, ci_95_lower float, ci_95_upper float,
  ci_90_lower float, ci_90_upper float, ci_80_lower float,
  ci_80_upper float);

--Create PL/R function to run model in R
DROP FUNCTION IF EXISTS wj_plr_RE(float [ ], text [ ]);
CREATE FUNCTION wj_plr_RE(response float [ ], cs text [ ])
RETURNS SETOF wj_model_results AS
$$
  library(arm)
  y<- log(response)
  cs<- cs
  d_temp<- data.frame(y,cs)
  m0 <- lmer (y ~ 1 + (1 | cs), data=d_temp)
  cs_unique<- sort(unique(cs))
  n_cs_unique<- length(cs_unique)
  temp_m0<- data.frame(matrix(0,n_cs_unique, 7))
  for (i in 1:n_cs_unique){temp_m0[i,<-
    c(exp(coef(m0)$cs[i,1] + c(0,-1.96,1.96,-1.65,1.65,
      -1.28,1.28)*se.ranef(m0)$cs[i]))}
  names(temp_m0)<- c("Coefest", "CI_95_Lower",
    "CI_95_Upper", "CI_90_Lower", "CI_90_Upper",
    "CI_80_Lower", "CI_80_Upper")
  temp_m0_v2<- data.frames(cs_unique, temp_m0)
  return(temp_m0_v2)
$$
LANGUAGE 'plr';

--Run modeling plr function and store model results in a
--table
DROP TABLE IF EXISTS wj_model_results_roi;
CREATE TABLE wj_model_results_roi AS SELECT *
  FROM wj_plr_RE('{1,1,1}', '{"a", "b", "c"}');
```

Downloading and Installing R Packages

R packages are modules that contain R functions and data sets. You can install R packages to extend R and PL/R functionality in Greenplum Database.

Greenplum Database provides a collection of data science-related R libraries that can be used with the Greenplum Database PL/R language. You can download these libraries in `.gppkg` format from [VMware Tanzu Network](#). For information about the libraries, see [R Data Science Library Package](#).

Note: If you expand Greenplum Database and add segment hosts, you must install the R packages in the R installation of the new hosts.

1. For an R package, identify all dependent R packages and each package web URL. The information can be found by selecting the given package from the following navigation page:

https://cran.r-project.org/web/packages/available_packages_by_name.html

As an example, the page for the R package arm indicates that the package requires the following R libraries: Matrix, lattice, lme4, R2WinBUGS, coda, abind, foreign, and MASS.

You can also try installing the package with R CMD INSTALL command to determine the dependent packages.

For the R installation included with the Greenplum Database PL/R extension, the required R packages are installed with the PL/R extension. However, the Matrix package requires a newer version.

2. From the command line, use the `wget` utility to download the `tar.gz` files for the arm package to the Greenplum Database master host:

```
wget https://cran.r-project.org/src/contrib/Archive/arm/arm_1.5-03.tar.gz
```

```
wget https://cran.r-project.org/src/contrib/Archive/Matrix/Matrix_0.9996875-1.tar.gz
```

3. Use the `gpscp` utility and the `hosts_all` file to copy the `tar.gz` files to the same directory on all nodes of the Greenplum Database cluster. The `hosts_all` file contains a list of all the Greenplum Database segment hosts. You might require root access to do this.

```
gpscp -f hosts_all Matrix_0.9996875-1.tar.gz =:/home/gpadmin
```

```
gpscp -f /hosts_all arm_1.5-03.tar.gz =:/home/gpadmin
```

4. Use the `gpssh` utility in interactive mode to log into each Greenplum Database segment host (`gpssh -f all_hosts`). Install the packages from the command prompt using the R CMD INSTALL command. Note that this may require root access. For example, this R install command installs the packages for the arm package.

```
$R_HOME/bin/R CMD INSTALL Matrix_0.9996875-1.tar.gz arm_1.5-03.tar.gz
```

5. Ensure that the package is installed in the `$R_HOME/library` directory on all the segments (the `gpssh` can be used to install the package). For example, this `gpssh` command list the contents of the R library directory.

```
gpssh -s -f all_hosts "ls $R_HOME/library"
```

The `gpssh` option `-s` sources the `greenplum_path.sh` file before running commands on the remote hosts.

6. Test if the R package can be loaded.

This function performs a simple test to determine if an R package can be loaded:

```
CREATE OR REPLACE FUNCTION R_test_require(fname text)
RETURNS boolean AS
$BODY$
    return(require(fname,character.only=T))
$BODY$
LANGUAGE 'plr';
```

This SQL command checks if the R package arm can be loaded:

```
SELECT R_test_require('arm');
```

Displaying R Library Information

You can use the R command line to display information about the installed libraries and functions on the Greenplum Database host. You can also add and remove libraries from the R installation. To start the R command line on the host, log into the host as the `gadmin` user and run the script `R` from the directory `$GPHOME/ext/R-3.3.3/bin`.

This R function lists the available R packages from the R command line:

```
> library()
```

Display the documentation for a particular R package

```
> library(help="<package_name>")
> help(package="<package_name>")
```

Display the help file for an R function:

```
> help("<function_name>")
> ?<function_name>
```

To see what packages are installed, use the R command `installed.packages()`. This will return a matrix with a row for each package that has been installed. Below, we look at the first 5 rows of this matrix.

```
> installed.packages()
```

Any package that does not appear in the installed packages matrix must be installed and loaded before its functions can be used.

An R package can be installed with `install.packages()`:

```
> install.packages("<package_name>")
> install.packages("mypkg", dependencies = TRUE, type="source")
```

Load a package from the R command line.

```
> library(" <package_name> ")
```

An R package can be removed with `remove.packages`

```
> remove.packages("<package_name>")
```

You can use the R command `-e` option to run functions from the command line. For example, this command displays help on the R package `MASS`.

```
$ R -e 'help("MASS")'
```

Loading R Modules at Startup

PL/R can automatically load saved R code during interpreter initialization. To use this feature, you create the `plr_modules` database table and then insert the R modules you want to auto-load into the table. If the table exists, PL/R will load the code it contains into the interpreter.

In a Greenplum Database system, table rows are usually distributed so that each row exists at only one segment instance. The R interpreter at each segment instance, however, needs to load all of the modules, so a normally distributed table will not work. You must create the `plr_modules` table as a *replicated table* in the default schema so that all rows in the table are present at every segment

instance. For example:

```
CREATE TABLE public.plr_modules {
  modseq int4,
  modsrc text
} DISTRIBUTED REPLICATED;
```

See <https://www.joeconway.com/plr/doc/plr-module-funcs.html> for more information about using the PL/R auto-load feature.

About Greenplum R

The Greenplum R Client (GreenplumR) is an interactive in-database data analytics tool for Greenplum Database. The client provides an R interface to tables and views, and requires no SQL knowledge to operate on these database objects.

You can use GreenplumR with the Greenplum PL/R procedural language to run an R function on data stored in Greenplum Database. GreenplumR parses the R function and creates a user-defined function (UDF) for execution in Greenplum. Greenplum runs the UDF in parallel on the segment hosts.

You can similarly use GreenplumR with Greenplum PL/Container 3 (Beta), to run an R function against Greenplum data in a high-performance R sandbox runtime environment.

No analytic data is loaded into R when you use GreenplumR, a key requirement when dealing with large data sets. Only the R function and minimal data is transferred between R and Greenplum.

Supported Platforms

GreenplumR supports the following component versions:

GreenplumR Version	R Version	Greenplum Version	PL/R Version	PL/Container Version
1,1,0, 1.0.0	3.6+	6.1+	3.0.2+	3.0.0 (Beta)

Prerequisites

You can use GreenplumR with Greenplum Database and the PL/R and PL/Container procedural languages. Before you install and run GreenplumR on a client system:

- Ensure that your Greenplum Database installation is running version 6.1 or newer.
- Ensure that your client development system has connectivity to the Greenplum Database master host.
- Ensure that **R** version 3.6.0 or newer is installed on your client system, and that you set the `$R_HOME` environment variable appropriately.
- Determine the procedural language(s) you plan to use with GreenplumR, and ensure that the language(s) is installed and configured in your Greenplum Database cluster. Refer to [PL/R Language](#) and [PL/Container Language](#) (3.0 Beta) for language installation and configuration instructions.
- Verify that you have registered the procedural language(s) in each database in which you plan to use GreenplumR to read data from or write data to Greenplum. For example, the following command lists the extensions and languages registered in the database named `testdb`:

```
$ psql -h gpmaster -d testdb -c '\dx'
```

List of installed extensions			
Name	Version	Schema	Description
plcontainer	1.0.0	public	GPDB execution sandboxing for Python and R
plpgsql	1.0	pg_catalog	PL/pgSQL procedural language
plr	8.3.0.16	public	load R interpreter and run R script from within a database

Check for the `plr` and/or `plcontainer` extension `Name`.

Installing the Greenplum R Client

GreenplumR is an R package. You obtain the package from VMware Tanzu Network (or the GreenplumR [github](#) repository) and install the package within the R console.

1. Download the package from the *Greenplum Procedural Languages* filegroup on [VMware Tanzu Network](#). The naming format of the downloaded file is `greenplumR- <version>- gp6.tar.gz`.

Note the file system location of the downloaded file.

2. Follow the instructions in [Verifying the Greenplum Database Software Download](#) to verify the integrity of the **Greenplum Procedural Languages GreenplumR** software.

3. Install the dependent R packages: `ini`, `shiny`, and `RPostgreSQL`. For example, enter the R console and run the following, or equivalent, command:

```
user@clientsys$ R
> install.packages(c("ini", "shiny", "RPostgreSQL"))
```

You may be prompted to select a CRAN download mirror. And, depending on your client system configuration, you may be prompted to use or create a personal library.

After downloading, R builds and installs these and dependent packages.

4. Install the GreenplumR R package:

```
> install.packages("/path/to/greenplumR- <version>- gp6.tar.gz", repos = NULL, type = "source")
```

5. Install the `Rdpack` documentation package:

```
> install.packages("Rdpack")
```

Example Data Sets

GreenplumR includes the `abalone` and `null.data` sample datasets. Refer to the reference pages for more information:

```
> help( abalone )
> help( null.data )
```

Using the Greenplum R Client

You use GreenplumR to perform in-database analytics. Typical operations that you may perform include:

- Loading the GreenplumR package.
- Connecting to and disconnecting from Greenplum Database.
- Examining database objects.
- Analyzing and manipulating data.
- Running R functions in Greenplum Database.

Loading GreenplumR

Use the R `library()` function to load GreenplumR:

```
user@clientsys$ R
> library("GreenplumR")
```

Connecting to Greenplum Database

The `db.connect()` and `db.connect.dsn()` GreenplumR functions establish a connection to Greenplum Database. The `db.disconnect()` function closes a database connection.

The GreenplumR connect and disconnect function signatures follow:

```
db.connect( host = "localhost", user = Sys.getenv("USER"),
            dbname = user, password = "", port = 5432, conn.pkg = "RPostgreSQL",
```

```

        default.schemas = NULL, verbose = TRUE, quick = FALSE )

db.connect.dsn( dsn.key, db.ini = "~/db.ini", default.schemas = NULL,
               verbose = TRUE, quick = FALSE )

db.disconnect( conn.id = 1, verbose = TRUE, force = FALSE )

```

When you connect to Greenplum Database, you provide the master host, port, database name, user name, password, and other information via function arguments or a data source name (DSN) file. If you do not specify an argument or value, GreenplumR uses the default.

The `db.connect[.dsn]()` functions return an integer connection identifier. You specify this identifier when you operate on tables or views in the database. You also specify this identifier when you close the connection.

The `db.disconnect()` function returns a logical that identifies whether or not the connection was successfully disconnected.

To list and display information about active Greenplum connections, use the `db.list()` function.

Example:

```

## connect to Greenplum database named testdb on host gpmaster
> cid_to_testdb <- db.connect( host = "gpmaster", port=5432, dbname = "testdb" )
Loading required package: DBI
Created a connection to database with ID 1
[1] 1

> db.list()
Database Connection Info
## -----
[Connection ID 1]
Host      : gpmaster
User      : gpadmin
Database  : testdb
DBMS      : Greenplum 6

> db.disconnect( cid_to_testdb )
Connection 1 is disconnected!
[1] TRUE

```

Examining Database Objects

The `db.objects()` function lists the tables and views in the database identified by a specific connection identifier. The function signature is:

```
db.objects( search = NULL, conn.id = 1 )
```

If you choose, you can specify a filter string to narrow the returned results. For example, to list the tables and views in the `public` schema in the database identified by the default connection identifier, invoke the function as follows:

```
> db.objects( search = "public." )
```

Analyzing and Manipulating Data

The fundamental data structure of R is the `data.frame`. A data frame is a collection of variables represented as a list of vectors. GreenplumR operates on `db.data.frame` objects, and exposes functions to convert to and manipulate objects of this type:

- `as.db.data.frame()` - writes data in a file or a `data.frame` into a Greenplum table. You can also use the function to write the results of a query into a table, or to create a local `db.data.frame`.
- `db.data.frame()` - creates a temporary R object that references a view or table in a Greenplum database. No data is loaded into R when you use this function.

Example:

```
## create a db.data.frame from the abalone example data set;
## abalone is a data.frame
> abdf1 <- as.db.data.frame(abalone, conn.id = cid_to_testdb, verbose = FALSE)

## sort on the id column and preview the first 5 rows
> lk( sort( abdf1, INDICES=abdf1$id ), 5 )
  id sex length diameter height  whole shucked viscera shell rings
1  1  M  0.455    0.365  0.095 0.5140  0.2245  0.1010 0.150    15
2  2  M  0.350    0.265  0.090 0.2255  0.0995  0.0485 0.070     7
3  3  F  0.530    0.420  0.135 0.6770  0.2565  0.1415 0.210     9
4  4  M  0.440    0.365  0.125 0.5160  0.2155  0.1140 0.155    10
5  5  I  0.330    0.255  0.080 0.2050  0.0895  0.0395 0.055     7

## write the data frame to a Greenplum table named abalone_from_r;
## use most of the function defaults
> as.db.data.frame( abdf1, table.name = "public.abalone_from_r" )
The data contained in table "pg_temp_93"."gp_temp_5bdf4ec7_42f9_9f9799_a0d76231be8f" which is wrapped by abdf1 is copied into "public"."abalone_from_r" in database testdb on gpmaster !
Table      :    "public"."abalone_from_r"
Database   :    testdb
Host       :    gpmaster
Connection :    1

## list database objects, should display the newly created table
> db.objects( search = "public." )
[1] "public.abalone_from_r"
```

Running R Functions in Greenplum Database

GreenplumR supports two functions that allow you to run an R function, in-database, on every row of a Greenplum Database table: `db.gpapply()` and `db.gptapply()`. You can use the Greenplum PL/R or PL/Container procedural language as the vehicle in which to run the function.

The function signatures follow:

```
db.gpapply( X, MARGIN = NULL, FUN = NULL, output.name = NULL, output.signature = NULL,
            clear.existing = FALSE, case.sensitive = FALSE, output.distributeOn = NULL
,
            debugger.mode = FALSE, runtime.id = "plc_r_shared", language = "plcontainer",
            input.signature = NULL, ... )

db.gptapply( X, INDEX, FUN = NULL, output.name = NULL, output.signature = NULL,
            clear.existing = FALSE, case.sensitive = FALSE,
            output.distributeOn = NULL, debugger.mode = FALSE,
            runtime.id = "plc_r_shared", language = "plcontainer",
            input.signature = NULL, ... )
```

Use the second variant of the function when the table data is indexed.

By default, `db.gp[t]apply()` passes a single data frame input argument to the R function `FUN`. If you define `FUN` to take a list of arguments, you must specify the function argument name to Greenplum table column name mapping in `input.signature`. You must specify this mapping in table column

order.

Example 1:

Create a Greenplum table named `table1` in the database named `testdb`. This table has a single integer-type field. Populate the table with some data:

```
user@clientsys$ psql -h gpmaster -d testdb
testdb=# CREATE TABLE table1( id int );
testdb=# INSERT INTO table1 SELECT generate_series(1,13);
testdb=# \q
```

Create an R function that increments an integer. Run the function on `table1` in Greenplum using the PL/R procedural language. Then write the new values to a table named `table1_r_inc`:

```
user@clientsys$ R
> ## create a reference to table1
> t1 <- db.data.frame("public.table1")

> ## create an R function that increment an integer by 1
> fn.function_plus_one <- function(num)
{
  return (num[[1]] + 1)
}

> ## create the function output signature
> .sig <- list( "num" = "int" )

> ## run the function in Greenplum and print
> x <- db.gpapply( t1, output.name = NULL, FUN = fn.function_plus_one,
  output.signature = .sig, clear.existing = TRUE, case.sensitive = TRUE, language = "plr" )
> print(x)
  num
1   2
2   6
3  12
4  13
5   3
6   4
7   5
8   7
9   8
10  9
11 10
12 11
13 14

> ## run the function in Greenplum and write to the output table
> db.gpapply(t1, output.name = "public.table1_r_inc", FUN = fn.function_plus_one,
  output.signature = .sig, clear.existing = TRUE, case.sensitive = TRUE,
  language = "plr" )

## list database objects, should display the newly created table
> db.objects( search = "public.")
[1] "public.abalone_from_r"  "public.table1_r_inc"
```

Example 2:

Create a Greenplum table named `table2` in the database named `testdb`. This table has two integer-type fields. Populate the table with some data:

```
user@clientsys$ psql -h gpmaster -d testdb
testdb=# CREATE TABLE table2( c1 int, c2 int );
testdb=# INSERT INTO table2 VALUES (1, 2);
testdb=#\q
```

Create an R function that takes two integer arguments, manipulates the arguments, and returns both. Run the function on the data in `table2` in Greenplum using the PL/R procedural language, writing the new values to a table named `table2_r_upd`:

```
user@clientsys$ R
> ## create a reference to table2
> t2 <- db.data.frame("public.table2")

> ## create the R function
> fn.func_with_two_args <- function(a, b)
{
  a <- a * 20
  b <- a + 66
  c <- list(a, b)
  return (as.data.frame(c))
}

> ## create the function input signature, mapping function argument name to
> ## table column name
> input.sig <- list('a' = 'c1', 'b' = 'c2')

> ## create the function output signature
> return.sig <- list('a' = 'int', 'b' = 'int')

> ## run the function in Greenplum and write to the output table
> db.gpapply(t2, output.name = "public.table2_r_upd", FUN = fn.func_with_two_args,
  output.signature = return.sig, clear.existing = TRUE, case.sensitive = TRUE,
  language = "plr", input.signature = input.sig )
```

View the contents of the Greenplum table named `table2_r_upd`:

```
user@clientsys$ psql -h gpmaster -d testdb
testdb=# SELECT * FROM table2_r_upd;
 a  | b
----+----
 20 | 86
(1 row)
testdb=# \q
```

Limitations

GreenplumR has the following limitations:

- The `db.gpapply()` and `db.gptapply()` functions currently operate only on `conn.id = 1`.
- The GreenplumR function reference pages are not yet published. You can find `html` versions of the reference pages in your R library `R/<platform>-library/3.6/GreenplumR/html` directory. Open the `00Index.html` file in the browser of your choice and select the function of interest.
- The `GreenplumR()` graphical user interface is currently unsupported.

Function Summary

GreenplumR provides several functions. To obtain reference information for GreenplumR functions

while running the R console, invoke the `help()` function. For example, to display the reference information for the GreenplumR `db.data.frame()` function:

```
> help( db.data.frame )
```

GreenplumR functions include:

Table 2. GreenplumR Functions

Category	Name	Description
Aggregate Functions	mean(), sum(), count(), max(), min(), sd(), var(), colMeans(), colSums(), colAgg(), db.array()	Functions that perform a calculation on multiple values and return a single value.
Connectivity Functions	connection info	Extract connection information.
	db.connect()	Create a database connection.
	db.connect.dsn()	Create a database connection using a DSN.
	db.disconnect()	Disconnect a database connection.
	db.list()	List database connections.
Database Object Functions	as.db.data.frame()	Create a db.data.frame from a file or data.frame, optionally writing the data to a Greenplum table.
	db.data.frame()	Create a data frame that references a view or table in the database.
	db.objects()	List the table and view objects in the database.
	db.existsObject()	Identifies whether a table or view exists in the database.
Mathematical Functions	exp(), abs(), log(), log10(), sign(), sqrt(), factorial(), sin(), cos(), tan(), asin(), acos(), atan(), atan2()	Mathematical functions that take db.obj as an argument.
Greenplum Functions	db.gpapply()	Wrap an R function with a UDF and run it on every row of data in a Greenplum table.
	db.gptapply()	Wrap an R function with a UDF and run it on every row of data grouped by an index in a Greenplum table.

Inserting, Updating, and Deleting Data

This section provides information about manipulating data and concurrent access in Greenplum Database.

This topic includes the following subtopics:

- [About Concurrency Control in Greenplum Database](#)
- [Inserting Rows](#)
- [Updating Existing Rows](#)
- [Deleting Rows](#)
- [Working With Transactions](#)
- [Global Deadlock Detector](#)

- [Vacuuming the Database](#)
- [Running Out of Locks](#)

Parent topic: [Greenplum Database Administrator Guide](#)

About Concurrency Control in Greenplum Database

Greenplum Database and PostgreSQL do not use locks for concurrency control. They maintain data consistency using a multiversion model, Multiversion Concurrency Control (MVCC). MVCC achieves transaction isolation for each database session, and each query transaction sees a snapshot of data. This ensures the transaction sees consistent data that is not affected by other concurrent transactions.

Because MVCC does not use explicit locks for concurrency control, lock contention is minimized and Greenplum Database maintains reasonable performance in multiuser environments. Locks acquired for querying (reading) data do not conflict with locks acquired for writing data.

Greenplum Database provides multiple lock modes to control concurrent access to data in tables. Most Greenplum Database SQL commands automatically acquire the appropriate locks to ensure that referenced tables are not dropped or modified in incompatible ways while a command runs. For applications that cannot adapt easily to MVCC behavior, you can use the `LOCK` command to acquire explicit locks. However, proper use of MVCC generally provides better performance.

Lock Mode	Associated SQL Commands	Conflicts With
ACCESS SHARE	<code>SELECT</code>	ACCESS EXCLUSIVE
ROW SHARE	<code>SELECT...FOR lock_strength</code>	EXCLUSIVE, ACCESS EXCLUSIVE
ROW EXCLUSIVE	<code>INSERT</code> , <code>COPY</code>	SHARE, SHARE ROW EXCLUSIVE, EXCLUSIVE, ACCESS EXCLUSIVE
SHARE UPDATE EXCLUSIVE	<code>VACUUM</code> (without <code>FULL</code>), <code>ANALYZE</code>	SHARE UPDATE EXCLUSIVE, SHARE, SHARE ROW EXCLUSIVE, EXCLUSIVE, ACCESS EXCLUSIVE
SHARE	<code>CREATE INDEX</code>	ROW EXCLUSIVE, SHARE UPDATE EXCLUSIVE, SHARE ROW EXCLUSIVE, EXCLUSIVE, ACCESS EXCLUSIVE
SHARE ROW EXCLUSIVE		ROW EXCLUSIVE, SHARE UPDATE EXCLUSIVE, SHARE, SHARE ROW EXCLUSIVE, EXCLUSIVE, ACCESS EXCLUSIVE
EXCLUSIVE	<code>DELETE</code> , <code>UPDATE</code> , <code>SELECT...FOR lock_strength</code> , <code>REFRESH MATERIALIZED VIEW CONCURRENTLY</code>	ROW SHARE, ROW EXCLUSIVE, SHARE UPDATE EXCLUSIVE, SHARE, SHARE ROW EXCLUSIVE, EXCLUSIVE, ACCESS EXCLUSIVE
ACCESS EXCLUSIVE	<code>ALTER TABLE</code> , <code>DROP TABLE</code> , <code>TRUNCATE</code> , <code>REINDEX</code> , <code>CLUSTER</code> , <code>REFRESH MATERIALIZED VIEW</code> (without <code>CONCURRENTLY</code>), <code>VACUUM FULL</code>	ACCESS SHARE, ROW SHARE, ROW EXCLUSIVE, SHARE UPDATE EXCLUSIVE, SHARE, SHARE ROW EXCLUSIVE, EXCLUSIVE, ACCESS EXCLUSIVE

Note: By default Greenplum Database acquires the more restrictive `EXCLUSIVE` lock (rather than `ROW EXCLUSIVE` in PostgreSQL) for `UPDATE`, `DELETE`, and `SELECT...FOR UPDATE` operations on heap tables. When the Global Deadlock Detector is enabled the lock mode for `UPDATE` and `DELETE` operations on heap tables is `ROW EXCLUSIVE`. See [Global Deadlock Detector](#). Greenplum always holds a table-level lock with `SELECT...FOR UPDATE` statements.

Inserting Rows

Use the **INSERT** command to create rows in a table. This command requires the table name and a value for each column in the table; you may optionally specify the column names in any order. If you do not specify column names, list the data values in the order of the columns in the table, separated by commas.

For example, to specify the column names and the values to insert:

```
INSERT INTO products (name, price, product_no) VALUES ('Cheese', 9.99, 1);
```

To specify only the values to insert:

```
INSERT INTO products VALUES (1, 'Cheese', 9.99);
```

Usually, the data values are literals (constants), but you can also use scalar expressions. For example:

```
INSERT INTO films SELECT * FROM tmp_films WHERE date_prod <
'2016-05-07';
```

You can insert multiple rows in a single command. For example:

```
INSERT INTO products (product_no, name, price) VALUES
(1, 'Cheese', 9.99),
(2, 'Bread', 1.99),
(3, 'Milk', 2.99);
```

To insert data into a partitioned table, you specify the root partitioned table, the table created with the **CREATE TABLE** command. You also can specify a leaf child table of the partitioned table in an **INSERT** command. An error is returned if the data is not valid for the specified leaf child table. Specifying a child table that is not a leaf child table in the **INSERT** command is not supported.

To insert large amounts of data, use external tables or the **COPY** command. These load mechanisms are more efficient than **INSERT** for inserting large quantities of rows. See [Loading and Unloading Data](#) for more information about bulk data loading.

The storage model of append-optimized tables is optimized for bulk data loading. Greenplum does not recommend single row **INSERT** statements for append-optimized tables. For append-optimized tables, Greenplum Database supports a maximum of 127 concurrent **INSERT** transactions into a single append-optimized table.

Updating Existing Rows

The **UPDATE** command updates rows in a table. You can update all rows, a subset of all rows, or individual rows in a table. You can update each column separately without affecting other columns.

To perform an update, you need:

- The name of the table and columns to update
- The new values of the columns
- One or more conditions specifying the row or rows to be updated.

For example, the following command updates all products that have a price of 5 to have a price of 10:

```
UPDATE products SET price = 10 WHERE price = 5;
```

Using **UPDATE** in Greenplum Database has the following restrictions:

- While GPORCA supports updates to Greenplum distribution key columns, the Postgres Planner does not.
- If mirrors are enabled, you cannot use **STABLE** or **VOLATILE** functions in an **UPDATE** statement.
- Greenplum Database partitioning columns cannot be updated.

Deleting Rows

The **DELETE** command deletes rows from a table. Specify a **WHERE** clause to delete rows that match certain criteria. If you do not specify a **WHERE** clause, all rows in the table are deleted. The result is a valid, but empty, table. For example, to remove all rows from the products table that have a price of 10:

```
DELETE FROM products WHERE price = 10;
```

To delete all rows from a table:

```
DELETE FROM products;
```

Using **DELETE** in Greenplum Database has similar restrictions to using **UPDATE**:

- If mirrors are enabled, you cannot use **STABLE** or **VOLATILE** functions in an **UPDATE** statement.

Truncating a Table

Use the **TRUNCATE** command to quickly remove all rows in a table. For example:

```
TRUNCATE mytable;
```

This command empties a table of all rows in one operation. Note that **TRUNCATE** does not scan the table, therefore it does not process inherited child tables or **ON DELETE** rewrite rules. The command truncates only rows in the named table.

Working With Transactions

Transactions allow you to bundle multiple SQL statements in one all-or-nothing operation.

The following are the Greenplum Database SQL transaction commands:

- **BEGIN** or **START TRANSACTION** starts a transaction block.
- **END** or **COMMIT** commits the results of a transaction.
- **ROLLBACK** abandons a transaction without making any changes.
- **SAVEPOINT** marks a place in a transaction and enables partial rollback. You can roll back commands run after a savepoint while maintaining commands run before the savepoint.
- **ROLLBACK TO SAVEPOINT** rolls back a transaction to a savepoint.
- **RELEASE SAVEPOINT** destroys a savepoint within a transaction.

Transaction Isolation Levels

Greenplum Database accepts the standard SQL transaction levels as follows:

- `READ UNCOMMITTED` and `READ COMMITTED` behave like the standard `READ COMMITTED`.
- `REPEATABLE READ` and `SERIALIZABLE` behave like `REPEATABLE READ`.

The following information describes the behavior of the Greenplum transaction levels.

Read Uncommitted and Read Committed

Greenplum Database does not allow any command to see an uncommitted update in another concurrent transaction, so `READ UNCOMMITTED` behaves the same as `READ COMMITTED`. `READ COMMITTED` provides fast, simple, partial transaction isolation. `SELECT`, `UPDATE`, and `DELETE` commands operate on a snapshot of the database taken when the query started.

A `SELECT` query:

- Sees data committed before the query starts.
- Sees updates run within the transaction.
- Does not see uncommitted data outside the transaction.
- Can possibly see changes that concurrent transactions made if the concurrent transaction is committed after the initial read in its own transaction.

Successive `SELECT` queries in the same transaction can see different data if other concurrent transactions commit changes between the successive queries. `UPDATE` and `DELETE` commands find only rows committed before the commands started.

`READ COMMITTED` transaction isolation allows concurrent transactions to modify or lock a row before `UPDATE` or `DELETE` find the row. `READ COMMITTED` transaction isolation may be inadequate for applications that perform complex queries and updates and require a consistent view of the database.

Repeatable Read and Serializable

`SERIALIZABLE` transaction isolation, as defined by the SQL standard, ensures that transactions that run concurrently produce the same results as if they were run one after another. If you specify `SERIALIZABLE` Greenplum Database falls back to `REPEATABLE READ`. `REPEATABLE READ` transactions prevent dirty reads, non-repeatable reads, and phantom reads without expensive locking, but Greenplum Database does not detect all serializability interactions that can occur during concurrent transaction execution. Concurrent transactions should be examined to identify interactions that are not prevented by disallowing concurrent updates of the same data. You can prevent these interactions by using explicit table locks or by requiring the conflicting transactions to update a dummy row introduced to represent the conflict.

With `REPEATABLE READ` transactions, a `SELECT` query:

- Sees a snapshot of the data as of the start of the transaction (not as of the start of the current query within the transaction).
- Sees only data committed before the query starts.
- Sees updates run within the transaction.
- Does not see uncommitted data outside the transaction.
- Does not see changes that concurrent transactions make.
- Successive `SELECT` commands within a single transaction always see the same data.
- `UPDATE`, `DELETE`, `SELECT FOR UPDATE`, and `SELECT FOR SHARE` commands find only rows

committed before the command started. If a concurrent transaction has updated, deleted, or locked a target row, the `REPEATABLE READ` transaction waits for the concurrent transaction to commit or roll back the change. If the concurrent transaction commits the change, the `REPEATABLE READ` transaction rolls back. If the concurrent transaction rolls back its change, the `REPEATABLE READ` transaction can commit its changes.

The default transaction isolation level in Greenplum Database is `READ COMMITTED`. To change the isolation level for a transaction, declare the isolation level when you `BEGIN` the transaction or use the `SET TRANSACTION` command after the transaction starts.

Global Deadlock Detector

The Greenplum Database Global Deadlock Detector background worker process collects lock information on all segments and uses a directed algorithm to detect the existence of local and global deadlocks. This algorithm allows Greenplum Database to relax concurrent update and delete restrictions on heap tables. (Greenplum Database still employs table-level locking on AO/CO tables, restricting concurrent `UPDATE`, `DELETE`, and `SELECT...FOR lock_strength` operations.)

By default, the Global Deadlock Detector is disabled and Greenplum Database runs the concurrent `UPDATE` and `DELETE` operations on a heap table serially. You can enable these concurrent updates and have the Global Deadlock Detector determine when a deadlock exists by setting the server configuration parameter `gp_enable_global_deadlock_detector`.

When the Global Deadlock Detector is enabled, the background worker process is automatically started on the master host when you start Greenplum Database. You configure the interval at which the Global Deadlock Detector collects and analyzes lock waiting data via the `gp_global_deadlock_detector_period` server configuration parameter.

If the Global Deadlock Detector determines that deadlock exists, it breaks the deadlock by cancelling one or more backend processes associated with the youngest transaction(s) involved.

When the Global Deadlock Detector determines a deadlock exists for the following types of transactions, only one of the transactions will succeed. The other transactions will fail with an error indicating that concurrent updates to the same row is not allowed.

- Concurrent transactions on the same row of a heap table where the first transaction is an update operation and a later transaction runs an update or delete and the query plan contains a motion operator.
- Concurrent update transactions on the same distribution key of a heap table that are run by the Postgres Planner.
- Concurrent update transactions on the same row of a hash table that are run by the GPORCA optimizer.

Note: Greenplum Database uses the interval specified in the `deadlock_timeout` server configuration parameter for local deadlock detection. Because the local and global deadlock detection algorithms differ, the cancelled process(es) may differ depending upon which detector (local or global) Greenplum Database triggers first.

Note: If the `lock_timeout` server configuration parameter is turned on and set to a value smaller than `deadlock_timeout` and `gp_global_deadlock_detector_period`, Greenplum Database will cancel a statement before it would ever trigger a deadlock check in that session.

To view lock waiting information for all segments, run the `gp_dist_wait_status()` user-defined function. You can use the output of this function to determine which transactions are waiting on locks, which transactions are holding locks, the lock types and mode, the waiter and holder session identifiers, and which segments are running the transactions. Sample output of the `gp_dist_wait_status()` function follows:

```

SELECT * FROM pg_catalog.gp_dist_wait_status();
-[ RECORD 1 ]-----+-----
segid          | 0
waiter_dxid    | 11
holder_dxid    | 12
holdTillEndXact | t
waiter_lpid    | 31249
holder_lpid    | 31458
waiter_lockmode | ShareLock
waiter_locktype | transactionid
waiter_sessionid | 8
holder_sessionid | 9
-[ RECORD 2 ]-----+-----
segid          | 1
waiter_dxid    | 12
holder_dxid    | 11
holdTillEndXact | t
waiter_lpid    | 31467
holder_lpid    | 31250
waiter_lockmode | ShareLock
waiter_locktype | transactionid
waiter_sessionid | 9
holder_sessionid | 8

```

When it cancels a transaction to break a deadlock, the Global Deadlock Detector reports the following error message:

```

ERROR:  canceling statement due to user request: "cancelled by global deadlock detector"

```

Global Deadlock Detector UPDATE and DELETE Compatibility

The Global Deadlock Detector can manage concurrent updates for these types of [UPDATE](#) and [DELETE](#) commands on heap tables:

- Simple [UPDATE](#) of a single table. Update a non-distribution key with the Postgres Planner. The command does not contain a [FROM](#) clause, or a sub-query in the [WHERE](#) clause.

```
UPDATE t SET c2 = c2 + 1 WHERE c1 > 10;
```

- Simple [DELETE](#) of a single table. The command does not contain a sub-query in the [FROM](#) or [WHERE](#) clauses.

```
DELETE FROM t WHERE c1 > 10;
```

- Split [UPDATE](#). For the Postgres Planner, the [UPDATE](#) command updates a distribution key.

```
UPDATE t SET c = c + 1; -- c is a distribution key
```

For GPORCA, the [UPDATE](#) command updates a distribution key or references a distribution key.

```
UPDATE t SET b = b + 1 WHERE c = 10; -- c is a distribution key
```

- Complex [UPDATE](#). The [UPDATE](#) command includes multiple table joins.

```
UPDATE t1 SET c = t1.c+1 FROM t2 WHERE t1.c = t2.c;
```

Or the command contains a sub-query in the `WHERE` clause.

```
UPDATE t SET c = c + 1 WHERE c > ALL(SELECT * FROM t1);
```

- **Complex `DELETE`.** A complex `DELETE` command is similar to a complex `UPDATE`, and involves multiple table joins or a sub-query.

```
DELETE FROM t USING t1 WHERE t.c > t1.c;
```

The following table shows the concurrent `UPDATE` or `DELETE` commands that are managed by the Global Deadlock Detector. For example, concurrent simple `UPDATE` commands on the same table row are managed by the Global Deadlock Detector. For a concurrent complex `UPDATE` and a simple `UPDATE`, only one `UPDATE` is performed, and an error is returned for the other `UPDATE`.

Command	Simple <code>UPDATE</code>	Simple <code>DELETE</code>	Split <code>UPDATE</code>	Complex <code>UPDATE</code>	Complex <code>DELETE</code>
Simple <code>UPDATE</code>	YES	YES	NO	NO	NO
Simple <code>DELETE</code>	YES	YES	NO	YES	YES
Split <code>UPDATE</code>	NO	NO	NO	NO	NO
Complex <code>UPDATE</code>	NO	YES	NO	NO	NO
Complex <code>DELETE</code>	NO	YES	NO	NO	YES

Vacuuming the Database

Deleted or updated data rows occupy physical space on disk even though new transactions cannot see them. Periodically running the `VACUUM` command removes these expired rows. For example:

```
VACUUM mytable;
```

The `VACUUM` command collects table-level statistics such as the number of rows and pages. Vacuum all tables after loading data, including append-optimized tables. For information about recommended routine vacuum operations, see [Routine Vacuum and Analyze](#).

Important: The `VACUUM`, `VACUUM FULL`, and `VACUUM ANALYZE` commands should be used to maintain the data in a Greenplum database especially if updates and deletes are frequently performed on your database data. See the `VACUUM` command in the *Greenplum Database Reference Guide* for information about using the command.

Running Out of Locks

Greenplum Database can potentially run out of locks when a database operation accesses multiple tables in a single transaction. Backup and restore are examples of such operations.

When Greenplum Database runs out of locks, the error message that you may observe references a shared memory error:

```
... "WARNING","53200","out of shared memory",,,,,,"LOCK TABLE ...
... "ERROR","53200","out of shared memory",,"You might need to increase max_locks_per_
transaction.",,,,,,"LOCK TABLE ...
```

Note: “shared memory” in this context refers to the shared memory of the internal object: the lock slots. “Out of shared memory” does *not* refer to exhaustion of system- or Greenplum-level memory resources.

As the hint describes, consider increasing the `max_locks_per_transaction` server configuration parameter when you encounter this error.

Managing a Greenplum System

This section describes basic system administration tasks performed by a Greenplum Database system administrator.

- **About the Greenplum Database Release Version Number**
Greenplum Database version numbers and the way they change identify what has been modified from one Greenplum Database release to the next.
- **Starting and Stopping Greenplum Database**
In a Greenplum Database DBMS, the database server instances (the master and all segments) are started or stopped across all of the hosts in the system in such a way that they can work together as a unified DBMS.
- **Accessing the Database**
This topic describes the various client tools you can use to connect to Greenplum Database, and how to establish a database session.
- **Configuring the Greenplum Database System**
Server configuration parameters affect the behavior of Greenplum Database.
- **Enabling Compression**
You can configure Greenplum Database to use data compression with some database features and with some utilities.
- **Configuring Proxies for the Greenplum Interconnect**
You can configure a Greenplum system to use proxies for interconnect communication to reduce the use of connections and ports during query processing.
- **Enabling High Availability and Data Consistency Features**
The fault tolerance and the high-availability features of Greenplum Database can be configured.
- **Backing Up and Restoring Databases**
This topic describes how to use Greenplum backup and restore features.
- **Expanding a Greenplum System**
To scale up performance and storage capacity, expand your Greenplum Database system by adding hosts to the system. In general, adding nodes to a Greenplum cluster achieves a linear scaling of performance and storage capacity.
- **Migrating Data with gpcopy**
You can use the `gpcopy` utility to transfer data between databases in different Greenplum Database clusters.
- **Monitoring a Greenplum System**
You can monitor a Greenplum Database system using a variety of tools included with the system or available as add-ons.
- **Routine System Maintenance Tasks**
To keep a Greenplum Database system running efficiently, the database must be regularly cleared of expired data and the table statistics must be updated so that the query optimizer has accurate information.

- **Recommended Monitoring and Maintenance Tasks**

This section lists monitoring and maintenance activities recommended to ensure high availability and consistent performance of your Greenplum Database cluster.

Parent topic: [Greenplum Database Administrator Guide](#)

About the Greenplum Database Release Version Number

Greenplum Database version numbers and the way they change identify what has been modified from one Greenplum Database release to the next.

A Greenplum Database release version number takes the format x.y.z, where:

- x identifies the Major version number
- y identifies the Minor version number
- z identifies the Patch version number

Greenplum Database releases that have the same Major release number are guaranteed to be backwards compatible. Greenplum Database increments the Major release number when the catalog changes or when incompatible feature changes or new features are introduced. Previously deprecated functionality may be removed in a major release.

The Minor release number for a given Major release increments when backwards compatible new features are introduced or when a Greenplum Database feature is deprecated. (Previously deprecated functionality will never be removed in a minor release.)

Greenplum Database increments the Patch release number for a given Minor release for backwards-compatible bug fixes.

Parent topic: [Managing a Greenplum System](#)

Starting and Stopping Greenplum Database

In a Greenplum Database DBMS, the database server instances (the master and all segments) are started or stopped across all of the hosts in the system in such a way that they can work together as a unified DBMS.

Because a Greenplum Database system is distributed across many machines, the process for starting and stopping a Greenplum Database system is different than the process for starting and stopping a regular PostgreSQL DBMS.

Use the `gpstart` and `gpstop` utilities to start and stop Greenplum Database, respectively. These utilities are located in the `$GPHOME/bin` directory on your Greenplum Database master host.

Important: Do not issue a `kill` command to end any Postgres process. Instead, use the database command `pg_cancel_backend()`.

Issuing a `kill -9` or `kill -11` can introduce database corruption and prevent root cause analysis from being performed.

For information about `gpstart` and `gpstop`, see the *Greenplum Database Utility Guide*.

Parent topic: [Managing a Greenplum System](#)

Starting Greenplum Database

Start an initialized Greenplum Database system by running the `gpstart` utility on the master instance.

Use the `gpstart` utility to start a Greenplum Database system that has already been initialized by the `gpinitssystem` utility, but has been stopped by the `gpstop` utility. The `gpstart` utility starts Greenplum

Database by starting all the Postgres database instances on the Greenplum Database cluster. `gpstart` orchestrates this process and performs the process in parallel.

Run `gpstart` on the master host to start Greenplum Database:

```
$ gpstart
```

Restarting Greenplum Database

Stop the Greenplum Database system and then restart it.

The `gpstop` utility with the `-r` option can stop and then restart Greenplum Database after the shutdown completes.

To restart Greenplum Database, enter the following command on the master host:

```
$ gpstop -r
```

Reloading Configuration File Changes Only

Reload changes to Greenplum Database configuration files without interrupting the system.

The `gpstop` utility can reload changes to the `pg_hba.conf` configuration file and to *runtime* parameters in the master `postgresql.conf` file without service interruption. Active sessions pick up changes when they reconnect to the database. Many server configuration parameters require a full system restart (`gpstop -r`) to activate. For information about server configuration parameters, see the *Greenplum Database Reference Guide*.

Reload configuration file changes without shutting down the Greenplum Database system using the `gpstop` utility:

```
$ gpstop -u
```

Starting the Master in Maintenance Mode

Start only the master to perform maintenance or administrative tasks without affecting data on the segments.

Maintenance mode should only be used with direction from VMware Technical Support. For example, you could connect to a database only on the master instance in maintenance mode and edit system catalog settings. For more information about system catalog tables, see the *Greenplum Database Reference Guide*.

1. Run `gpstart` using the `-m` option:

```
$ gpstart -m
```

2. Connect to the master in maintenance mode to do catalog maintenance. For example:

```
$ PGOPTIONS='-c gp_role=utility' psql postgres
```

3. After completing your administrative tasks, stop the master in maintenance mode. Then, restart it in production mode.

```
$ gpstop -m  
$ gpstart
```

Warning:

Incorrect use of maintenance mode connections can result in an inconsistent system state. Only Technical Support should perform this operation.

Stopping Greenplum Database

The `gpstop` utility stops or restarts your Greenplum Database system and always runs on the master host. When activated, `gpstop` stops all `postgres` processes in the system, including the master and all segment instances. The `gpstop` utility uses a default of up to 64 parallel worker threads to bring down the Postgres instances that make up the Greenplum Database cluster. The system waits for any active transactions to finish before shutting down. If after two minutes there are still active connections, `gpstop` will prompt you to either continue waiting in smart mode, stop in fast mode, or stop in immediate mode. To stop Greenplum Database immediately, use fast mode.

Important: Immediate shut down mode is not recommended. This mode stops all database processes without allowing the database server to complete transaction processing or clean up any temporary or in-process work files.

- To stop Greenplum Database:

```
$ gpstop
```

- To stop Greenplum Database in fast mode:

```
$ gpstop -M fast
```

By default, you are not allowed to shut down Greenplum Database if there are any client connections to the database. Use the `-M fast` option to roll back all in progress transactions and terminate any connections before shutting down.

Stopping Client Processes

Greenplum Database launches a new backend process for each client connection. A Greenplum Database user with `SUPERUSER` privileges can cancel and terminate these client backend processes.

Canceling a backend process with the `pg_cancel_backend()` function ends a specific queued or active client query. Terminating a backend process with the `pg_terminate_backend()` function terminates a client connection to a database.

The `pg_cancel_backend()` function has two signatures:

- `pg_cancel_backend(pid int4)`
- `pg_cancel_backend(pid int4, msg text)`

The `pg_terminate_backend()` function has two similar signatures:

- `pg_terminate_backend(pid int4)`
- `pg_terminate_backend(pid int4, msg text)`

If you provide a `msg`, Greenplum Database includes the text in the cancel message returned to the client. `msg` is limited to 128 bytes; Greenplum Database truncates anything longer.

The `pg_cancel_backend()` and `pg_terminate_backend()` functions return `true` if successful, and `false` otherwise.

To cancel or terminate a backend process, you must first identify the process ID of the backend. You can obtain the process ID from the `pid` column of the `pg_stat_activity` view. For example, to view

the process information associated with all running and queued queries:

```
=# SELECT username, pid, waiting, state, query, datname
FROM pg_stat_activity;
```

Sample partial query output:

username	pid	waiting	state	query	datname
sammy	31861	f	idle	SELECT * FROM testtbl;	testdb
billy	31905	t	active	SELECT * FROM topten;	testdb

Use the output to identify the process id ([pid](#)) of the query or client connection.

For example, to cancel the waiting query identified in the sample output above and include 'Admin canceled long-running query.' as the message returned to the client:

```
=# SELECT pg_cancel_backend(31905 , 'Admin canceled long-running query.');
```

ERROR: canceling statement due to user request: "Admin canceled long-running query."

Managing Greenplum Database Access

Securing Greenplum Database includes protecting access to the database through network configuration, database user authentication, and encryption.

- **Configuring Client Authentication**
This topic explains how to configure client connections and authentication for Greenplum Database.
- **Managing Roles and Privileges**
The Greenplum Database authorization mechanism stores roles and permissions to access database objects in the database and is administered using SQL statements or command-line utilities.

Parent topic: [Greenplum Database Administrator Guide](#)

Configuring Client Authentication

This topic explains how to configure client connections and authentication for Greenplum Database.

When a Greenplum Database system is first initialized, the system contains one predefined *superuser* role. This role will have the same name as the operating system user who initialized the Greenplum Database system. This role is referred to as `gpadmin`. By default, the system is configured to only allow local connections to the database from the `gpadmin` role. If you want to allow any other roles to connect, or if you want to allow connections from remote hosts, you have to configure Greenplum Database to allow such connections. This section explains how to configure client connections and authentication to Greenplum Database.

- **Using LDAP Authentication with TLS/SSL**
You can control access to Greenplum Database with an LDAP server and, optionally, secure the connection with encryption by adding parameters to `pg_hba.conf` file entries.
- **Using Kerberos Authentication**
You can control access to Greenplum Database with a Kerberos authentication server.
- **Configuring Kerberos for Linux Clients**
You can configure Linux client applications to connect to a Greenplum Database system that is configured to authenticate with Kerberos.

- **Configuring Kerberos For Windows Clients**

You can configure Microsoft Windows client applications to connect to a Greenplum Database system that is configured to authenticate with Kerberos.

Parent topic: [Managing Greenplum Database Access](#)

Allowing Connections to Greenplum Database

Client access and authentication is controlled by the standard PostgreSQL host-based authentication file, `pg_hba.conf`. For detailed information about this file, see [The pg_hba.conf File](#) in the PostgreSQL documentation.

In Greenplum Database, the `pg_hba.conf` file of the master instance controls client access and authentication to your Greenplum Database system. The Greenplum Database segments also have `pg_hba.conf` files, but these are already correctly configured to allow only client connections from the master host. The segments never accept outside client connections, so there is no need to alter the `pg_hba.conf` file on segments.

The general format of the `pg_hba.conf` file is a set of records, one per line. Greenplum Database ignores blank lines and any text after the `#` comment character. A record consists of a number of fields that are separated by spaces or tabs. Fields can contain white space if the field value is quoted. Records cannot be continued across lines. Each remote client access record has the following format:

```
host      database  role      address      authentication-method
```

Each UNIX-domain socket access record is in this format:

```
local     database  role      authentication-method
```

The following table describes meaning of each field.

Table 1. `pg_hba.conf` Fields

Field	Description
local	Matches connection attempts using UNIX-domain sockets. Without a record of this type, UNIX-domain socket connections are disallowed.
host	Matches connection attempts made using TCP/IP. Remote TCP/IP connections will not be possible unless the server is started with an appropriate value for the <code>listen_addresses</code> server configuration parameter.
hostssl	Matches connection attempts made using TCP/IP, but only when the connection is made with SSL encryption. SSL must be enabled at server start time by setting the <code>ssl</code> server configuration parameter.
hostnossl	Matches connection attempts made over TCP/IP that do not use SSL.
database	Specifies which database names this record matches. The value <code>all</code> specifies that it matches all databases. Multiple database names can be supplied by separating them with commas. A separate file containing database names can be specified by preceding the file name with a <code>@</code> .
role	Specifies which database role names this record matches. The value <code>all</code> specifies that it matches all roles. If the specified role is a group and you want all members of that group to be included, precede the role name with a <code>+</code> . Multiple role names can be supplied by separating them with commas. A separate file containing role names can be specified by preceding the file name with a <code>@</code> .

Table 1. pg_hba.conf Fields

Field	Description
address	<p>Specifies the client machine addresses that this record matches. This field can contain an IP address, an IP address range, or a host name.</p> <p>An IP address range is specified using standard numeric notation for the range's starting address, then a slash (/) and a CIDR mask length. The mask length indicates the number of high-order bits of the client IP address that must match. Bits to the right of this should be zero in the given IP address. There must not be any white space between the IP address, the /, and the CIDR mask length.</p> <p>Typical examples of an IPv4 address range specified this way are <code>172.20.143.89/32</code> for a single host, or <code>172.20.143.0/24</code> for a small network, or <code>10.6.0.0/16</code> for a larger one. An IPv6 address range might look like <code>::1/128</code> for a single host (in this case the IPv6 loopback address) or <code>fe80::7a31:c1ff:0000:0000/96</code> for a small network. <code>0.0.0.0/0</code> represents all IPv4 addresses, and <code>::0/0</code> represents all IPv6 addresses. To specify a single host, use a mask length of 32 for IPv4 or 128 for IPv6. In a network address, do not omit trailing zeroes.</p> <p>An entry given in IPv4 format will match only IPv4 connections, and an entry given in IPv6 format will match only IPv6 connections, even if the represented address is in the IPv4-in-IPv6 range.</p> <p>Note: Entries in IPv6 format will be rejected if the host system C library does not have support for IPv6 addresses.</p> <p>If a host name is specified (an address that is not an IP address or IP range is treated as a host name), that name is compared with the result of a reverse name resolution of the client IP address (for example, reverse DNS lookup, if DNS is used). Host name comparisons are case insensitive. If there is a match, then a forward name resolution (for example, forward DNS lookup) is performed on the host name to check whether any of the addresses it resolves to are equal to the client IP address. If both directions match, then the entry is considered to match.</p> <p>Some host name databases allow associating an IP address with multiple host names, but the operating system only returns one host name when asked to resolve an IP address. The host name that is used in <code>pg_hba.conf</code> must be the one that the address-to-name resolution of the client IP address returns, otherwise the line will not be considered a match.</p> <p>When host names are specified in <code>pg_hba.conf</code>, you should ensure that name resolution is reasonably fast. It can be of advantage to set up a local name resolution cache such as <code>nscd</code>. Also, you can enable the server configuration parameter <code>log_hostname</code> to see the client host name instead of the IP address in the log.</p>
IP-address IP-mask	<p>These fields can be used as an alternative to the CIDR address notation. Instead of specifying the mask length, the actual mask is specified in a separate column. For example, <code>255.0.0.0</code> represents an IPv4 CIDR mask length of 8, and <code>255.255.255.255</code> represents a CIDR mask length of 32.</p>
authentication-method	<p>Specifies the authentication method to use when connecting. Greenplum supports the authentication methods supported by PostgreSQL 9.4.</p>

CAUTION: For a more secure system, consider removing records for remote connections that use trust authentication from the `pg_hba.conf` file. Trust authentication grants any user who can connect to the server access to the database using any role they specify. You can safely replace trust authentication with ident authentication for local UNIX-socket connections. You can also use ident authentication for local and remote TCP clients, but the client host must be running an ident service and you must trust the integrity of that machine.

Editing the pg_hba.conf File

Initially, the `pg_hba.conf` file is set up with generous permissions for the `gpadmin` user and no database access for other Greenplum Database roles. You will need to edit the `pg_hba.conf` file to enable users' access to databases and to secure the `gpadmin` user. Consider removing entries that

have trust authentication, since they allow anyone with access to the server to connect with any role they choose. For local (UNIX socket) connections, use ident authentication, which requires the operating system user to match the role specified. For local and remote TCP connections, ident authentication requires the client's host to run an indent service. You can install an indent service on the master host and then use ident authentication for local TCP connections, for example `127.0.0.1/28`. Using ident authentication for remote TCP connections is less secure because it requires you to trust the integrity of the indent service on the client's host.

This example shows how to edit the `pg_hba.conf` file of the master to allow remote client access to all databases from all roles using encrypted password authentication.

Editing `pg_hba.conf`

1. Open the file `$MASTER_DATA_DIRECTORY/pg_hba.conf` in a text editor.
2. Add a line to the file for each type of connection you want to allow. Records are read sequentially, so the order of the records is significant. Typically, earlier records will have tight connection match parameters and weaker authentication methods, while later records will have looser match parameters and stronger authentication methods. For example:

```
# allow the gpadmin user local access to all databases
# using ident authentication
local    all    gpadmin    ident            sameuser
host     all    gpadmin    127.0.0.1/32    ident
host     all    gpadmin    ::1/128      ident
# allow the 'dba' role access to any database from any
# host with IP address 192.168.x.x and use md5 encrypted
# passwords to authenticate the user
# Note that to use SHA-256 encryption, replace md5 with
# password in the line below
host     all    dba        192.168.0.0/32    md5
# allow all roles access to any database from any
# host and use ldap to authenticate the user. Greenplum role
# names must match the LDAP common name.
host     all    all        192.168.0.0/32    ldap ldapserver=usldap1 ldapport=1389 ldapp
refix="cn=" ldapsuffix=",ou=People,dc=company,dc=com"
```

3. Save and close the file.
4. Reload the `pg_hba.conf` configuration file for your changes to take effect:

```
$ gpstop -u
```

Note: Note that you can also control database access by setting object privileges as described in [Managing Object Privileges](#). The `pg_hba.conf` file just controls who can initiate a database session and how those connections are authenticated.

Limiting Concurrent Connections

Greenplum Database allocates some resources on a per-connection basis, so setting the maximum number of connections allowed is recommended.

To limit the number of active concurrent sessions to your Greenplum Database system, you can configure the `max_connections` server configuration parameter. This is a *local* parameter, meaning that you must set it in the `postgresql.conf` file of the master, the standby master, and each segment instance (primary and mirror). The recommended value of `max_connections` on segments is 5-10 times the value on the master.

When you set `max_connections`, you must also set the dependent parameter

`max_prepared_transactions`. This value must be at least as large as the value of `max_connections` on the master, and segment instances should be set to the same value as the master.

For example:

- In `$MASTER_DATA_DIRECTORY/postgresql.conf` (including standby master):

```
max_connections=100
max_prepared_transactions=100
```

- In `SEGMENT_DATA_DIRECTORY/postgresql.conf` for all segment instances:

```
max_connections=500
max_prepared_transactions=100
```

The following steps set the parameter values with the Greenplum Database utility `gpconfig`.

For information about `gpconfig`, see the *Greenplum Database Utility Guide*.

To change the number of allowed connections

1. Log into the Greenplum Database master host as the Greenplum Database administrator and source the file `$GPHOME/greenplum_path.sh`.
2. Set the value of the `max_connections` parameter. This `gpconfig` command sets the value on the segments to 1000 and the value on the master to 200.

```
$ gpconfig -c max_connections -v 1000 -m 200
```

The value on the segments must be greater than the value on the master. The recommended value of `max_connections` on segments is 5-10 times the value on the master.

3. Set the value of the `max_prepared_transactions` parameter. This `gpconfig` command sets the value to 200 on the master and all segments.

```
$ gpconfig -c max_prepared_transactions -v 200
```

The value of `max_prepared_transactions` must be greater than or equal to `max_connections` on the master.

4. Stop and restart your Greenplum Database system.

```
$ gpstop -r
```

5. You can check the value of parameters on the master and segments with the `gpconfig -s` option. This `gpconfig` command displays the values of the `max_connections` parameter.

```
$ gpconfig -s max_connections
```

Note: Raising the values of these parameters may cause Greenplum Database to request more shared memory. To mitigate this effect, consider decreasing other memory-related parameters such as `gp_cached_segworkers_threshold`.

Encrypting Client/Server Connections

Enable SSL for client connections to Greenplum Database to encrypt the data passed over the network between the client and the database.

Greenplum Database has native support for SSL connections between the client and the master server. SSL connections prevent third parties from snooping on the packets, and also prevent man-in-the-middle attacks. SSL should be used whenever the client connection goes through an insecure link, and must be used whenever client certificate authentication is used.

Enabling Greenplum Database in SSL mode requires the following items.

- OpenSSL installed on both the client and the master server hosts (master and standby master).
- The SSL files `server.key` (server private key) and `server.crt` (server certificate) should be correctly generated for the master host and standby master host.
 - The private key should not be protected with a passphrase. The server does not prompt for a passphrase for the private key, and Greenplum Database start up fails with an error if one is required.
 - On a production system, there should be a key and certificate pair for the master host and a pair for the standby master host with a subject CN (Common Name) for the master host and standby master host. A self-signed certificate can be used for testing, but a certificate signed by a certificate authority (CA) should be used in production, so the client can verify the identity of the server. Either a global or local CA can be used. If all the clients are local to the organization, a local CA is recommended.
- Ensure that Greenplum Database can access `server.key` and `server.crt`, and any additional authentication files such as `root.crt` (for trusted certificate authorities). When starting in SSL mode, the Greenplum Database master looks for `server.key` and `server.crt`. As the default, Greenplum Database does not start if the files are not in the master data directory (`$MASTER_DATA_DIRECTORY`). Also, if you use other SSL authentication files such as `root.crt` (trusted certificate authorities), the files must be on the master host.

If Greenplum Database master mirroring is enabled with SSL client authentication, SSL authentication files must be on both the master host and standby master host and *should not be placed* in the default directory `$MASTER_DATA_DIRECTORY`. When master mirroring is enabled, an `initstandby` operation copies the contents of the `$MASTER_DATA_DIRECTORY` from the master to the standby master and the incorrect SSL key, and cert files (the master files, and not the standby master files) will prevent standby master start up.

You can specify a different directory for the location of the SSL server files with the `postgresql.conf` parameters `sslcert`, `sslkey`, `sslrootcert`, and `sslcrcl`. For more information about the parameters, see [SSL Client Authentication](#) in the *Security Configuration Guide*.

Greenplum Database can be started with SSL enabled by setting the server configuration parameter `ssl=on` in the `postgresql.conf` file on the master and standby master hosts. This `gpconfig` command sets the parameter:

```
gpconfig -c ssl -m on -v off
```

Setting the parameter requires a server restart. This command restarts the system: `gpstop -ra`.

Creating a Self-signed Certificate without a Passphrase for Testing

Only

To create a quick self-signed certificate for the server for testing, use the following OpenSSL command:

```
# openssl req -new -text -out server.req
```

Enter the information requested by the prompts. Be sure to enter the local host name as *Common Name*. The challenge password can be left blank.

The program will generate a key that is passphrase protected, and does not accept a passphrase that is less than four characters long.

To use this certificate with Greenplum Database, remove the passphrase with the following commands:

```
# openssl rsa -in privkey.pem -out server.key
# rm privkey.pem
```

Enter the old passphrase when prompted to unlock the existing key.

Then, enter the following command to turn the certificate into a self-signed certificate and to copy the key and certificate to a location where the server will look for them.

```
# openssl req -x509 -in server.req -text -key server.key -out server.crt
```

Finally, change the permissions on the key with the following command. The server will reject the file if the permissions are less restrictive than these.

```
# chmod og-rwx server.key
```

For more details on how to create your server private key and certificate, refer to the [OpenSSL documentation](#).

Using LDAP Authentication with TLS/SSL

You can control access to Greenplum Database with an LDAP server and, optionally, secure the connection with encryption by adding parameters to `pg_hba.conf` file entries.

Greenplum Database supports LDAP authentication with the TLS/SSL protocol to encrypt communication with an LDAP server:

- LDAP authentication with STARTTLS and TLS protocol – STARTTLS starts with a clear text connection (no encryption) and upgrades it to a secure connection (with encryption).
- LDAP authentication with a secure connection and TLS/SSL (LDAPS) – Greenplum Database uses the TLS or SSL protocol based on the protocol that is used by the LDAP server.

If no protocol is specified, Greenplum Database communicates with the LDAP server with a clear text connection.

To use LDAP authentication, the Greenplum Database master host must be configured as an LDAP client. See your LDAP documentation for information about configuring LDAP clients.

Enabling LDAP Authentication with STARTTLS and TLS

To enable STARTTLS with the TLS protocol, in the `pg_hba.conf` file, add an `ldap` line and specify the

`ldaptls` parameter with the value 1. The default port is 389. In this example, the authentication method parameters include the `ldaptls` parameter.

```
ldap ldapserver=myldap.com ldaptls=1 ldaprefix="uid=" ldapsuffix=",ou=People,dc=example,dc=com"
```

Specify a non-default port with the `ldapport` parameter. In this example, the authentication method includes the `ldaptls` parameter and the `ldapport` parameter to specify the port 550.

```
ldap ldapserver=myldap.com ldaptls=1 ldapport=550 ldaprefix="uid=" ldapsuffix=",ou=People,dc=example,dc=com"
```

Enabling LDAP Authentication with a Secure Connection and TLS/SSL

To enable a secure connection with TLS/SSL, add `ldaps://` as the prefix to the LDAP server name specified in the `ldapserver` parameter. The default port is 636.

This example `ldapserver` parameter specifies a secure connection and the TLS/SSL protocol for the LDAP server `myldap.com`.

```
ldapserver=ldaps://myldap.com
```

To specify a non-default port, add a colon (:) and the port number after the LDAP server name. This example `ldapserver` parameter includes the `ldaps://` prefix and the non-default port 550.

```
ldapserver=ldaps://myldap.com:550
```

Configuring Authentication with a System-wide OpenLDAP System

If you have a system-wide OpenLDAP system and logins are configured to use LDAP with TLS or SSL in the `pg_hba.conf` file, logins may fail with the following message:

```
could not start LDAP TLS session: error code '-11'
```

To use an existing OpenLDAP system for authentication, Greenplum Database must be set up to use the LDAP server's CA certificate to validate user certificates. Follow these steps on both the master and standby hosts to configure Greenplum Database:

1. Copy the base64-encoded root CA chain file from the Active Directory or LDAP server to the Greenplum Database master and standby master hosts. This example uses the directory `/etc/pki/tls/certs`.
2. Change to the directory where you copied the CA certificate file and, as the root user, generate the hash for OpenLDAP:

```
# cd /etc/pki/tls/certs
# openssl x509 -noout -hash -in <ca-certificate-file>
# ln -s <ca-certificate-file> <ca-certificate-file>.0
```

3. Configure an OpenLDAP configuration file for Greenplum Database with the CA certificate directory and certificate file specified.

As the root user, edit the OpenLDAP configuration file `/etc/openldap/ldap.conf`:

```
SASL_NOCANON on
URI ldaps://ldapA.example.priv ldaps://ldapB.example.priv ldaps://ldapC.example.priv
BASE dc=example,dc=priv
TLS_CACERTDIR /etc/pki/tls/certs
TLS_CACERT /etc/pki/tls/certs/<ca-certificate-file>
```

Note: For certificate validation to succeed, the hostname in the certificate must match a hostname in the URI property. Otherwise, you must also add `TLS_REQCERT allow` to the file.

- As the `gpadmin` user, edit `/usr/local/greenplum-db/greenplum_path.sh` and add the following line.

```
export LDAPCONF=/etc/openldap/ldap.conf
```

Notes

Greenplum Database logs an error if the following are specified in an `pg_hba.conf` file entry:

- If both the `ldaps://` prefix and the `ldaptls=1` parameter are specified.
- If both the `ldaps://` prefix and the `ldapport` parameter are specified.

Enabling encrypted communication for LDAP authentication only encrypts the communication between Greenplum Database and the LDAP server.

See [Encrypting Client/Server Connections](#) for information about encrypting client connections.

Examples

These are example entries from an `pg_hba.conf` file.

This example specifies LDAP authentication with no encryption between Greenplum Database and the LDAP server.

```
host all plainuser 0.0.0.0/0 ldap ldapserver=myldap.com ldapprefix="uid=" ldapsuffix="
,ou=People,dc=example,dc=com"
```

This example specifies LDAP authentication with the STARTTLS and TLS protocol between Greenplum Database and the LDAP server.

```
host all tlsuser 0.0.0.0/0 ldap ldapserver=myldap.com ldaptls=1 ldapprefix="uid=" ldap
suffix=",ou=People,dc=example,dc=com"
```

This example specifies LDAP authentication with a secure connection and TLS/SSL protocol between Greenplum Database and the LDAP server.

```
host all ldapsuser 0.0.0.0/0 ldap ldapserver=ldaps://myldap.com ldapprefix="uid=" ldap
suffix=",ou=People,dc=example,dc=com"
```

Parent topic: [Configuring Client Authentication](#)

Using Kerberos Authentication

You can control access to Greenplum Database with a Kerberos authentication server.

Greenplum Database supports the Generic Security Service Application Program Interface (GSSAPI) with Kerberos authentication. GSSAPI provides automatic authentication (single sign-on) for systems that support it. You specify the Greenplum Database users (roles) that require Kerberos

authentication in the Greenplum Database configuration file `pg_hba.conf`. The login fails if Kerberos authentication is not available when a role attempts to log in to Greenplum Database.

Kerberos provides a secure, encrypted authentication service. It does not encrypt data exchanged between the client and database and provides no authorization services. To encrypt data exchanged over the network, you must use an SSL connection. To manage authorization for access to Greenplum databases and objects such as schemas and tables, you use settings in the `pg_hba.conf` file and privileges given to Greenplum Database users and roles within the database. For information about managing authorization privileges, see [Managing Roles and Privileges](#).

For more information about Kerberos, see <http://web.mit.edu/kerberos/>.

Prerequisites

Before configuring Kerberos authentication for Greenplum Database, ensure that:

- You can identify the KDC server you use for Kerberos authentication and the Kerberos realm for your Greenplum Database system. If you have not yet configured your MIT Kerberos KDC server, see [Installing and Configuring a Kerberos KDC Server](#) for example instructions.
- System time on the Kerberos Key Distribution Center (KDC) server and Greenplum Database master is synchronized. (For example, install the `ntp` package on both servers.)
- Network connectivity exists between the KDC server and the Greenplum Database master host.
- Java 1.7.0_17 or later is installed on all Greenplum Database hosts. Java 1.7.0_17 is required to use Kerberos-authenticated JDBC on Red Hat Enterprise Linux 6.x or 7.x.

Procedure

Following are the tasks to complete to set up Kerberos authentication for Greenplum Database.

- [Creating Greenplum Database Principals in the KDC Database](#)
- [Installing the Kerberos Client on the Master Host](#)
- [Configuring Greenplum Database to use Kerberos Authentication](#)
- [Mapping Kerberos Principals to Greenplum Database Roles](#)
- [Configuring JDBC Kerberos Authentication for Greenplum Database](#)
- [Configuring Kerberos for Linux Clients](#)
- [Configuring Kerberos For Windows Clients](#)

Parent topic: [Configuring Client Authentication](#)

Creating Greenplum Database Principals in the KDC Database

Create a service principal for the Greenplum Database service and a Kerberos admin principal that allows managing the KDC database as the `gpadmin` user.

1. Log in to the Kerberos KDC server as the root user.

```
$ ssh root@<kdc-server>
```

2. Create a principal for the Greenplum Database service.

```
# kadmin.local -q "addprinc -randkey postgres/mdw@GPDB.KRB"
```

The `-randkey` option prevents the command from prompting for a password.

The `postgres` part of the principal names matches the value of the Greenplum Database `krb_srvname` server configuration parameter, which is `postgres` by default.

The host name part of the principal name must match the output of the `hostname` command on the Greenplum Database master host. If the `hostname` command shows the fully qualified domain name (FQDN), use it in the principal name, for example `postgres/mdw.example.com@GPDB.KRB`.

The `GPDB.KRB` part of the principal name is the Kerberos realm name.

3. Create a principal for the `gpadmin/admin` role.

```
# kadmin.local -q "addprinc gpadmin/admin@GPDB.KRB"
```

This principal allows you to manage the KDC database when you are logged in as `gpadmin`. Make sure that the Kerberos `kadm.acl` configuration file contains an ACL to grant permissions to this principal. For example, this ACL grants all permissions to any admin user in the `GPDB.KRB` realm.

```
*/admin@GPDB.KRB *
```

4. Create a keytab file with `kadmin.local`. The following example creates a keytab file `gpdb-kerberos.keytab` in the current directory with authentication information for the Greenplum Database service principal and the `gpadmin/admin` principal.

```
# kadmin.local -q "ktadd -k gpdb-kerberos.keytab postgres/mdw@GPDB.KRB gpadmin/admin@GPDB.KRB"
```

5. Copy the keytab file to the master host.

```
# scp gpdb-kerberos.keytab gpadmin@mdw:~
```

Installing the Kerberos Client on the Master Host

Install the Kerberos client utilities and libraries on the Greenplum Database master.

1. Install the Kerberos packages on the Greenplum Database master.

```
$ sudo yum install krb5-libs krb5-workstation
```

2. Copy the `/etc/krb5.conf` file from the KDC server to `/etc/krb5.conf` on the Greenplum Master host.

Configuring Greenplum Database to use Kerberos Authentication

Configure Greenplum Database to use Kerberos.

1. Log in to the Greenplum Database master host as the `gpadmin` user.

```
$ ssh gpadmin@<master>
$ source /usr/local/greenplum-db/greenplum_path.sh
```

2. Set the ownership and permissions of the keytab file you copied from the KDC server.

```
$ chown gpadmin:gpadmin /home/gpadmin/gpdb-kerberos.keytab
$ chmod 400 /home/gpadmin/gpdb-kerberos.keytab
```

3. Configure the location of the keytab file by setting the Greenplum Database `krb_server_keyfile` server configuration parameter. This `gpconfig` command specifies the folder `/home/gpadmin` as the location of the keytab file `gpdb-kerberos.keytab`.

```
$ gpconfig -c krb_server_keyfile -v '/home/gpadmin/gpdb-kerberos.keytab'
```

4. Modify the Greenplum Database file `pg_hba.conf` to enable Kerberos support. For example, adding the following line to `pg_hba.conf` adds GSSAPI and Kerberos authentication support for connection requests from all users and hosts on the same network to all Greenplum Database databases.

```
host all all 0.0.0.0/0 gss include_realm=0 krb_realm=GPDB.KRB
```

Setting the `krb_realm` option to a realm name ensures that only users from that realm can successfully authenticate with Kerberos. Setting the `include_realm` option to `0` excludes the realm name from the authenticated user name. For information about the `pg_hba.conf` file, see [The `pg_hba.conf` file](#) in the PostgreSQL documentation.

5. Restart Greenplum Database after updating the `krb_server_keyfile` parameter and the `pg_hba.conf` file.

```
$ gpstop -ar
```

6. Create the `gpadmin/admin` Greenplum Database superuser role.

```
$ createuser gpadmin/admin --superuser
```

The Kerberos keys for this database role are in the keyfile you copied from the KDC server.

7. Create a ticket using `kinit` and show the tickets in the Kerberos ticket cache with `klist`.

```
$ LD_LIBRARY_PATH= kinit -k -t /home/gpadmin/gpdb-kerberos.keytab gpadmin/admin
@GPDB.KRB
$ LD_LIBRARY_PATH= klist
Ticket cache: FILE:/tmp/krb5cc_1000
Default principal: gpadmin/admin@GPDB.KRB

Valid starting          Expires                Service principal
06/13/2018 17:37:35    06/14/2018 17:37:35    krbtgt/GPDB.KRB@GPDB.KRB
```

Note: When you set up the Greenplum Database environment by sourcing the `greenplum-db_path.sh` script, the `LD_LIBRARY_PATH` environment variable is set to include the Greenplum Database `lib` directory, which includes Kerberos libraries. This may cause Kerberos utility commands such as `kinit` and `klist` to fail due to version conflicts. The solution is to run Kerberos utilities before you source the `greenplum-db_path.sh` file or temporarily unset the `LD_LIBRARY_PATH` variable when you run Kerberos utilities, as shown in the example.

8. As a test, log in to the postgres database with the `gpadmin/admin` role:

```
$ psql -U "gpadmin/admin" -h mdw postgres
psql (9.4.20)
Type "help" for help.

postgres=# select current_user;
current_user
```

```
-----
gpadmin/admin
(1 row)
```

Note: When you start `psql` on the master host, you must include the `-h <master-hostname>` option to force a TCP connection because Kerberos authentication does not work with local connections.

If a Kerberos principal is not a Greenplum Database user, a message similar to the following is displayed from the `psql` command line when the user attempts to log in to the database:

```
psql: krb5_sendauth: Bad response
```

The principal must be added as a Greenplum Database user.

Mapping Kerberos Principals to Greenplum Database Roles

To connect to a Greenplum Database system with Kerberos authentication enabled, a user first requests a ticket-granting ticket from the KDC server using the `kinit` utility with a password or a keytab file provided by the Kerberos admin. When the user then connects to the Kerberos-enabled Greenplum Database system, the user's Kerberos principal name will be the Greenplum Database role name, subject to transformations specified in the options field of the `gss` entry in the Greenplum Database `pg_hba.conf` file:

- If the `krb_realm=<realm>` option is present, Greenplum Database only accepts Kerberos principals who are members of the specified realm.
- If the `include_realm=0` option is specified, the Greenplum Database role name is the Kerberos principal name without the Kerberos realm. If the `include_realm=1` option is instead specified, the Kerberos realm is not stripped from the Greenplum Database rolename. The role must have been created with the Greenplum Database `CREATE ROLE` command.
- If the `map=<map-name>` option is specified, the Kerberos principal name is compared to entries labeled with the specified `<map-name>` in the `$MASTER_DATA_DIRECTORY/pg_ident.conf` file and replaced with the Greenplum Database role name specified in the first matching entry.

A user name map is defined in the `$MASTER_DATA_DIRECTORY/pg_ident.conf` configuration file. This example defines a map named `mymap` with two entries.

```
# MAPNAME      SYSTEM-USERNAME      GP-USERNAME
mymap          /^admin@GPDB.KRB$      gpadmin
mymap          /^(.*)_gp)@GPDB.KRB$  \1
```

The map name is specified in the `pg_hba.conf` Kerberos entry in the options field:

```
host all all 0.0.0.0/0 gss include_realm=0 krb_realm=GPDB.KRB map=mymap
```

The first map entry matches the Kerberos principal `admin@GPDB.KRB` and replaces it with the Greenplum Database `gpadmin` role name. The second entry uses a wildcard to match any Kerberos principal in the `GPDB-KRB` realm with a name ending with the characters `_gp` and replaces it with the initial portion of the principal name. Greenplum Database applies the first matching map entry in the `pg_ident.conf` file, so the order of entries is significant.

For more information about using username maps see [Username maps](#) in the PostgreSQL documentation.

Configuring JDBC Kerberos Authentication for Greenplum Database

Enable Kerberos-authenticated JDBC access to Greenplum Database.

You can configure Greenplum Database to use Kerberos to run user-defined Java functions.

1. Ensure that Kerberos is installed and configured on the Greenplum Database master. See [Installing the Kerberos Client on the Master Host](#).
2. Create the file `.java.login.config` in the folder `/home/gpadmin` and add the following text to the file:

```
pgjdbc {
    com.sun.security.auth.module.Krb5LoginModule required
    doNotPrompt=true
    useTicketCache=true
    debug=true
    client=true;
};
```

3. Create a Java application that connects to Greenplum Database using Kerberos authentication. The following example database connection URL uses a PostgreSQL JDBC driver and specifies parameters for Kerberos authentication:

```
jdbc:postgresql://mdw:5432/mytest?kerberosServerName=postgres
&jaasApplicationName=pgjdbc&user=gpadmin/gpdb-kdc
```

The parameter names and values specified depend on how the Java application performs Kerberos authentication.

4. Test the Kerberos login by running a sample Java application from Greenplum Database.

Installing and Configuring a Kerberos KDC Server

Steps to set up a Kerberos Key Distribution Center (KDC) server on a Red Hat Enterprise Linux host for use with Greenplum Database.

If you do not already have a KDC, follow these steps to install and configure a KDC server on a Red Hat Enterprise Linux host with a `GPDB.KRB` realm. The host name of the KDC server in this example is `gpdb-kdc`.

1. Install the Kerberos server and client packages:

```
$ sudo yum install krb5-libs krb5-server krb5-workstation
```

2. Edit the `/etc/krb5.conf` configuration file. The following example shows a Kerberos server configured with a default `GPDB.KRB` realm.

```
[logging]
default = FILE:/var/log/krb5libs.log
kdc = FILE:/var/log/krb5kdc.log
admin_server = FILE:/var/log/kadmind.log

[libdefaults]
default_realm = GPDB.KRB
dns_lookup_realm = false
dns_lookup_kdc = false
ticket_lifetime = 24h
renew_lifetime = 7d
```

```

forwardable = true
default_tgs_enctypes = aes128-cts des3-hmac-sha1 des-cbc-crc des-cbc-md5
default_tkt_enctypes = aes128-cts des3-hmac-sha1 des-cbc-crc des-cbc-md5
permitted_enctypes = aes128-cts des3-hmac-sha1 des-cbc-crc des-cbc-md5

[realms]
GPDB.KRB = {
    kdc = gpdb-kdc:88
    admin_server = gpdb-kdc:749
    default_domain = gpdb.krb
}

[domain_realm]
.gpdb.krb = GPDB.KRB
gpdb.krb = GPDB.KRB

[appdefaults]
pam = {
    debug = false
    ticket_lifetime = 36000
    renew_lifetime = 36000
    forwardable = true
    krb4_convert = false
}

```

The `kdc` and `admin_server` keys in the `[realms]` section specify the host (`gpdb-kdc`) and port where the Kerberos server is running. IP numbers can be used in place of host names.

If your Kerberos server manages authentication for other realms, you would instead add the `GPDB.KRB` realm in the `[realms]` and `[domain_realm]` section of the `kdc.conf` file. See the [Kerberos documentation](#) for information about the `kdc.conf` file.

3. To create the Kerberos database, run the `kdb5_util`.

```
# kdb5_util create -s
```

The `kdb5_util create` command creates the database to store keys for the Kerberos realms that are managed by this KDC server. The `-s` option creates a stash file. Without the stash file, every time the KDC server starts it requests a password.

4. Add an administrative user to the KDC database with the `kadmin.local` utility. Because it does not itself depend on Kerberos authentication, the `kadmin.local` utility allows you to add an initial administrative user to the local Kerberos server. To add the user `gpadmin` as an administrative user to the KDC database, run the following command:

```
# kadmin.local -q "addprinc gpadmin/admin"
```

Most users do not need administrative access to the Kerberos server. They can use `kadmin` to manage their own principals (for example, to change their own password). For information about `kadmin`, see the [Kerberos documentation](#).

5. If needed, edit the `/var/kerberos/krb5kdc/kadm5.acl` file to grant the appropriate permissions to `gpadmin`.
6. Start the Kerberos daemons:

```
# /sbin/service krb5kdc start#
/sbin/service kadmin start
```

7. To start Kerberos automatically upon restart:

```
# /sbin/chkconfig krb5kdc on
# /sbin/chkconfig kadmin on
```

Configuring Kerberos for Linux Clients

You can configure Linux client applications to connect to a Greenplum Database system that is configured to authenticate with Kerberos.

If your JDBC application on Red Hat Enterprise Linux uses Kerberos authentication when it connects to your Greenplum Database, your client system must be configured to use Kerberos authentication. If you are not using Kerberos authentication to connect to a Greenplum Database, Kerberos is not needed on your client system.

- [Requirements](#)
- [Setting Up Client System with Kerberos Authentication](#)
- [Running a Java Application](#)

For information about enabling Kerberos authentication with Greenplum Database, see the chapter “Setting Up Kerberos Authentication” in the *Greenplum Database Administrator Guide*.

Parent topic: [Configuring Client Authentication](#)

Requirements

The following are requirements to connect to a Greenplum Database that is enabled with Kerberos authentication from a client system with a JDBC application.

- [Prerequisites](#)
- [Required Software on the Client Machine](#)

Prerequisites

- Kerberos must be installed and configured on the Greenplum Database master host.
Important: Greenplum Database must be configured so that a remote user can connect to Greenplum Database with Kerberos authentication. Authorization to access Greenplum Database is controlled by the `pg_hba.conf` file. For details, see “Editing the `pg_hba.conf` File” in the *Greenplum Database Administration Guide*, and also see the *Greenplum Database Security Configuration Guide*.
- The client system requires the Kerberos configuration file `krb5.conf` from the Greenplum Database master.
- The client system requires a Kerberos keytab file that contains the authentication credentials for the Greenplum Database user that is used to log into the database.
- The client machine must be able to connect to Greenplum Database master host.

If necessary, add the Greenplum Database master host name and IP address to the system `hosts` file. On Linux systems, the `hosts` file is in `/etc`.

Required Software on the Client Machine

- The Kerberos `kinit` utility is required on the client machine. The `kinit` utility is available when you install the Kerberos packages:
 - ◊ `krb5-libs`
 - ◊ `krb5-workstation`

Note: When you install the Kerberos packages, you can use other Kerberos utilities such as `klist` to display Kerberos ticket information.

Java applications require this additional software:

- Java JDK

Java JDK 1.7.0_17 is supported on Red Hat Enterprise Linux 6.x.

- Ensure that `JAVA_HOME` is set to the installation directory of the supported Java JDK.

Setting Up Client System with Kerberos Authentication

To connect to Greenplum Database with Kerberos authentication requires a Kerberos ticket. On client systems, tickets are generated from Kerberos keytab files with the `kinit` utility and are stored in a cache file.

1. Install a copy of the Kerberos configuration file `krb5.conf` from the Greenplum Database master. The file is used by the Greenplum Database client software and the Kerberos utilities.

Install `krb5.conf` in the directory `/etc`.

If needed, add the parameter `default_ccache_name` to the `[libdefaults]` section of the `krb5.ini` file and specify location of the Kerberos ticket cache file on the client system.

2. Obtain a Kerberos keytab file that contains the authentication credentials for the Greenplum Database user.
3. Run `kinit` specifying the keytab file to create a ticket on the client machine. For this example, the keytab file `gpdb-kerberos.keytab` is in the current directory. The ticket cache file is in the `gpadmin` user home directory.

```
> kinit -k -t gpdb-kerberos.keytab -c /home/gpadmin/cache.txt
gpadmin/kerberos-gpdb@KRB.EXAMPLE.COM
```

Running psql

From a remote system, you can access a Greenplum Database that has Kerberos authentication enabled.

To connect to Greenplum Database with psql

1. As the `gpadmin` user, open a command window.
2. Start `psql` from the command window and specify a connection to the Greenplum Database specifying the user that is configured with Kerberos authentication.

The following example logs into the Greenplum Database on the machine `kerberos-gpdb` as the `gpadmin` user with the Kerberos credentials `gpadmin/kerberos-gpdb`:

```
$ psql -U "gpadmin/kerberos-gpdb" -h kerberos-gpdb postgres
```

Running a Java Application

Accessing Greenplum Database from a Java application with Kerberos authentication uses the Java Authentication and Authorization Service (JAAS)

1. Create the file `.java.login.config` in the user home folder.

For example, on a Linux system, the home folder is similar to `/home/gpadmin`.

Add the following text to the file:

```
pgjdbc {
    com.sun.security.auth.module.Krb5LoginModule required
    doNotPrompt=true
    useTicketCache=true
    ticketCache = "/home/gpadmin/cache.txt"
    debug=true
    client=true;
};
```

2. Create a Java application that connects to Greenplum Database using Kerberos authentication and run the application as the user.

This example database connection URL uses a PostgreSQL JDBC driver and specifies parameters for Kerberos authentication.

```
jdbc:postgresql://kerberos-gpdb:5432/mytest?
kerberosServerName=postgres&jaasApplicationName=pgjdbc&
user=gpadmin/kerberos-gpdb
```

The parameter names and values specified depend on how the Java application performs Kerberos authentication.

Configuring Kerberos For Windows Clients

You can configure Microsoft Windows client applications to connect to a Greenplum Database system that is configured to authenticate with Kerberos.

When a Greenplum Database system is configured to authenticate with Kerberos, you can configure Kerberos authentication for the Greenplum Database client utilities `gpload` and `psql` on a Microsoft Windows system. The Greenplum Database clients authenticate with Kerberos directly.

This section contains the following information.

- [Installing and Configuring Kerberos on a Windows System](#)
- [Running the psql Utility](#)
- [Example gpload YAML File](#)
- [Creating a Kerberos Keytab File](#)
- [Issues and Possible Solutions](#)

These topics assume that the Greenplum Database system is configured to authenticate with Kerberos. For information about configuring Greenplum Database with Kerberos authentication, refer to [Using Kerberos Authentication](#).

Parent topic: [Configuring Client Authentication](#)

Installing and Configuring Kerberos on a Windows System

The `kinit`, `kdestroy`, and `klist` MIT Kerberos Windows client programs and supporting libraries are installed on your system when you install the Greenplum Database Client and Load Tools package:

- `kinit` - generate a Kerberos ticket
- `kdestroy` - destroy active Kerberos tickets
- `klist` - list Kerberos tickets

You must configure Kerberos on the Windows client to authenticate with Greenplum Database:

1. Copy the Kerberos configuration file `/etc/krb5.conf` from the Greenplum Database master to the Windows system, rename it to `krb5.ini`, and place it in the default Kerberos location on the Windows system, `C:\ProgramData\MIT\Kerberos5\krb5.ini`. This directory may be hidden. This step requires administrative privileges on the Windows client system. You may also choose to place the `/etc/krb5.ini` file in a custom location. If you choose to do this, you must configure and set a system environment variable named `KRB5_CONFIG` to the custom location.
2. Locate the `[libdefaults]` section of the `krb5.ini` file, and remove the entry identifying the location of the Kerberos credentials cache file, `default_ccache_name`. This step requires administrative privileges on the Windows client system.

This is an example configuration file with `default_ccache_name` removed. The `[logging]` section is also removed.

```
[libdefaults]
debug = true
default_etypes = aes256-cts-hmac-shal-96
default_realm = EXAMPLE.LOCAL
dns_lookup_realm = false
dns_lookup_kdc = false
ticket_lifetime = 24h
renew_lifetime = 7d
forwardable = true

[realms]
EXAMPLE.LOCAL = {
    kdc = bocdc.example.local
    admin_server = bocdc.example.local
}

[domain_realm]
.example.local = EXAMPLE.LOCAL
example.local = EXAMPLE.LOCAL
```

3. Set up the Kerberos credential cache file. On the Windows system, set the environment variable `KRB5CCNAME` to specify the file system location of the cache file. The file must be named `krb5cache`. This location identifies a file, not a directory, and should be unique to each login on the server. When you set `KRB5CCNAME`, you can specify the value in either a local user environment or within a session. For example, the following command sets `KRB5CCNAME` in the session:

```
set KRB5CCNAME=%USERPROFILE%\krb5cache
```

4. Obtain your Kerberos principal and password or keytab file from your system administrator.
5. Generate a Kerberos ticket using a password or a keytab. For example, to generate a ticket using a password:

```
kinit [<principal>]
```

To generate a ticket using a keytab (as described in [Creating a Kerberos Keytab File](#)):

```
kinit -k -t <keytab_filepath> [<principal>]
```

6. Set up the Greenplum clients environment:

```
set PGGSSLIB=gssapi
"c:\Program Files\Greenplum\greenplum-clients\greenplum_clients_path.bat"
```

Running the psql Utility

After you configure Kerberos and generate the Kerberos ticket on a Windows system, you can run the Greenplum Database command line client `psql`.

If you get warnings indicating that the Console code page differs from Windows code page, you can run the Windows utility `chcp` to change the code page. This is an example of the warning and fix:

```
psql -h prod1.example.local warehouse
psql (9.4.20)
WARNING: Console code page (850) differs from Windows code page (1252)
8-bit characters might not work correctly. See psql reference
page "Notes for Windows users" for details.
Type "help" for help.

warehouse=# \q

chcp 1252
Active code page: 1252

psql -h prod1.example.local warehouse
psql (9.4.20)
Type "help" for help.
```

Creating a Kerberos Keytab File

You can create and use a Kerberos `keytab` file to avoid entering a password at the command line or listing a password in a script file when you connect to a Greenplum Database system, perhaps when automating a scheduled Greenplum task such as `gpload`. You can create a keytab file with the Java JRE keytab utility `ktab`. If you use AES256-CTS-HMAC-SHA1-96 encryption, you need to download and install the Java extension *Java Cryptography Extension (JCE) Unlimited Strength Jurisdiction Policy Files for JDK/JRE* from Oracle.

Note: You must enter the password to create a keytab file. The password is visible onscreen as you enter it.

This example runs the Java `ktab.exe` program to create a keytab file (`-a` option) and list the keytab name and entries (`-l -e -t` options).

```
C:\Users\dev1>"\Program Files\Java\jre1.8.0_77\bin"\ktab -a dev1
Password for dev1@EXAMPLE.LOCAL:<your_password>
Done!
Service key for dev1 is saved in C:\Users\dev1\krb5.keytab

C:\Users\dev1>"\Program Files\Java\jre1.8.0_77\bin"\ktab -l -e -t
Keytab name: C:\Users\dev1\krb5.keytab
KVNO Timestamp Principal
-----
4 13/04/16 19:14 dev1@EXAMPLE.LOCAL (18:AES256 CTS mode with HMAC SHA1-96)
4 13/04/16 19:14 dev1@EXAMPLE.LOCAL (17:AES128 CTS mode with HMAC SHA1-96)
4 13/04/16 19:14 dev1@EXAMPLE.LOCAL (16:DES3 CBC mode with SHA1-KD)
4 13/04/16 19:14 dev1@EXAMPLE.LOCAL (23:RC4 with HMAC)
```

You can then generate a Kerberos ticket using a keytab with the following command:

```
kinit -kt dev1.keytab dev1
```

or

```
kinit -kt %USERPROFILE%\krb5.keytab dev1
```

Example gpload YAML File

When you initiate a `gpload` job to a Greenplum Database system using Kerberos authentication, you omit the `USER:` property and value from the YAML control file.

This example `gpload` YAML control file named `test.yaml` does not include a `USER:` entry:

```
---
VERSION: 1.0.0.1
DATABASE: warehouse
HOST: prod1.example.local
PORT: 5432

GLOAD:
  INPUT:
    - SOURCE:
        PORT_RANGE: [18080,18080]
        FILE:
          - /Users/dev1/Downloads/test.csv
    - FORMAT: text
    - DELIMITER: ','
    - QUOTE: '"'
    - ERROR_LIMIT: 25
    - LOG_ERRORS: true
  OUTPUT:
    - TABLE: public.test
    - MODE: INSERT
  PRELOAD:
    - REUSE_TABLES: true
```

These commands run `kinit` using a keytab file, run `gpload.bat` with the `test.yaml` file, and then display successful `gpload` output.

```
kinit -kt %USERPROFILE%\krb5.keytab dev1

gpload.bat -f test.yaml
2016-04-10 16:54:12|INFO|gpload session started 2016-04-10 16:54:12
2016-04-10 16:54:12|INFO|started gpfdist -p 18080 -P 18080 -f "/Users/dev1/Downloads/test.csv" -t 30
2016-04-10 16:54:13|INFO|running time: 0.23 seconds
2016-04-10 16:54:13|INFO|rows Inserted = 3
2016-04-10 16:54:13|INFO|rows Updated = 0
2016-04-10 16:54:13|INFO|data formatting errors = 0
2016-04-10 16:54:13|INFO|gpload succeeded
```

Issues and Possible Solutions

- This message indicates that Kerberos cannot find your Kerberos credentials cache file:

```
Credentials cache I/O operation failed XXX
(Kerberos error 193)
krb5_cc_default() failed
```

To ensure that Kerberos can find the file, set the environment variable `KRB5CCNAME` and run `kinit`.

```
set KRB5CCNAME=%USERPROFILE%\krb5cache
```

```
kinit
```

- This `kinit` message indicates that the `kinit -k -t` command could not find the keytab.

```
kinit: Generic preauthentication failure while getting initial credentials
```

Confirm that the full path and filename for the Kerberos keytab file is correct.

Managing Roles and Privileges

The Greenplum Database authorization mechanism stores roles and permissions to access database objects in the database and is administered using SQL statements or command-line utilities.

Greenplum Database manages database access permissions using *roles*. The concept of roles subsumes the concepts of *users* and *groups*. A role can be a database user, a group, or both. Roles can own database objects (for example, tables) and can assign privileges on those objects to other roles to control access to the objects. Roles can be members of other roles, thus a member role can inherit the object privileges of its parent role.

Every Greenplum Database system contains a set of database roles (users and groups). Those roles are separate from the users and groups managed by the operating system on which the server runs. However, for convenience you may want to maintain a relationship between operating system user names and Greenplum Database role names, since many of the client applications use the current operating system user name as the default.

In Greenplum Database, users log in and connect through the master instance, which then verifies their role and access privileges. The master then issues commands to the segment instances behind the scenes as the currently logged in role.

Roles are defined at the system level, meaning they are valid for all databases in the system.

In order to bootstrap the Greenplum Database system, a freshly initialized system always contains one predefined *superuser* role (also referred to as the system user). This role will have the same name as the operating system user that initialized the Greenplum Database system. Customarily, this role is named `gpadmin`. In order to create more roles you first have to connect as this initial role.
